We now define the frequency-dependent complex dielectric constant $\varepsilon(p,\omega)$ of the system by $\varepsilon(p,\omega) = G(p,\omega)/i\omega$, which is a generalization of the usual static dielectric constant ε_0. For an insulating dielectric medium $G \simeq i\omega\varepsilon_0$ as $\omega \to 0$. Bergman and Imry (1977) derived the following relationships:

$$G(p_c,\omega) \sim \omega^x, \tag{62}$$

$$\varepsilon(p_c,\omega) \sim \omega^{-y}, \tag{63}$$

where the exponents x and y satisfy

$$x + y = 1. \tag{64}$$

Gefen *et al.* (1983) argued that the fractal nature of diffusion and percolation clusters at length scales up to ξ_p dominates the contributions to the ac properties, and hence proposed that

$$x = \mu/\nu(2 + \theta), \tag{65}$$

$$y = (2\nu - \beta)/\nu(2 + \theta), \tag{66}$$

where the exponents ν, β, and θ were defined in Secs. 1.5 and 1.6.

Another important consequence of Eq. (60) is that

$$\varepsilon_0 \sim A_{\pm}C|p - p_c|^{-s}, \tag{67}$$

that is, the static dielectric constant *diverges* as p_c is approached from *both sides*, and the critical exponent that characterizes this divergence is s, the critical exponent of a percolation network of superconductors–conductors defined by Eq. (9). This spectacular result was first derived by Efros and Shklovskii (1976). Although Eq. (67) is supposed to be valid in the limit $\omega = 0$, its validity extends to higher frequencies as long as $\omega \ll 1/t_s$, where t_s is given by Eq. (61). The amplitude ratio A_+/A_- is universal. If we now write $G(p,\omega) =$

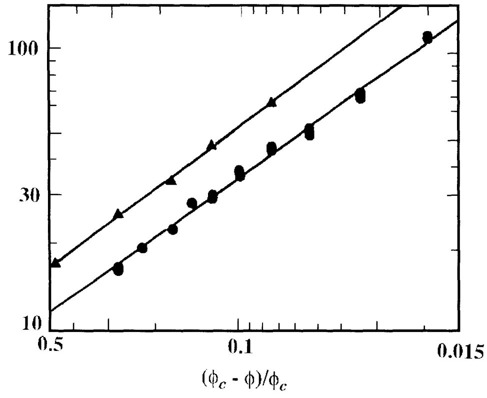

FIG. 13. Logarithmic plot of the dielectric constant of two series of Ag–KCl composites *versus* the volume fraction φ of Ag. The solid lines are the best fit of the data (after Grannan *et al.*, 1981).

$G' + iG'' = i\omega\varepsilon(p,\omega) = i\omega(\varepsilon' - i\varepsilon'')$, then a loss angle is defined by

$$\tan\delta = G'/G'' = \varepsilon''/\varepsilon', \tag{68}$$

and it is clear that $0 \le \delta \le \pi$. At p_c the loss angle δ_c is universal and is given by

$$\delta_c = \tfrac{1}{2}\pi s/(\mu + s). \tag{69}$$

Although Eq. (69) is supposed to be valid exactly at $p = p_c$, its validity extends to a broad frequency range if $|p - p_c|$ is small enough, *i.e.*, $1/t_s \ll \omega \ll \omega_0$. Moreover, since for 2D percolation we have $s = \mu$, we must have $\delta_c = \pi/4$, another remarkable result.

Equations (64)–(66) were confirmed by the experiments of Hundley and Zettl (1988), who measured the ac conductivity and dielectric constant of thin Au films in the frequency range 100 Hz–1 GHz. Their measurements indicated that at high frequencies $x \simeq 0.32$ and $y \simeq 0.8$, in reasonable agreement with the predictions of Eqs. (65) and (66), $x \simeq 0.34$ and $y \simeq 0.66$. A definitive verification of Eq. (67) was provided by Grannan *et al.* (1981), who used a composite consisting of small spherical Ag particles randomly distributed in a nonconducting KCl host. Figure 13 shows the scaling plot of their data as a function of the volume fraction of Ag, indicating that ε_0 diverges as ϕ_c is approached with an exponent $s \simeq 0.73 \pm 0.01$, in perfect agreement with the 3D percolation prediction $s \simeq 0.735$. Similar results were obtained by Nicklasson and Grangvist (1984).

2.4 Hall Conductivity of Composite Media

In the presence of a magnetic field H the conductivity of a composite is described by a tensor $\boldsymbol{G}$ which has nonzero off-diagonal terms, even if the system is isotropic. Some of the off-diagonal terms are symmetric and even in the magnetic field H, while others are antisymmetric and odd in H. Suppose that an electric field $\mathbf{E}$ has also been imposed on the system. Then the system has an electrical (Ohmic) conductivity G and a Hall conductivity $\boldsymbol{G}_H$. For an isotropic medium and small H, $\boldsymbol{G}_H$ is proportional to H and is defined by the Kirchhoff's law relating the current density $\boldsymbol{J}$ and the electric field $\boldsymbol{E}$,

$$\boldsymbol{J} = G\boldsymbol{E} + \boldsymbol{E} \times \boldsymbol{G}_H. \tag{70}$$

If Eq. (70) is inverted for small H, the Hall coefficient $R_H = G_H/HG^2$ appears along with the Ohmic resistivity $\rho = 1/G$: $\boldsymbol{E} = \rho\boldsymbol{J} + R_H(\boldsymbol{H} \times \boldsymbol{J})$. Cohen and Jortner (1973) developed an EMA for this problem. Note that, because of the presence of the magnetic field, the general circuit element of a bond of the network for calculating G_H and R_H is not a simple resistor but a conductance matrix. Straley (1980b) and Bergman *et al.* (1990) proposed network models for calculating G_H and R_H.

Study of the scaling behavior of G_H and R_H near p_c was initiated by Levinshtein *et al.* (1976), Shklovskii (1977), and Straley (1980a). However, a complete scaling theory was developed by Bergman and Stroud (1985). Consider a two-component network in which each bond has good Ohmic and Hall conductivities g_1 and g_{H1} with probability p, and poor Ohmic and Hall conductivities g_2 and g_{H2} with probability $1 - p$. Bergman and Stroud (1985) proposed that for $g_{H2}/g_{H1} \ll 1$ and for p close to p_c,

$$\frac{G_H - g_{H2}}{g_{H1} - g_{H2}} = |p - p_c|^{\tau} F\left(\frac{g_{H2}/g_{H1}}{|p - p_c|^{\mu+s}}\right), \tag{71}$$

where τ is a new critical exponent characterizing the scaling behavior of G_H near p_c when $p > p_c$, $g_2 = 0$, and $g_{H2} = 0$. Equation (71) has been written in complete analogy with Eq. (12). The scaling function $F(x)$ has the properties that $F(x) \simeq$ const. if $x \ll 1$ and $p > p_c$ (Regime I), $F(x) \sim x^2$ for $x \ll 1$ and $p < p_c$ (Regime II), and $F(x) \sim x^{\tau/(\mu+s)}$ for $x \gg 1$ and $p \simeq p_c$ (Regime III). However, a better way of understanding Eq. (71) is in terms of the Hall coefficient R_H. To each bond we assign a Hall coefficient $R_{H1} = g_{H1}/g_1^2$ with probability p, or $R_{H2} = g_{H2}/g_2^2$ with probability $1 - p$. Then one has (Bergman and Stroud, 1985)

$$R_H \sim a_1 R_{H1}|p - p_c|^{-\zeta} + b_1 R_{H2}(g_2/g_1)^2 \times |p - p_c|^{-2\mu}, \quad \text{Regime I;} \tag{72}$$

$$R_H \sim a_2 R_{H1}|p - p_c|^{-\zeta} + b_2 R_{H2}|p - p_c|^{2s}, \quad \text{Regime II;} \tag{73}$$

$$R_H \sim a_3 R_{H1}(g_2/g_1)^{-\zeta/(\mu+s)} + b_3 R_{H2}(g_2/g_1)^{2s/(\mu+s)}, \quad \text{Regime III;} \tag{74}$$

where a_i and b_i are constant, and ζ is a critical exponent that characterizes the divergence of R_H as p_c is approached from below and is related to μ and τ by

$$\zeta = 2\mu - \tau. \tag{75}$$

In 2D, $\zeta = 0$ exactly (Shklovskii, 1977), *i.e.*, the Hall coefficient remains finite at $p = p_c$, and in 3D, $\zeta \simeq 0.5$. The important point to remember is that in Regime I the ratio of the second to the first term is of order $(g_{H2}/g_{H1}) \times |p - p_c|^{-\tau}$, and therefore, depending on the parameters of the system, either term may dominate, so that experimental verification of these scaling laws is not straightforward.

Early experimental studies of Hall conductivity and coefficient in percolating composites were carried out by Levinshtein *et al.* (1976) and Sichel and Gittleman (1982). Experimental verification of Eqs. (72)–(74) was provided by Palevski *et al.* (1984), who showed that the Hall coefficient does indeed remain finite in thin (2D) metal films, and by Uri *et al.* (1987), who studied the problem in thick (3D) Al–Ge metal–insulator films. In Regime I, the poor conductor was Al–doped Ge, which was found to dominate the Hall effect. To make the first term of Eq. (72) dominant, Uri *et al.* dissolved the metallic aluminum in KOH, leaving the doped Ge as the good conductor, the poor-conductor role now being played by the vacuum. In such a situation, the first term of Eq. (72) is dominant, and therefore ζ and τ could be measured directly. The results were $\tau \simeq 3.8 \pm 0.2$ and $\zeta \simeq 0.38 \pm 0.05$, compatible with simulation results, $\tau \simeq 3.56 \pm 0.06$ and $\zeta \simeq 0.49 \pm 0.06$.

3. APPLICATION TO POROUS-MEDIA PROBLEMS

A major application of percolation theory has been characterization of the morphology of heterogeneous porous media, and the description of various flow phenomena therein. It is not possible to describe all the efforts that have been made in this direction, as the literature on the subject is too extensive (see, for example, Sahimi, 1993b, 1995). Thus, in what follows we only outline some of the major issues, and discuss applications of percolation theory for addressing them.

3.1 Characterization of Porous Media

An important quantity for characterization of a porous system is the capillary pressure P_c. If two immiscible fluids, *e.g.*, water and oil, are in contact in a bounded system, such as a cylindrical tube, then there is a discontinuity in the pressure field as one moves across the interface from one fluid phase to the other. That is, if we consider two points in the immediate vicinity of the interface, one in the water phase at pressure P_w and one in the oil phase at pressure P_o, then the pressure difference $P_c = P_o - P_w$, usually called the capillary pressure, is given by the Laplace equation

$$P_c = \sigma \cos\theta(1/r_1 + 1/r_2). \tag{76}$$

Here r_1 and r_2 are the principal radii of curvature of the interface, θ is the contact angle, and σ is the interfacial tension between the two fluids. For an interface in a cylindrical tube

$r_1 = r_2 = r$, where r is the tube's radius. In a cylindrical tube P_c depends uniquely on the amount of the fluid in the system. However, in a porous medium with many irregularly shaped pores different amounts of fluids, measured by their saturations (the volume fraction of the fluids), may yield the same P_c, and *vice versa*, since there are several interfaces in the pore space at different locations. For example, suppose that we initially fill our porous medium with water, and then expel it gradually by injecting oil into the pore space. For each value of the water saturation S_w we have a corresponding P_c. After continuing this for long enough, we reach a point where no more water is produced, although there is still some water left in the pore space. The saturation of water at this value of P_c is called the *irreducible* saturation S_{wi}, and the process of expelling water (more generally, a wetting fluid) by oil (more generally, a nonwetting fluid) is called *drainage*. Now, if we start with the porous system at the end of drainage (at the highest P_c) and expel the oil gradually by injecting water into the system, a process called *imbibition*, we obtain another curve of P_c *versus* S_w, very different from what we obtained during drainage, and thus there is hysteresis between the two curves. Figure 14 shows a typical P_c–saturation diagram during both drainage and imbibition, indicating that even when $P_c = 0$, there is still some oil left in the system. The saturation S_{or} of oil at this point is called the *residual* saturation. The all-important goal of enhanced oil-recovery methods is extracting this residual oil from the reservoir.

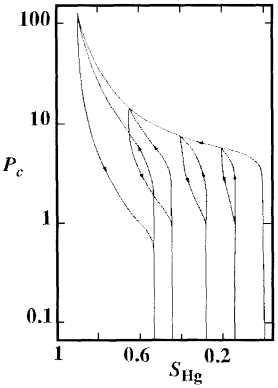

FIG. 14. Typical capillary pressure P_c *versus* mercury saturation S_{Hg} during mercury porosimetry.

Two important morphological characteristics of any porous medium are its pore size distribution (PSD) and pore connectivity. Careful examination of natural porous media reveals that what are usually referred to as pores are in fact either pore bodies, where most of the porosity resides, or pore throats, which are the narrow channels that connect the pore bodies and through which a fluid flows. One usually assigns effective radii to the pore bodies and throats that are nothing but the radii of spheres that have the same volumes as the pores and throats. In a network representation of the pore space, the pore bodies and throats are represented by the sites and bonds of the network, respectively. There are several experimental techniques for measuring the PSD of a porous medium, two of which, mercury porosimetry and adsorption–desorption experiments, require the concepts of percolation theory for proper interpretation of the data. Here we discuss mercury porosimetry. Adsorption techniques have also proven to be very valuable for measuring the connectivity of a pore space, and hence we discuss them in that context.

3.1.1 Mercury Porosimetry In this method, the porous medium is first evacuated and then immersed in mercury. The pressure is then increased (incrementally or continuously) and the volume of mercury injected into the porous medium is measured as a function of the applied (capillary) pressure. This corresponds to a drainage process, since mercury acts as a nonwetting fluid. Larger and larger pressures are needed to penetrate progressively smaller pores. In general if a nonwetting fluid (in this case mercury) is to displace a wetting fluid, it must overcome a capillary pressure P_c at the pore throat of radius r_t [see Eq. (76)],

$$P_c = 2\sigma / r_t. \tag{77}$$

Equation (77) means that the nonwetting phase penerates the largest throats (that require the smallest P_c) that it can reach. The pressure is then lowered back to atmospheric pressure to retract the mercury from the pores (imbibition), but with a characteristic shift or hysteresis between the injection and retraction curves. During imbibition, if the wetting phase is to displace the nonwetting phase in the pore body, the capillary pressure must be

$$P_c = 2\sigma / r_b, \tag{78}$$

implying that the wetting phase will occupy the smallest pore bodies. Some mercury stays in the medium even after the pressure is lowered back to atmospheric pressure.

While mercury porosimetry is a relatively straightforward experiment, the interpretation of the data is not simple. By measuring P_c and the mercury saturation, one tries to deduce the PSD of the pore space. The sequence of the pores that are penetrated by mercury during mercury porosimetry depends not only on the PSD, but also on the topology—the way the pores are connected to each other. Although at a given P_c a throat may be large enough for mercury penetration, a connection between the throat and the external surface of the pore space, *via* the already penetrated pore bodies and throats, has to be established, *i.e.*, that throat has to be accessible in the percolation sense described in Sec. 1.3. Therefore, mercury porosimetry represents a percolation phenomenon, and hence interpretation of porosimetry data and obtaining the PSD requires use of a network model of the pore space. However, it was only in 1977 that the connection between this phenomenon and percolation was recognized. Chatzis and Dullien (1977) and Larson and Morrow (1981) were among the first to recognize this connection. Many other workers have studied this problem, a list of whom is too long to be given here (for reviews see, for example, Sahimi, 1993b, 1995).

To give the reader some idea about percolation modelling of capillary pressure, we outline the model for mercury injection (drainage). Suppose that r_m is the minimum throat radius into which the mercury penetrates. Then, the fraction of the throats that can potentially be penetrated by mercury, *i.e.*, the allowed fraction, is given by

$$p(r_m) = \int_{r_m}^{\infty} \Psi(r)\, dr, \tag{79}$$

where $\Psi(r)$ is the PSD of the pore space. However, not all the allowed throats will be penetrated by mercury, but only a fraction $P_A(p(r_m))$ of them, where $P_A(p)$ is the percolation accessiblity function defined in Sec. 1.3. Therefore, the PSD $\Psi_i(r)$ of the throats that are actually penetrated by the injected mercury is

$$\Psi_i(r) = \Psi(r)/p(r_m), \quad r \geq r_m, \tag{80}$$

and clearly $\Psi_i(r) = 0$ for $r < r_m$. The saturation S_{Hg} of mercury during injection is given by

$$S_{Hg} = \frac{P_A(p(r_m))}{p(r_m)} \frac{\int_{r_m}^{\infty} \Psi(r) V(r)\, dr}{\int_0^{\infty} \Psi(r) V(r)\, dr}, \tag{81}$$

where $V(r)$ is the volume of a throat of radius r. Corresponding to any S_{Hg} there is a capillary pressure given by Eq. (77). Clearly, data on P_c and S_{Hg}, together with Eqs. (79)–(81), can be converted into a PSD for the pore space. This model has been used with great success for interpreting porosimetry data and obtaining the PSD of porous media; see the reviews by Sahimi (1993b, 1995) for detailed discussion.

3.1.2 Pore-space Connectivity and Sorption Phenomena One of the simplest concepts for characterizing the topology of a porous medium is the coordination number Z, loosely defined as the number of pore throats that meet at a pore body. For an irregular pore space one has to define an average coordination number $\langle Z \rangle$, with the average taken over a large enough sample. Although several experimental techniques have been developed for determining $\langle Z \rangle$, percolation theory has proven to be invaluable for interpreting adsorption–desorption data and estimating $\langle Z \rangle$ from them. Thus, let us first discuss typical adsorption–desorption experiments and why percolation theory is relevant to them. Liquid nitrogen is usually used in such experiments, and thus consider nitrogen adsorption in a single pore. As the pressure is increased an adsorbed film of nitrogen forms on the pore walls whose thickness increases with increasing pressure. At condensation pressure P_{co} the pore is filled with a (liquid-like) condensed phase, which results in a steep increase in the adsorption isotherm. The condensation pressure P_{co} is given by the Kelvin equation which, for a pore of radius r, is given by

$$\frac{P_{\mathrm{co}}}{P_0} = \exp\left[-\frac{2\sigma V_{\mathrm{L}}}{RT(r-l)}\right] \qquad (82)$$

in which P_0 is the saturation pressure, σ the liquid–vapor surface tension, R the gas constant, T the temperature, V_{L} the molar volume of the liquid, and l the thickness of the adsorbed layer present on the surface of the pore when condensation occurs. Equation (82) tells us that for any P_{co}/P_0 the adsorption process can be uniquely parameterized by an effective pore radius, which hereafter is referred to as r_{a}. Hence, adsorption or the reverse process of desorption corresponds, respectively, to an increase or decrease in r_{a}, with the change being caused by the disordered morphology of the pore space.

Now consider adsorption in a porous medium. During this process all the pores are equally accessible, vapor condenses in all pores of radius $r > r_{\mathrm{a}}$, and liquid nitrogen fills the pores. For $r < r_{\mathrm{a}}$ the pores fill rapidly and continuously with nitrogen. Thus, during adsorption connectivity of the pores plays no role. In contrast, desorption does depend on the pore-space connectivity. As the pressure is reduced, the desorption isotherm does not retrace that of adsorption but, similar to mercury porosimetry, forms a hysteresis loop before rejoining the adsorption isotherm. Two mechanisms contribute to this hysteresis, the first of which is thermodynamic in nature: a metastable phase may exist beyond the coexistence pressure during adsorption and/or desorption. This means that during adsorption a vapor phase may exist at pressures above P_{co}, or during desorption a liquid phase may exist below P_{co}. Thus, this is a pore-level mechanism and has nothing to do with pore connectivity, *i.e.*, percolation. The second mechanism is due to the connectivity of the pore space: a pore with an effective radius r is allowed to desorb (allowed to contain vapor) if $r > r_{\mathrm{a}}$ (so that at given pressure the liquid phase is metastable with respect to the vapor phase), *and* if it is connected to the bulk vapor in desorption. Expressing it in another way, a pore can desorb if it is accessible from the bulk vapor phase, and thus this is a percolation effect. Unless the PSD of the pore space is very narrow, the percolation effect is more important in the formation of the hysteresis loops than the thermodynamic mechanism. Typical adsorption–desorption isotherms are shown in Fig. 15.

Seaton (1991) (see also Liu *et al.*, 1992, for further elaboration) developed a percolation method for estimating $\langle Z \rangle$ on the basis of adsorption–desorption experiments. This method is based on finite-size scaling analysis, Eq. (23), according to which

$$P_{\mathrm{A}}(p) = L^{-\beta/\nu} f((p-p_c)L^{1/\nu}), \qquad (83)$$

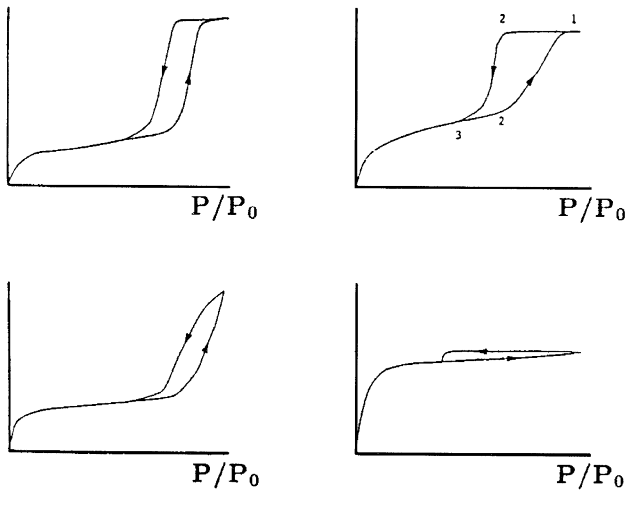

FIG. 15. Typical adsorption–desorption isotherms as a function of the pressure *P*. Segments 3–2–1 represent the adsorption isotherm, while 1–2–3 (decreasing *P*) indicates the desorption isotherm.

which can be rewritten as

$$\langle Z\rangle P_A(p) = L^{-\beta/\nu} f((\langle Z\rangle p - B_c)L^{1/\nu}), \qquad (84)$$

using $B_c = \langle Z\rangle p_{cb}$ (see Table 3). Thus, it remains to calculate $P_A(p)$ during the experiments. Consider, as an example, Fig. 15. The desorption curve has three segments indicated by 1, 2, and 3 in the figure. In the 1–2 interval, the isotherm is almost linear and occurs because of decompression of the liquid nitrogen in the pores. In the corresponding percolation network, the fraction p of the open pores (*i.e.*, those in which the nitrogen pressure is below P_{co}) increases, but $P_A(p)$ is still zero because a sample-spanning cluster of open pores has not yet formed. At point 2, the network reaches its p_c, a sample-spanning cluster of open pores is formed, and the metastable liquid nitrogen in the pores of the cluster vaporizes. If one decreases the pressure further, the number of pores containing metastable nitrogen and the number of pores whose nitrogen has vaporized both increase. At point 3, almost all the pores in which the nitrogen pressure is below their condensation pressure can also vaporize, and therefore $P_A(p) \simeq p$.

Thus a percolation method for estimating $\langle Z\rangle$ consists of two steps:

1. $P_A(p)$ is determined from the adsorption–desorption data; and
2. $\langle Z\rangle$ and L are determined by fitting Eq. (84) to $P_A(p)$.

Note that $P_A(p)/p$, the ratio of the number of pores in the sample-spanning cluster and the number of pores below their P_{co}, can also be written as N_p/N_b, where N_b is the number of moles of nitrogen that would desorb if all the pores containing nitrogen below its P_{co} had access to the vapor phase, and N_p is the number of moles of nitrogen that actually have desorbed at that pressure. Now, if N_A is the number of moles of nitrogen in the pores at a given pressure during the adsorption experiments, N_D is the number of moles of nitrogen in the pores at that pressure during the desorption experiment, and N_F is the number of moles of nitrogen that would have been present in the pores at that pressure during the desorption experiment if no nitrogen had vaporized from the pores that contain nitrogen below its P_{co}, then $N_p = N_F - N_D$, and $N_b = N_F - N_A$, and therefore

$$\frac{P_A(p)}{p} = \frac{N_F - N_D}{N_F - N_A}. \qquad (85)$$

The final step is to determine p, so that $P_A(p)$ can be calculated from Eq. (85). If $\Psi(r)$ is the PSD of the pore space, then for a given pressure one has

$$p = \int_r^\infty \Psi(x)\,\mathrm{d}x, \qquad (86)$$

where r is the pore radius in which nitrogen condenses at that pressure. Therefore, given $\Psi(r)$, p and hence $P_A(p)$ are determined. Using this method, the average connectivities of a variety of porous materials have been determined very accurately.

3.2 Single-phase Flow in Porous Media

Although the effective permeability K and conductivity G of porous media can be estimated by EMA and PSRG methods discussed above, these methods require very detailed information about the morphology of porous media. Katz and Thompson (1986, 1987) used percolation theory successfully for predicting K and G. Their method was based on a concept called critical-path analysis, first proposed by Ambegaokar *et al.* (AHL) in 1971. These authors argued that transport in a disordered medium with a broad distribution of heterogeneities is dominated by those conductances whose magnitudes are larger than some characteristic g_c, which is the smallest conductance such that the set of conductances $\{g|g > g_c\}$ forms a sample-spanning cluster called the critical path. Therefore, transport in a disordered medium with a broad conductance distribution reduces to a percolation problem with threshold conductance g_c. Shante (1977) and Kirkpatrick (1979) modified this idea by assigning g_c to all the local conductances with $g \geq g_c$, and setting all conductances with $g < g_c$ equal to zero (since the contribution of such bonds to the overall transport properties is negligible), and obtained a trial solution for G which has the same form as Eq. (8):

$$G = a g_c[p(g_c) - p_c]^\mu, \qquad (87)$$

where $p(g_c)$ is the probability that a given conductance $g \geq g_c$ and a is a constant. Equation (87) was then maximized with respect to g_c to obtain an estimate of g_c and thus G.

Katz and Thompson (1986, 1987) extended the ideas of AHL to estimate the permeability and electrical conductivity of porous media. In a porous medium the local hydraulic conductance is a function of a length scale l. Therefore there is a characteristic length scale l_c corresponding to g_c. The length that signals the percolation threshold in the flow problem also defines the threshold in the conduction problem. Thus we rewrite Eq. (87) as

$$G = \varphi g_c(l)[p(l) - p_c]^{\mu}, \tag{88}$$

where the porosity φ ensures a proper normalization of the fluid or the electric-charge density; $g_c(l)$ is equal to $c_f l^3$ for the flow problem and $c_e l$ for conduction. For appropriate choices of $p(l), G(l)$ achieves a maximum for some $l_{\max} \leq l_c$. In general $l^{\rm f}_{\max}$ for the flow problem is different from $l^{\rm c}_{\max}$ for the conduction problem, because the transport paths have different weights for the two problems. If $p(l)$ allows for a maximum in the conductance which occurs for $l_{\max} \leq l_c$, then for $l^{\rm f}_{\max} = l_c - \Delta l_{\rm f}$ and $l^{\rm c}_{\max} = l_c - \Delta l_c$, and $l^{\rm c}\mu p''(l_c)/p'(l_c) \ll 1$ (which is valid if the PSD is broad), we can write

$$\begin{aligned} l^{\rm f}_{\max} &= l_c\left[1 - \frac{\mu}{1 + \mu + l_c\mu p''(l_c)/p'(l_c)}\right] \\ &\simeq l_c\left(1 - \frac{\mu}{1+\mu}\right) \simeq \frac{1}{3}l_c, \end{aligned} \tag{89}$$

$$\begin{aligned} l^{\rm c}_{\max} &= l_c\left[1 - \frac{\mu}{3 + \mu + l_c\mu p''(l_c)/p'(l_c)}\right] \\ &\simeq l_c\left(1 - \frac{\mu}{3+\mu}\right) \simeq \frac{3}{5}l_c, \end{aligned} \tag{90}$$

where we used $\mu \simeq 2$ for 3D percolation. Thus, writing

$$G = a_1\varphi[p(l^{\rm c}_{\max}) - p_c]^{\mu} \tag{91}$$

and

$$K = a_2\varphi(l^{\rm f}_{\max})^2[p(l^{\rm f}_{\max}) - p_c]^{\mu}, \tag{92}$$

we obtain, to first order in Δl_c or in $\Delta l_{\rm f}$, $p(l^{\rm f,c}_{\max}) - p_c = -\Delta l_{\rm f,c}p'(l_c)$. To obtain a_1 and a_2, Katz and Thompson (1986) assumed that at the local level the conductivity of the porous medium is $g_{\rm f}$, the conductivity of the fluid (usually brine) that saturates the pore space, and that the local pore geometry is cylindrical, implying that $a_1 = g_{\rm f}$ and $a_2 = 1/32$. Therefore, one obtains

$$K = \frac{1}{226}\frac{G}{g_{\rm f}}l_c^2 \tag{93}$$

and (Katz and Thompson, 1987)

$$\frac{G}{g_{\rm f}} = \frac{l^{\rm c}_{\max}}{l_c}\varphi S(l^{c}_{\max}), \tag{94}$$

where $S(l^{\rm c}_{\max})$ is the volume fraction of connected pore space involving pore widths of size $l^{\rm c}_{\max}$ and larger. Note that it has been assumed that the permeability and conductivity exponents are equal, $\chi = \mu$, which is true if inequality (30) is satisfied.

Equations (93) and (94) involve no adjustable parameters. To obtain the characteristic length l_c, Katz and Thompson (1986, 1987) used mercury porosimetry discussed above, and proposed that $l_c = -(4\sigma\cos\theta)/P_c$, where σ is the surface tension between the mercury and the vacuum, θ the contact angle between the mercury and the pore surface, and P_c is the capillary pressure at the point when a sample-spanning cluster of mercury is formed in the pore space for the first time. Thus, a single set of porosimetry measurements yields l_c and hence K and G. Figure 16 compares the logarithm of the calculated K for a set of sandstones with the measured values. The dashed lines mark a factor of two; the agreement between the predictions and the data is very good. Equally impressive predictions were obtained for the electrical conductivity of the same porous media. This percolation method has also been extended for estimating the permeability of a porous medium saturated by a *non-Newtonian* fluid (Sahimi, 1993a), such as polymer solution.

3.3 Anomalous Diffusion in Porous Media

As mentioned in Section 1.6, diffusion in a porous medium at length scales $L < \xi_p$ is

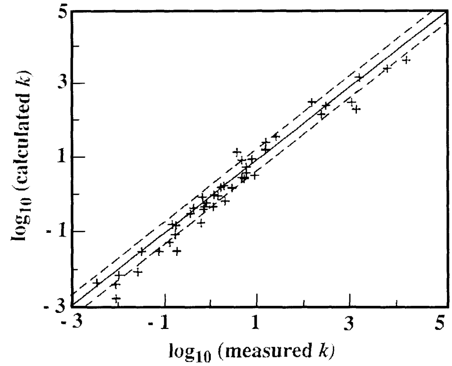

FIG. 16. Percolation predictions of the permeability k (in millidarcy) of various porous media *versus* the predicted values. Dashed lines denote a factor two of possible difference (after Katz and Thompson, 1986).

anomalous or fractal. A useful characteristic of diffusion is the mean square displacement $\langle R^2(t)\rangle$ of the diffusing particles, which is related to the effective diffusivity D by

$$\langle R^2(t)\rangle = 2dDt, \tag{95}$$

and therefore, depending on how $\langle R^2(t)\rangle$ grows with t, one can have three distinct diffusion regimes. Let us write

$$\langle R^2(t)\rangle \sim t^{2/D_W}, \tag{96}$$

where D_W is called the fractal dimension of the random walk or diffusion. In general, there are three possibilities.

1. $D_W = 2$, which means that $\langle R^2(t)\rangle$ grows linearly with t, and D is a constant. This happens when $R_d = \sqrt{\langle R^2(t)\rangle}$ is larger than the dominant length scale of the medium, which for percolation disorder is the correlation length ξ_p.
2. If $D_W > 2$, $\langle R^2(t)\rangle$ grows with t slower than linearly. In this case diffusion is called anomalous (Ben Avraham and Havlin, 1982; Gefen *et al.*, 1983) or fractal (Sahimi *et al.*, 1983a). In this regime $D \sim t^{2/D_W-1}$ vanishes as $t \to \infty$, *i.e.*, diffusion is very slow and inefficient. This happens when R_d is smaller than the dominant length scale of the medium, which for percolation disorder is the case if $R_d < \xi_p$. In general, diffusion in *all* fractal media is anomalous. Note that ξ_p is divergent at p_c, and therefore one always has fractal diffusion at p_c.
3. Finally, if $D_W < 2$, then $\langle R^2(t)\rangle$ grows with t faster than linearly. This is called *superdiffusion* (Sahimi, 1987).

Turbulent flow is an example of a transport process that gives rise to superdiffusion. We should point out that neither fractal diffusion nor superdiffusion is described by the classical diffusion equation, and the exact form of the governing equation is unknown.

In case **2** for $L < \xi_p$ (or equivalently at p_c), we can relate D_W to the critical exponents of percolation defined above. Suppose that diffusion occurs only in the sample-spanning cluster. Equations (14) and (20) tell us that near p_c, $D \sim \xi_p^{-\theta}$, where $\theta = (\mu - \beta)/\nu$. Because fractal diffusion occurs only if $R_d < \xi_p$, we can replace ξ_p with $R_d = \langle R^2(t)\rangle^{1/2}$ and write $D \sim \langle R^2(t)\rangle^{-\theta/2} \sim d\langle R^2(t)\rangle/dt$, which after integration yields $\langle R^2(t)\rangle \sim t^{2/(2+\theta)}$, implying that (Gefen *et al.*, 1983)

$$D_W = 2 + \frac{\mu - \beta}{\nu} = 2 + \theta. \tag{97}$$

Thus, we find that (see Table 3) $D_W(d = 2) \simeq 2.87$ and $D_W(d = 3) \simeq 3.8$. It can be shown (Sahimi *et al.*, 1983a) that EMA predicts that $D_W = 4$ for both $d = 2$ and $d = 3$. The crossover between fractal and Fickian diffusion occurs at a time t_{co} such that

$$t_{co} \sim \xi_p^{D_W} \sim (p - p_c)^{-2\nu+\beta-\mu}, \tag{98}$$

so that for $t < t_{co}$ diffusion is fractal, whereas for $t > t_{co}$ it is Fickian. Equation (98) tells that t_{co} diverges as $p \to p_c$, which is because as $p \to p_c$ the correlation length ξ_p diverges, and thus the percolation medium is a fractal object on a rapidly increasing length scale. If diffusion takes place on all the percolation clusters, then it can be shown (Gefen *et al.*, 1983) that

$$D_W = 2 + \frac{2\mu}{2\nu - \beta}. \tag{99}$$

Equations (96) and (97) were verified experimentally by Knackstedt *et al.* (1995), who obtained, with a model porous medium, $D_W \simeq 3.7 \pm 0.2$, consistent with Eq. (97).

3.4 Immiscible Displacements in Porous Media

We now turn our attention to percolation models of immiscible displacements and two-phase flows in porous media. A large number of factors affect this class of phenomena, among which are capillary, viscous, and gravity forces, the viscosities of the two fluids and the interfacial tension between them, chemical and physical properties of the surface of the pores, *i.e.*, whether there are surface active agents, or whether the surface is rough and fractal, the morphology of the pore space, and the wettability of the fluids. Thus, two-phase flow in a porous medium involves a set of complex phenomena, and to date no model has been developed that can take into account the effect of all the factors.

We already discussed, in the context of mercury porosimetry, a percolation model of drainage processes, *i.e.*, the displacement of a wetting fluid by a nonwetting one. In Section 3.5 we discuss such models in more detail. A more complex process is imbibition, by which a wetting fluid displaces a nonwetting fluid in a porous medium. The main difficulty is due to formation of thin films of the wetting fluids on the surface of the pores: even when the bulk of the pore is occupied by the nonwetting fluid, the presence of the wetting film on the pore surface makes the process very complex (Blunt and Scher, 1995; Hashemi *et al.*, 1998). Depending on the boundary conditions and a variety of other factors, one can have several types of imbibition processes, not all of which can be described by a percolation model. We describe here two of them that are described by percolation.

3.4.1 Spontaneous Imbibition The driving force for this process is capillary suction, because of which the smallest pore bodies that are next to the interface are always invaded. At any given time step, many pore-level interfaces advance in the porous medium. Usually, the displacement takes place at small but finite capillary numbers, the ratio of viscous and capillary forces defined by

$$Ca = \eta v/\sigma, \tag{100}$$

where η is the average viscosity and v is the average fluid velocity. However, Ca does not remain a constant, but varies over a range of values. When relatively large values of Ca are created, a transition zone develops in which there is a high saturation gradient. As the interface advances in the medium, two separate regions develop. One is in front of the transition zone where the saturation of the displaced fluid is high. The other moves behind the transition zone where the saturation of the displacing fluid is high. This region expands as the interface advances. The transition zone remains essentially the same throughout the displacement, except when the interface nears the end of the porous medium.

3.4.2 Quasistatic Imbibition A main difference between this process and spontaneous imbibition is that in this process at any given step only one pore is invaded by the displacing fluid. This can be achieved by adjusting the backpressure so that the *narrowest* pore throat is invaded, while the interface at other larger throats remains essentially motionless. Since even the largest pore throats are smaller than the pore body to which they are connected, once a pore body is invaded, so also are all the throats that are connected to it. As soon as the interface enters such throats, the smallest pore body that is connected to them is invaded, and so on. Thus at any given step of the displacement the smallest pore body that is accessible from the surface through a continuous path of the displacing fluid is invaded. This implies that a percolation model is applicable to this phenomenon.

A breakthough is achieved when the displacing fluid forms a sample-spanning cluster. Just before the breakthrough the displaced fluid is mostly connected. However, as the displacement proceeds small blobs of the displaced fluid are formed and get trapped. At the end of this process, one ends up with a large number of isolated blobs whose volume fraction in unconsolidated media varies between 0.14 and 0.2 and in consolidated porous media between 0.4 and 0.8. Experimental data (see, for example, Chatzis *et al.*, 1983) indicate that the size distribution of the blobs, when expressed in terms of the number of pore bodies they occupy (remember that most of the porosity and volume of a porous medium are provided by its pore bodies), follows Eq. (15), confirming the applicability of a percolation model.

3.5 Percolation Models of Two-phase Flow in Porous Media

In this section we discuss percolation models of two-phase flow and displacement in porous media, which, strictly speaking, are applicable only when *Ca* is small, although their range of applicability is often larger. At the outset we should point out that a fundamental assumption in all percolation models of two-phase flow is that the (bond or site) occupation probability p is proportional to the capillary pressure. Without such an assumption, it would be difficult to make a one-to-one correspondence between a percolation model and the two-phase flow problem.

3.5.1 Random Percolation Models The first random percolation model of two-phase flow in porous media was proposed by Larson *et al.* (1977, 1981a,b). To model drainage, the porous medium was represented by a cubic network. It was assumed that a bond is penetrated by the displacing fluid if the P_c at that point exceeds a critical value, implying that the bond's radius $r \geq r_m$, where r_m is defined by Eq. (79). All the bonds that are connected to the displacing fluid by a path of throats with $r \geq r_m$ were considered accessible, the accessibility being defined in the sense of percolation discussed in Sec. 1.3. It was also assumed that all the accessible throats with $r \geq r_m$ are filled by the nonwetting fluid (in reality this is not true, as the interface has to travel along a certain path before it reaches an accessible throat; see below). The displaced fluid was assumed to be compressible, so that it could not be trapped by the displacing fluid. Larson *et al.* (1981b) also proposed a percolation model of imbibition for calculating the residual nonwetting phase saturation S_{nwr} and its dependence on *Ca*. They modelled the creation of isolated blobs of the nonwetting phase by random site percolation. At p_{cs} they calculated the fraction $\hat{a}(s)$ of the active sites that are in clusters of length s in the direction of flow, and argued that this represents the desired blob size distribution. To calculate S_{nwr}, they assumed that once a blob is mobilized, it is permanently displaced (which is not always the case, because a blob can get trapped again, or join another blob and create a larger one).

Despite their shortcomings, the predictions of percolation models of Larson *et al.* were in qualitative agreement with experimental data. The fundamental assumption behind Larson *et al.*'s models is that pore-level events are controlled by capillary forces. Simple scaling arguments can be used for estimating the values of *Ca* for which this assumption is valid. It turns out that the ratio of viscous pressure drop and the capillary pressure is given by

$$P_{vis}/P_c \sim Ca/K_d, \tag{101}$$

where $K_d = K/l^2$ is a small dimensionless permeability (of order 10^{-3} or smaller) and l is the typical grain size. Thus, for capillary-controlled displacements, one must have $Ca \ll 1$ (typically, $Ca \sim 10^{-5}$–10^{-6}); experimental data do support this conclusion.

Heiba *et al.* (1982, 1983, 1984, 1992) further developed these ideas by distinguishing between pore throats that are allowed to a phase, and those that are actually occupied by the phase (*i.e.*, those that are accessible to it). Then, given the PSD of the pore space, they calculated the PSD of the allowed and occupied pores. For example, during drainage the PSD of the throats occupied by the nonwetting fluid is given by Eq. (80). Such PSDs are essential for calculating the permeability of each fluid phase and a related quantity, the *relative* permeability. It can be shown that if two immiscible fluids β and γ flow in a porous medium, then the governing equations for the average flow velocities and saturations of the fluids, for $Ca \ll 1$, are given by

$$\mathbf{v}_\beta = -\frac{\boldsymbol{K}_\beta}{\eta_\beta} \cdot (\boldsymbol{\nabla} \langle P_\beta \rangle^\beta - \rho_\beta g) + \boldsymbol{K}_{\beta\gamma} \cdot \mathbf{v}_\gamma, \tag{102}$$

$$\varphi \partial S_\beta / \partial t + \boldsymbol{\nabla} \cdot \mathbf{v}_\beta = 0, \tag{103}$$

with similar equations for fluid γ. Here $\boldsymbol{K}_\beta$, P_β, and ρ_β are respectively the permeability, pressure, and density of fluid β, and g is the acceleration due to gravity. The first term of (102) is the usual Darcy's law, while the second term is a coupling between the two phases, with $\boldsymbol{K}_{\beta\gamma} = \boldsymbol{K}_{\gamma\beta}$. Generally speaking, $\boldsymbol{K}_{\beta\gamma}$ is small unless $\eta_\beta \simeq \eta_\gamma$ (when a thin film of one phase coats the walls of a pore whose bulk volume is filled with the other phase). In practice one writes

$$\boldsymbol{K}_\beta = \boldsymbol{K} k_{\beta r}, \tag{104}$$

with a similar equation for the γ-phase, where $k_{\beta r}$ is called the relative permeability (RP) to the β phase, and $\boldsymbol{K}$ is the absolute permeability tensor of the porous medium. A major problem in multiphase flows in porous media is the prediction of the RPs. Unlike the absolute permeability $\boldsymbol{K}$, $k_{\beta r}$ depends on many parameters, including saturation and saturation histories of the fluids, pore-space morphology, the wetting characteristics of the fluids, the viscosity ratio, and the capillary number *Ca*. Experiments show that (see below) the RP to a phase typically becomes very small when its saturation is less than a critical value, which is distinctly larger than zero. This is, of course, the signature of a percolation problem.

If we use the PSDs of the pores and throats occupied by each fluid during drainage and imbibition (see Sec. 3.1.1), calculating the phase and relative permeabilities becomes a percolation problem. Therefore, EMA, PSRG, or REMA can be used for calculating the phase permeabilities and hence the RPs (Heiba *et al.*, 1982, 1983, 1984, 1992; Sahimi *et al.*, 1986). Figure 17 shows the results obtained with a cubic network, which are in excellent agreement with experimental data.

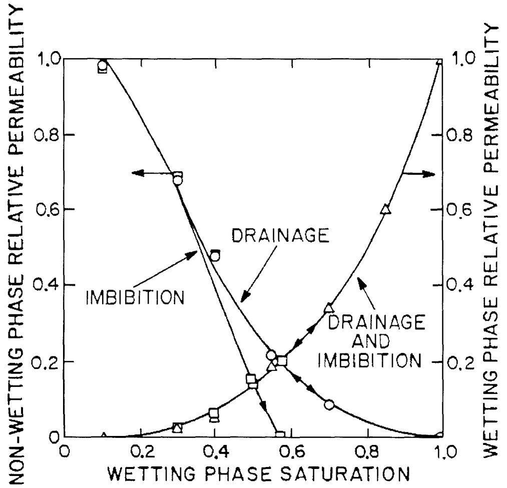

FIG. 17. Two-phase relative permeabilities as predicted by the random percolation model, using a simple cubic network model of porous media. The individual drainage and imbibition curves represent the relative permeabilities to the nonwetting phase during these processes, while the curve marked drainage and imbibition gives the relative permeability to the wetting phase during both processes (*i.e.*, there is no hysteresis in the wetting phase).

3.5.2 Invasion Percolation This model was first proposed by Lenormand and Bories (1980) and Chandler *et al.* (1982). In this model the network is initially filled with a fluid called the defender. To each site of the network is assigned a random number uniformly distributed in (0,1]. Then the displacing fluid (the invader) is injected into the medium and displaces the defender, at each time step, by choosing the site next to the interface that has the smallest random number. If we interpret the random numbers as the resistance that the sites offer to the invading fluid, then choosing the site with the smallest random number is equivalent to selecting a pore with the largest size, and hence this model simulates a drainage process. A slightly more tedious procedure can be used for working with bonds instead of sites. Two versions of the model have been developed. In one model the defender is incompressible, and therefore if its blobs are surrounded by the invader they become trapped (Chandler *et al.*, 1982; Wilkinson and Willemsen, 1983). In the second model, trapping is ignored, i.e., the defender is infinitely compressible (Wilkinson and Barsony, 1984).

There is a close connection between invasion percolation without trapping and random percolation (Wilkinson and Barsony, 1984). Define an *acceptance profile* $a_n(r)$ such that $a_n(r)\,\mathrm{d}r$ is the probability that random number r, selected at the nth step of the invasion, is in the interval $[r, r+\mathrm{d}r]$. Then as $n \to \infty$ one has

$$a_\infty(r) = 1/p_c, \quad r < p_c, \tag{105}$$

and $a_\infty = 0$ for $r > p_c$, where p_c is the percolation threshold. In practice a cumulative acceptance profile $b_n(r)$ is computed by

$$b_n(r) = (n + \langle n_b \rangle_n - 1)^{-1} \sum_{m=1}^{n} a_m(r), \tag{106}$$

where $\langle n_b \rangle_n$ is the average number of sites on the boundary immediately before the site is selected. In the limit $n \to \infty$ one has

$$b_n(r) = 1, \quad r < p_c, \tag{107}$$

and $b_n(r) = 0$ for $r > p_c$. Wilkinson and Barsony (1984) also defined two other quantities

$$B_1(n) = \int_0^{p_c} [1 - b_n(r)]\, \mathrm{d}r, \quad B_2(n) = \int_{p_c}^{1} b_n(r)\, \mathrm{d}r, \tag{108}$$

and postulated that $B_1(n) \sim B_2(n) \sim n^{-1/\Delta}$, where $\Delta = \nu D_F$ is called the gap exponent of percolation and D_F is the fractal dimension of the sample-spanning percolation cluster. Their Monte-Carlo simulations indicated that Δ is the same for invasion and random percolation.

For invasion percolation with trapping, Monte-Carlo simulations by Wilkinson and Willemsen (1983) indicated that the fractal dimension D_F of the sample-spanning cluster is $D_F(d = 2) \simeq 1.82$, somewhat smaller than $D_F(d = 2) = 91/48 \simeq 1.896$ for random percolation (see Table 3). This was confirmed by the experiments of Lenormand and Zarcone (1985) who displaced oil (the wetting fluid) by air (the nonwetting fluid) in a large and transparent 2D etched network and obtained $D_F \simeq 1.82$, consistent with 2D invasion percolation with trapping. Moreover, Shaw (1987) showed that if a porous medium, filled with water, is dried by hot air, the dried pores (*i.e.*, those filled with air) form a percolation cluster with the same D_F as that of invasion percolation. In 3D, recent results (Porto *et al.*, 1997) indicate that there may be significant differences between random percolation and invasion percolation with trapping, but a definitive picture has not yet emerged. A large number of workers have used an invasion percolation model or its variants to simulate two-phase flow in porous media; for comprehensive reviews see Sahimi (1993b, 1995).

3.5.3 Gradient Percolation So far, we have neglected the effect of gravity on an immiscible displacement. However, this effect cannot be neglected in a real porous medium, as the hydrostatic component of pressure adds to the applied pressure, and this creates a vertical gradient in the effective injection pressure. Because of this gradient, the fraction of the accessible pores decreases with the height of the system. A modification of the invasion percolation by Wilkinson (1984), by Sapoval *et al.* (1985) and by Gouyet *et al.* (1988) succeeded in taking into account such effects. The competition between gravity and capillary forces is usually quantified by the Bond number Bo defined as

$$Bo = gl^2 \Delta\rho/\sigma, \tag{109}$$

where $\Delta\rho$ is the density difference between the two fluids, g the acceleration due to gravity, and l the typical size of the grains or pores of the porous medium. Wilkinson (1984) showed that in an immiscible displacement under gravity, the correlation length ξ_g does *not* diverge (unlike random and invasion percolation which have a diverging correlation length ξ_p), but reaches a maximum value given by

$$\xi_g \sim Bo^{-\nu/(1+\nu)}, \tag{110}$$

where ν is the critical exponent of percolation correlation length, so that $\xi_g \sim Bo^{-0.47}$ and $\xi_g \sim Bo^{-4/7}$ in 3D and 2D, respectively. In 3D there is a transition region where both fluid phases can span the system (percolate), and the width w of this region is given by

$$w \sim Bo^{-1}. \tag{111}$$

Similar results were obtained by Sapoval *et al.* (1985) and Gouyet *et al.* (1988) in the context of *gradient percolation*, which is a model in which a gradient $\mathcal{G}$ for the occupation probability p is imposed on one direction of the network. They used arguments similar to Wilkinson's to show that

$$\xi_g \sim \mathcal{G}^{-\nu/(1+\nu)}, \tag{112}$$

which is completely similar to (110), in which Bo has been replaced with $\mathcal{G}$. The experiments of Hulin *et al.* (1988) and Birovljev *et al.* (1991) were completely consistent with these results. For example, Birovljev *et al.* (1991) used transparent 2D models consisting of a monolayer of 1-mm glass beads placed at random and sandwiched between two plates. The system was filled with a glycerol–water mixture, which was displaced by air invading the system at one end. They obtained $\xi_g \sim Bo^{-0.57}$, where the exponent 0.57 agrees with the prediction $\nu/(1 + \nu) = 4/7 \simeq 0.57$.

3.5.4 Crossover from Fractal to Compact Displacement Although we discussed the relative permeabilities for both imbibition and drainage in terms of a percolation model, there are certain qualitative differences between the two that need to be discussed. A clue to these differences is already evident in Fig. 17: the RP to the nonwetting phase during primary imbibition by a strongly wetting fluid vanishes only at zero residual nonwetting saturation, *i.e.*, the nonwetting phase is completely expelled from the medium and the wetting phase fills the system, indicating that imbibition is an essentially compact displacement. However, during drainage the RP to the wetting phase vanishes at a finite value of residual water saturation, *i.e.*, the nonwetting phase does not fill the porous medium, and a fractal percolation cluster is formed. This was nicely demonstrated by Lenormand and Zarcone (1984), who used a 2D etched network, injected mercury into the system (drainage) and then withdrew it (imbibition). The cluster formed during imbibition was compact and filled the network.

The crossover between the two types of displacement was clarified in a definitive study by Cieplak and Robbins (1988, 1990). In their study the porous medium was represented by a 2D array of disks with random radii, where the underlying lattice was either a triangular or a square network. The limit of low *Ca* was considered, and the displacement dynamics was modeled as a stepwise process where each unstable section of the interface moved to the next stable or nearly stable configuration. Trapping of the defending fluid was also allowed. If all the disks have the same radius, the resulting patterns are very regular and faceted which also preserve the symmetry of the lattice, consistent with experimental observations. However, when the radii of the disks are randomly distributed, then the behavior of the system depends on the contact angle θ [Eq. (76)]. To quantify the effect of θ, we define an interface width w. When θ is near 180°, *i.e.*, one has a drainage process, then the phenomenon is an invasion percolation and w is of the order of pore size. However, Cieplak and Robbins (1988, 1990) showed that as θ decreases, the cluster of the invading fluid becomes more compact, and w increases and finally diverges at a critical contact angle θ_c according to a power law

$$w \sim (\theta - \theta_c)^{-\nu_\theta}, \qquad (113)$$

where $\nu_\theta \simeq 2.3$ in 2D. The critical angle θ_c was found to depend on the porosity φ of the system; for example, $\theta_c \simeq 29°$ for $\varphi = 0.322$ and $\theta_c \simeq 69°$ for $\varphi = 0.73$. The exponent ν_θ was found to be universal. The compactness of the cluster for $\theta < \theta_c$ is consistent with the imbibition picture discussed above.

4. APPLICATION TO HOPPING CONDUCTIVITY OF AMORPHOUS SEMICONDUCTORS

Miller and Abrahams (1960) were probably the first to study hopping conductivity of amorphous semiconductors in the framework of a random resistor network. Over a decade after their work, it was realized that hopping conduction in semiconductors can be modeled successfully by percolation theory. This section summarizes the important elements of this successful application of percolation to a technologically important problem. Let us first discuss how the Miller–Abrahams network model was constructed, and then outline the percolation approach to this problem. The starting point in the Miller–Abrahams work was the Boltzmann equation

$$\frac{\partial P_i}{\partial t} = \sum_j [W_{ji}P_j(1 - P_i) - W_{ij}P_i(1 - P_j)], \qquad (114)$$

where P_i is the probability that site i of the network is occupied. It is assumed that the P_i's are uncorrelated. If repulsion can cause strong correlations, then the exclusion factor $1 - P_i$ is omitted. In the linear (Ohmic) regime, the current is proportional to the applied field, and we linearize Eq. (114) by writing $P_i = P_i^0 + \Delta P_i$ and $W_{ij} = W_{ij}^0 + \Delta W_{ij}$, where 0 denotes the equilibrium value and Δ an increment proportional to the applied field. Since $\Delta W_{ij} = -\Delta W_{ji}$, we obtain the linearized version of Eq. (114),

$$\frac{\partial \Delta P_i}{\partial t} + \sum_j A_{ij}\Delta P_i - \sum_j A_{ji}\Delta P_j = \sum_j B_{ji}\Delta W_{ji}, \qquad (115)$$

where $A_{ij} = W_{ij}^0(1 - P_j^0) + W_{ji}P_j^0$ and $B_{ij} =$

$P_i^0(1-P_j^0)+P_j^0(1-P_i^0)$. Equation (115) is a set of linear equations for the unknowns ΔP_i. The equilibrium values P_i^0 are given by the Fermi distribution

$$P_i^0 = [\exp(E_i/k_\mathrm{B}T)+1]^{-1}, \tag{116}$$

where E_i is the energy of a carrier on site i, as measured from the Fermi level, and k_B is the Boltzmann constant. The equilibrium values W_{ij}^0 are given by

$$W_{ij}^0 = u_{ij}/|\exp[(E_j-E_i)/k_\mathrm{B}T]-1|, \tag{117}$$

with

$$u_{ij}=u_{ji}=\exp(-2r_{ij}/a)/\tau_0. \tag{118}$$

Here $1/\tau_0$ is of the order of a phonon frequency, r_{ij} is the distance between i and j, and a is a Bohr radius. It is assumed that τ_0 depends only weakly on r_{ij} and the temperature T.

Suppose that $\boldsymbol{F}$ is the intensity of an applied field, and $\boldsymbol{r}_i$ is the radius vector of site i. The applied field changes the difference $\Delta_{ij}=E_i-E_j$ between the energies of sites i and j. We define a new variable V_i by

$$P_i = P_i^0+\Delta P_i \equiv |\exp[(E_i-eV_i)/k_\mathrm{B}T]+1|^{-1}, \tag{119}$$

where e is the charge of an electron. In the linear regime V_i is proportional to $\boldsymbol{F}$. Thus, one can transform the set of linear equations for P_i to one for V_i given by

$$\frac{P_i^0e^2(1-P_i^0)}{k_\mathrm{B}T}\frac{\partial V_i}{\partial t} = \sum_j[(V_i-\boldsymbol{F}\cdot\boldsymbol{r}_i)-(V_j-\boldsymbol{F}\cdot\boldsymbol{r}_j)]g_{ij}. \tag{120}$$

Equation (120) represents the Miller–Abrahams network which, at steady state, represents a resistor network if we think of $V_i-\boldsymbol{F}\cdot\boldsymbol{r}_i$ as the potential at site i. Then $z_{ij}=1/g_{ij}$ is the resistance (more generally, an impedance) between i and j, and Eq. (120) is simply Kirchhoff's law for site j. For the unsteady-state case, we define a capacitance $C=P_i^0e^2(1-P_i^0)/k_\mathrm{B}T$ with a potential V_i across it, and refer all the potentials to "ground" potential which is zero. Because $\boldsymbol{F}\cdot\boldsymbol{r}_i$ is the applied potential at i, it is represented as an output from a generator connected in series with C between the ground and site i. The impedance z_{ij} connects two junctions i and j, and the capacitor C_i is in series with a generator connected to the ground. Restricting our attention to the case when various site energies are of the order or larger than $k_\mathrm{B}T$, we obtain

$$z_{ij} = k_\mathrm{B}T\frac{\exp[(|E_i|+|E_j|+|E_i-E_j|)/2k_\mathrm{B}T]}{e^2u_{ij}}$$

$$= \frac{k_\mathrm{B}T}{e^2}\exp\left(\frac{E_{ij}}{k_\mathrm{B}T}+\frac{2r_{ij}}{a}\right)\tau_0, \tag{121}$$

$$C_i = \frac{e^2}{k_\mathrm{B}T}\exp\left(-\frac{E_i}{k_\mathrm{B}T}\right), \tag{122}$$

where either E_{ij} is the energy of the site farther from the Fermi energy, or $E_{ij}=(|E_i|+|E_j|+|E_i-E_j|)/2$. Equation (121) has an important implication: even if E_i is moderately distributed, the exponential dependence of z_{ij} and C_i on the energies makes them enormously broadly distributed quantities. This fact is used to reduce the computations of the effective properties of the network, since the broadness of the distribution of z_{ij} implies that there are many small conductances that can be removed from the network. The resulting network is called the *reduced* network, and the procedure for constructing it is discussed in detail by Pollak (1978).

In the Miller–Abraham model the hopping is between the nearest-neighbor sites. Mott (1968) pointed out that, if the activation energy of a nearest-neighbour site is large, a hop to a distant site whose energy is lower may be easier than one to a nearest-neighbour site. The range l_h of the hopper depends on the ease of activation to higher energies, and therefore l_h (and thus the resistance) depends on the temperature. This mechanism of hopping conduction, usually called *variable-range* hopping, is believed to be operating at low temperatures, whereas nearest-neighbour hopping occurs at high temperatures. Moreover, Mott showed that at low temperatures

$$G = G_0\exp[-(T_0/T)^\alpha]. \tag{123}$$

In general, α depends on the density of states near the Fermi level (see below). In Mott's theory, $\alpha = 1/(d+1)$ for a d-dimensional system, and G_0 and T_0 are some constants with

$$T_0 = \frac{\lambda a^3}{k_B N(E_F)}, \tag{124}$$

where $N(E_F)$ is the density of states at the Fermi level E_F, and λ is a dimensionless parameter. Equation (123) is particularly accurate for amorphous germanium in the range $60\,\mathrm{K} \leq T \leq 300\,\mathrm{K}$, with $T_0 \simeq 7 \times 10^7\,\mathrm{K}$. Similar results have also been found for amorphous silicon and carbon and vanadium oxide.

4.1 Percolation Models of Hopping Conductivity

Ambegaokar *et al.* (AHL) (1971), Shklovskii and Efros (1971), Brenig *et al.* (1971), and Pollak (1972) proposed that hopping conductivity of amorphous semiconductors can be modelled by percolation theory. As already mentioned in Sec. 3.2, AHL argued that an accurate estimate of G is the critical percolation conductance g_c, which is the largest value of the conductance such that the subset of the network with $g_{ij} > g_c$ still contains a conducting sample-spanning cluster. Thus, the network is divided into three parts:

1. a set of isolated clusters of high conductivity, each cluster consisting of a group of sites connected together by conductances $g_{ij} \gg g_c$;
2. a small number of resistors with g_{ij} of order g_c, which connect together a subset of high-conductance clusters to form the sample-spanning cluster, called the critical subnetwork, which is essentially the static limit of reduced network discussed above and dominates the overall conductance of the network;
3. the remaining resistors with $g_{ij} \ll g_c$.

Thus, the condition that $g_{ij} > g_c$, together with Eq. (121), is expressed as

$$\frac{r_{ij}}{r_m} + \frac{|E_i| + |E_j| + |E_i - E_j|}{2E_m} \leq 1, \tag{125}$$

where $r_m = a\ln(G_0/g_c)/2$ is the maximum distance between any two sites between which a hop can occur, $E_m = k_B T \ln(G_0/g_c)$ is the maximum energy that any initial or final state can have, and r_{ij} is the distance between nodes i and j.

To construct the critical subnetwork, AHL started with the smallest resistors and inserted them in an empty network one by one. As more resistors are inserted, clusters of connected resistors are formed until the critical value $z_c = 1/g_c$ is reached at which a sample-spanning cluster is formed. To calculate z_c, AHL used Eq. (121) and assumed that τ_0 is constant and that $N(E)$ is constant near the Fermi level, $N(E) = N(E_F)$. Thus, z_{ij} is a monotonic function of the random variable $\zeta = E_{ij}/k_B T + 2r_{ij}/a$, and z_c defines a corresponding critical value ζ_c. Around each site i such that $E_i < \zeta k_B T/2$, a sphere of radius

$$r_i = \frac{a}{2}\left(\frac{\zeta}{2} - \frac{E_i}{k_B T}\right), \tag{126}$$

is drawn. The radius of the sphere increases with ζ. When two spheres overlap, a bond is inserted between the two sites with overlapping spheres, which happens only if inequality (125) is satisfied. Percolation occurs at ζ_c, corresponding to a critical radius r_c. Equation (126) tells us that there is a maximum radius $r_m = a\zeta_c/4$ and a maximum energy $E_m = \zeta_c k_B T/2$, with $\zeta_c = 2\ln(G_0/g_c)$. Thus, if two sites are separated by a distance larger than r_m, or farther from energy level E_m, they will not contribute significantly to G. The volume of the sphere defined by Eq. (126) is $(\pi/6)a^3(\zeta_c/2 - E_i/k_B T)^3$, and the volume $\langle V\rangle$ averaged over all sites with a sphere with a non-zero radius (*i.e.*, those for which $E_i < \zeta k_B T/2$) is given by

$$\langle V\rangle = \frac{\pi}{384}a^3\zeta_c^3 = \frac{\pi}{48}r_m^3. \tag{127}$$

The volume fraction ϕ_c of the spheres at the percolation threshold is given by $\phi_c \simeq n\langle V\rangle$, where $n = N\zeta_c k_B T$ is the fraction of the sites with a sphere, *i.e.*, those with an energy in the interval $(-E_m, E_m)$. AHL estimated that $\phi_c \simeq 1/4$, somewhat larger than $\phi_c \simeq 0.15 - 0.17$ for 3D continuum percolation. One can also use the number of bonds per sites $B_c \simeq d/(d-1)$ (see Sec. 1.8). For 3D amorphous materials (or continuum percolation) $B_c =$

$4\pi n r_c^3/3$ and is related to $N(E)$ by

$$B_c = \frac{4\pi n}{3} \frac{\int_{-E_m}^{+E_m} N(E_i)\,dE_i \int_{-Em}^{+E_m} (r_m^3 + 3r_m^2 D_m + 3r_m D_m^2) N(E_j)\,dE_j}{\int_{-E_m}^{+E_m} N(E_i)\,dE_i}, \tag{128}$$

where D_m is the mean size of the sites. Combining $\phi_c = n\langle V\rangle \simeq 1/4$ with Eq. (127), or using Eq. (128) with the lattice or continuum value of B_c and the appropriate expression for r_m, one finally obtains Eqs. (123) and (124) with $\alpha = 1/4$ and $\lambda = 16$.

Equation (123) gives a lower bound to the true hopping conductivity of a network whose individual conductances vary over a broad range, because the critical subnetwork corresponds to replacing all $g_{ij} < g_c$ by 0 and all $g_{ij} \geq g_c$ by g_c in the original network. Equation (123) is exact only in the limit $T \to 0$. If $T > 0$, hops with conductance $g < g_c$ also contribute to the macroscopic conductivity, which means that the optimal cutoff should be somewhat larger than g_c. Moreover, the percolation approach of AHL cannot be used for 1D or quasi-1D conductors, since percolation disorder divides a linear chain into finite segments and the problem becomes meaningless. An example is a class of compounds which consist of weakly coupled parallel chains of strongly coupled atoms or molecules. The conductivity of such composites is highly anisotropic, and therefore they may be treated as essentially 1D conductors. Well-known examples of such systems are salts of the organic ion-radical tetracyanoquinodimethane (TCNQ) and the square planar complexes of transition metals such as platinum and iridium. Shante (1977) proposed a modification of the percolation model of AHL that took into account the effect of such complexities. His model was a bundle of chains in which hopping could occur along the chains and between them. However, interchain hopping was assumed to be much more difficult than intrachain hopping, but was still allowed. Shante's model also allowed the possibility of such intrachain hoppings in either 1D or 2D. At low temperatures Shante's model corresponded to 2D and 3D percolation, respectively, and consequently $T^{-1/3}$ and $T^{-1/4}$ behaviors were obtained (when ln G was plotted versus T). At high temperatures the percolation model is no longer applicable, and Shante obtained a T^{-1} behavior. The predictions were in excellent agreement with data. A completely different verification of Eq. (123) was provided by Ball *et al.* (1994), who studied the metal–insulator transition in excimer-laser–irradiated polyimide. The hopping conductivity of these composites was found to follow Eq. (123) with $\alpha = 1/4$. The electrical conductivity of the composite near its percolation threshold was found to follow Eq. (8) with $\mu \simeq 2 \pm 0.05$, completely consistent with 3D percolation (see Table 3). The pre-exponential factor G_0 has also been calculated by a percolation model. For example, Shklovskii and Efros (1975) proposed that $1/G_0 = r_c(2r_c/a)^{\nu} R_0$, where ν is the correlation length exponent of 3D percolation and R_0 is the resistance for $\zeta = \zeta_c$.

Finally, we should mention that hopping conductivity of disordered solids has also been studied by an EMA. For nearest-neighbor hopping the predictions of the EMA (see, for example, Odagaki and Lax, 1981; Sahimi *et al.*, 1983a) and the percolation model agree with each other, as well as with the experimental data. For variable-range hopping conductivity, Movaghar *et al.* (1980) showed that Mott's law, Eq. (123), can be predicted by a modified EMA. More recent works on this subject are those of Dyre (1994), Bleibaum *et al.* (1996) and Parris (1998).

4.2 Effect of a Variable Density of States

In the above percolation model, it was assumed that $N(E)$ is constant near the Fermi level. Although the basic $T^{-1/4}$ law has been observed in many semiconductors, criticism of this model was raised by many (see, *e.g.*, Szpilka and Viscor 1982), mainly because the predicted and measured G_0 differed by several orders of magnitude. This large difference was attributed to the assumption of a constant $N(E)$. Ortuno and Pollak (1983) proposed that if $N(E)$ is concave, then a modified percolation model can predict G_0 quantitatively. They used Eq. (128) with $N(E) = N(E_F)\exp(E/E_0)$, where E_0 is the exponential decay rate, and found good agreement between the predictions and the data for amorphous Si and Ge. Maloufi *et al.* (1988) used Ortuno and Pollak's theory to fit their conductivity data for amorphous Si_ySn_{1-y} with $y = 0.47$–1, and found excellent agreement over much of the temperature range. Moreover, if we assume that $N(E) \sim |E|^{\varpi}$, where ϖ is a positive constant, we find $\alpha = (\varpi + 1)/(\varpi + 4)$, which reduces to Eq. (123) when $\varpi = 0$. The limit $\varpi \to \infty$ is also interesting because it corresponds to a system that has a sudden onset of states away from the Fermi level, and we thus obtain a T^{-1} behavior for such systems. An experimental realization of a power-law density of states was provided by Redfield (1973), who carried out a careful study of hopping conductivity of heavily doped and strongly compensated GaAs; see also Sheng and Klafter (1983) and Mehbod *et al.* (1987) for related experiments.

4.3 Effect of Coulomb Interactions

Despite its success, the origin of a power-law density of states was not clear for some time until Efros and Shklovskii (1975) suggested that Coulomb interactions between localized electrons can create a soft gap (called Coulomb gap) in $N(E)$ near the Fermi level E_F. This means that $N(E)$ is not a constant in a narrow gap centered around E_F, whereas outside the gap $N(E)$ vanishes. If δ is the width of this gap, Efros and Shklovskii (1975) showed that $N(\delta) \sim \delta^{d-1}$. They also suggested that in 3D there is a crossover from a $T^{-1/4}$ behavior at relatively high temperatures, where the Coulomb gap is not effective, to $T^{-1/2}$ at lower temperatures. We point out that the Coulomb gap affects only those systems which have localized electronic states, such as doped crystalline semiconductors. Convincing experimental evidence for this crossover was provided by Zhang *et al.* (1990), who measured resistivity of five insulating compensated *n*-type CdSe samples, which are doped semiconductors. Their data clearly indicated a crossover from $T^{-1/4}$ behavior to $T^{-1/2}$ as the temperature was lowered by about three orders of magnitude from 15 to 0.04 K. The crossover temperature T_{co} was found to decrease as the concentration of the donor was increased. Aharony *et al.* (1992) (see also Meir, 1996) proposed that the resistivity $Z = 1/G$ of the samples obeys the scaling law

$$\ln(Z/Z_0) = Ah(T/T_{co}), \tag{129}$$

where A and T_{co} both depend on the sample properties, but the scaling function $h(x)$ is universal with $h(x) \sim x^{-1/4}$ for $x \gg 1$ and $h(x) \sim x^{-1/2}$ for $x \ll 1$. Moreover, using the percolation model, Aharony *et al.* proposed that

$$h(x) = \frac{x + [(x+1)^{1/2} - 1]}{x[1 + x^{1/2} - 1]^{1/2}}. \tag{130}$$

According to Eq. (129), if $\ln(Z/Z_0)$ for various samples is plotted as a function of T/T_{co}, all the data should collapse onto a single curve. Figure 18 shows such a collapse for the data of Zhang *et al.*, and the agreement is excellent.

4.4 Fractal Structures and Superlocalization

As discussed above, a $T^{-1/2}$ behavior for hopping conductivity can be explained in terms of the Coulomb interactions and gap. However, Coulomb interactions do not play any role in many semiconductors that do exhibit a $T^{-1/2}$ behavior. There has been some experimental evidence that one reason for the $T^{-1/2}$ behavior can be a fractal structure for the semiconductor. Lévy and Souillard (1987) suggested that in a fractal system impurity quantum states are *superlocalized*, *i.e.*, their wave functions decay with the distance r like $\exp(-r^{\gamma})$, with $\gamma > 1$ (in the classical Anderson

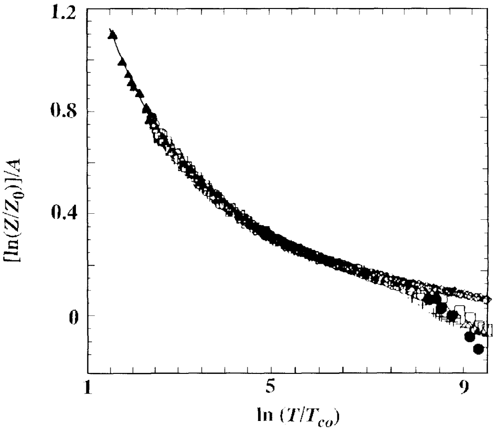

FIG. 18. Collapse of hopping conductivity $G = 1/Z$ of carbon black–polymer composites versus temperature T (in kelvins) (after Aharony *et al.*, 1992).

localization, $\gamma = 1$). Although no experimental evidence for superlocalization of electrons has been found yet, the problem has been studied theoretically by many workers. For example, Harris and Aharony (1987) and Aharony and Harris (1990) argued that one has to distinguish between the behavior of a *typical* geometry and that of a system that has been averaged over *all* the possible geometries. Moreover, they argued that an average over all the possible geometries yields $\gamma = 1$ (*i.e.*, there is no superlocalization of electrons). Early numerical studies of this problem were carried out by Lambert and Hughes (1991). The most definitive numerical study of this problem was carried out by Kantelhardt and Bunde (1997), who studied localization of electronic eigenfunctions and vibrational excitations (usually called *fractons*; see Sec. 8) on percolation clusters, in both the topological (r_t) and Euclidian (r_e) spaces, and found three different regimes. In the first regime, which corresponds to small r_t and r_e, electrons and fractons are superlocalized in the r_t space, but the localization is not exponential in the r_e space. In the intermediate regime, stretched-exponential *sublocalization* was found in both spaces with $\gamma \simeq 0.6$. In the third regime, corresponding to large r_t and r_e, the average behavior was found to depend strongly on the number of percolation configurations used in the averaging, but the asymptotic regime was a simple exponential decay with $\gamma = 1$, in agreement with the argument of Aharony and Harris.

However, none of these results supports the view that the existence of a fractal structure can by itself explain the observed $T^{-1/2}$ behavior of hopping conductivity of semiconductors in which Coulomb interactions are unimportant. van der Putten *et al.* (1992) measured the conductivity of carbon-black–polymer composites as a function of carbon-black concentration from a point in the vicinity of the percolation threshold up to $33p_c$, and in the temperature range from 4 to 300 K. Their data indicated that $\alpha \simeq 2/3$. To interpret this, they assumed that $N(E) \sim E^{\varpi}$, and proposed that

$$\alpha = \frac{\gamma(\varpi + 1)}{D_F + \gamma(\varpi + 1)}, \tag{131}$$

so that with $\alpha = 2/3$ and $D_F \simeq 2.53$ one obtains $\varpi \simeq 11/4$. Thus, their data can be best explained by a combination of a percolating fractal structure and a power-law $N(E)$. Moreover, if we take $\varpi = 1$, then Eq. (131) predicts that $\alpha \simeq 1/2$, indicating that a linear density of states and a percolating fractal structure may be responsible for the observed $T^{-1/2}$ behavior of hopping conductivity of semiconductors in which Coulomb interactions are unimportant. However, Aharony *et al.* (1993) argued that there is more than one way of interpreting the data of van der Putten *et al.* (1992), and therefore their interpretation is not unique. For the most recent experimental data for the conductivity of carbon-black–polymer composites see Mandal *et al.* (1997).

5. APPLICATION TO GRANULAR SUPERCONDUCTORS

Percolation theory can also explain some of the observed properties of granular superconductors, which are composed of superconducting grains separated by thin insulating grains that are called Josephson junctions. A granular superconductor is characterized by the size of the grains and the energy barrier between the grains, which determine the Josephson energy coupling E_J. Garland (1989) has reviwed many granular properties of superconducting materials.

Deutscher *et al.* (1980) proposed a percolation model for the onset of superconductivity by assuming that the grains are coupled if $E_J > k_B T$. Because the coupling energy depends on T, more and more grains become coupled as T is lowered. The coupling was obtained randomly with a T-dependent probability for which, when it was equal to the percolation threshold, a sample-spanning cluster of coupled superconducting grains was formed. If the temperature is still further lowered, the sample-spanning cluster of the superconducting grains grows in size. The distributions of the grain sizes and the junction resistances give rise to randomness in the coupling energy. The model was used to calculate the temperature dependence of the specific heat of the superconducting system; the agreement with the experimental data for granular Al–Al_2O_3 films was excellent.

Although there is Josephson tunnelling through the junctions, it does not generate any potential difference between the grains up to a critical current J_c. If T is decreased below the superconducting critical temperature T_c of the system, the number of superconducting links N_l (per unit cross-section area) increases, and percolation theory can be used for estimating N_l, J_c, and T_c. For example, consider the scaling behavior of J_c. Near p_c one has the power law

$$J_c \sim (p - p_c)^{\upsilon}, \tag{132}$$

where υ is a new critical exponent. Near p_c the granular superconductor can be viewed as a network of superconducting blobs connected by links (see Sec. 1.3). The links are quasi-linear chains of Josephson junctions. The current that flows through parallel links is inversely proportional to N_l, and the distance between the links is roughly proportional to the percolation correlation length ξ_p. Thus, for a d-dimensional system N_l is of the order $1/\xi_p^{d-1}$. Since $J_c \sim N_l$, we obtain

$$J_c \sim (p - p_c)^{\upsilon} \sim (p - p_c)^{\nu(d-1)}. \tag{133}$$

This prediction was confirmed by Monte-Carlo simulations in 2D percolation networks (Kirkpatrick 1979; Lobb and Frank 1979), and by careful experiments of Deutscher and Rappaport (1979) who prepared thin superconductor–semiconductor films of Pb–Ge and measured their critical currents. They obtained $\upsilon \simeq 1.3 \pm 0.1$, in excellent agreement with the prediction $\upsilon = \nu = 4/3$.

How does a magnetic field affect the behavior of a granular superconductor? There are two types of superconductors that behave quite differently in an external magnetic field.

1. Type-*I* superconductors remain superconducting and expel the magnetic field up to a critical field H_c. They then abruptly cross over to the normal state.
2. Type-*II* superconductors allow the magnetic field to penetrate into the system if H is greater than a lower critical field H_{c1}, but lose their superconductivity at an upper critical field H_{c2}.

A characteristic length scale of granular superconductors is their superconducting coherence length ξ_s, which is defined as the diffusion length over a characteristic time t_c for the relaxation of the order parameter at a given T. Therefore, one has $\xi_s \sim \sqrt{Dt_c}$, where D is a diffusion coefficient. Moreover, t_c is given by $t_c \sim (T_c - T)^{-1}$. If $\xi_s > \xi_p$, one is in the homogeneous regime in which $H_{c2} \sim T_c - T$ near T_c. The upper critical field of a type-II superconductor is proportional to ξ_s^{-2}. In the inhomogeneous regime, $\xi_s \ll \xi_p$, one has fractal diffusion (see Sec. 3.3) instead of Fickian diffusion. Since ξ_s is defined as a diffusion length scale, ξ_s^2 is proportional to $\langle R^2(t)\rangle$, the mean square displacement of a random walker given by Eqs. (95) and (96). Therefore, one obtains $H_{c2} \sim \xi_s^{-2} \sim t_c^{-2/(2+\theta)}$, which implies that

$$H_{c2} \sim (T_c - T)^{2/(2+\theta)}, \tag{134}$$

where $\theta = (\mu - \beta)/\nu$, defined in Sec. 1.5. Equation (134) was confirmed by Gerber and Deutscher (1989), who measured the upper critical field of thin semicontinuous lead films on germanium substrates and found that $H_{c2} \sim (T_c - T)^{\gamma}$ with $\gamma = 0.66 \pm 0.06$. Since in 2D $\theta \simeq 0.87$, the percolation prediction $\gamma = 2/(2 + \theta) \simeq 0.7$ is in very good agreement with the measured value.

6. APPLICATION TO ELASTIC AND VISCOELASTIC PROPERTIES OF HETEROGENEOUS MATERIALS

So far, we have discussed those applications of percolation theory in which only the connectivity of the clusters was important. We now consider more general percolation models—those in which one needs more than mere connectivity of percolation clusters in order to have macroscopic phenomena happening. An important example of such models is a class of elastic percolation networks that are examples of vector percolation. To begin with, let us consider a percolation network in which each bond represents an elastic element, *e.g.*, a spring, with an elastic constant e which takes on values from a probability density function $\psi(e)$. Since we focus mainly on the universal properties of such models, we consider the simplest case in which e is distributed according to a binary distribution,

$$\psi(e) = p\delta(e-a) + (1-p)\delta(e-b). \qquad (135)$$

If a is finite and $b = 0$, we obtain an elastic percolation network (EPN). Another case of interest is when $a = \infty$ and b is finite, *i.e.*, a fraction p of the springs are totally rigid and the rest are soft. We call this a superelastic percolation network (SEPN), which is the elastic analog of percolation models of conductor–superconductor mixtures discussed in Sec. 1.4. The percolation threshold p_{ce} of such models is not necessarily the same as p_{c}, the threshold of scalar and random percolation discussed above. As $p \rightarrow p_{\mathrm{ce}}^{+}$, all elastic moduli E of the system decrease and eventually vanish at p_{ce}. Near p_{ce} the elastic moduli of an EPN obey the power law

$$E \sim (p \sim p_{\mathrm{ce}})^{f}, \qquad (136)$$

whereas in an SEPN all the elastic moduli diverge as $p \rightarrow p_{\mathrm{ce}}^{-}$ according to

$$E \sim (p_{\mathrm{ce}} - p)^{-T}. \qquad (137)$$

The elastic percolation threshold p_{ce} and the critical exponents f and T may depend on the microscopic force laws between the sites of the network.

Let us briefly discuss how Monte-Carlo calculations with EPNs and SEPNs are carried out. To calculate elastic properties of these models we minimize their elastic energy $\mathscr{H}$ with respect to the displacement $\boldsymbol{u}_i$ of node i (*i.e.*, with respect to its components u_{ix}, u_{iy}, and u_{iz}), $\partial\mathscr{H}/\partial\boldsymbol{u}_i = 0$. Writing down this equation for every interior node of the network results in dN simultaneous equations for the nodal displacements $\boldsymbol{u}_i$ of a d-dimensional network of N internal nodes. The boundary conditions depend on the modulus that we would like to calculate. For example, to calculate the elastic constant C_{11} we stretch two opposite faces of the network by a given strain $\mathscr{S}$ (a tensile experiment), and impose periodic boundary conditions in the other directions. The resulting set of linear equations is solved typically by an iterative method such as the conjugate-gradient method. From the solution of the set of equations for nodal displacements we calculate $\mathscr{H}$, and hence the elastic modulus $C_{11} = 2\mathscr{H}/\mathscr{S}^2$. Alternatively, one can use a transfer-matrix method (Zabolitzky *et al.*, 1986), an efficient technique for calculating the elastic properties of percolation networks and their scaling properties.

6.1 Rigidity Percolation

The simplest model of vector percolation is the central-force (CF) model in which only stretching or central forces are present. The elastic energy of this model is given by

$$\mathscr{H} = \frac{\alpha}{2}\sum_{ij}[(\boldsymbol{u}_i - \boldsymbol{u}_j)\cdot\boldsymbol{R}_{ij}]^2 e_{ij} \qquad (138)$$

where α is the CF constant. Percolation on such networks is called *rigidity percolation.* Such networks are of both theoretical and practical interest. In many engineering problems, structures composed of bars or beams connected at nodes, which are called trusses, acquire their rigidity mainly from the tensile and compressive stiffness of the beams, and these are CF type of contributions. In contrast, those in which angular forces, *e.g.*, covalent bonds at the molecular level, are the most important are usually referred to as frames. For example, in the absence of friction between the particles of a granular packing the mechanical behavior of the packing is similar to that of rigidity percolation. It is not difficult to see that rigid systems in which angular forces dominate their behavior support an applied stress as long as they are simply connected. In contrast, CF systems require higher degrees of connectivity, and because of their importance to granular media, glasses, and gels they must be carefully studied. It was established in the mid 1980s (Feng and Sen, 1984) that the bond percolation threshold $p_{\mathrm{ce}}^{\mathrm{B}}$ of rigidity percolation is much larger than $p_{\mathrm{c}}^{\mathrm{B}}$, the corresponding threshold of scalar percolation. The reason for this is clear: on a CF percolation network there are many connected configurations of the network that, although sample-spanning, are not rigid, *i.e.*, their deformation does not cost any energy, and the elastic energy of the system remains unchanged. For example, for a d-dimensional cubic network one has

$p^B_{ce} = p^S_{ce} = 1$, where p^S_{ce} is the site percolation threshold of the system, which should be compared with those in Tables 1 and 2. Therefore, a meaningful study of rigidity percolation is restricted to certain lattices, *e.g.*, the triangular and bcc networks, which are regular lattices, or random lattices. Some typical values of p^B_{ce} and p^S_{ce} are

$$p^B_{ce} \simeq 0.641 \pm 0.001,$$

$$p^S_{ce} \simeq 0.713 \pm 0.002.$$

for the triangular network (Hansen and Roux, 1989; Arbabi and Sahimi, 1993), and

$$p^B_{ce} \simeq 0.737 \pm 0.002,$$

for the bcc network (Arbabi and Sahimi, 1993). These estimates should be compared with the corresponding p^B_c and p^S_c given in Tables 1 and 2. For rigidity percolation a correlation length ξ_e is defined that, similar to ξ_p for scalar percolation, diverges as p_{ce} is approached as

$$\xi_e \sim (p - p_{ce})^{-\nu_e}, \tag{139}$$

where in 2D $\nu_e \sim 1.1$.

Scaling properties of the elastic moduli of CF percolation networks have been studied extensively. For bond percolation in 2D, numerical simulations (Hansen and Roux, 1989; Sahimi and Arbabi, 1989; Arbabi and Sahimi, 1993) show that

$$f/\nu_e \simeq 2.95, \tag{140}$$

while for site percolation (Arbabi and Sahimi, 1993), $f/\nu_e \simeq 1.12 \pm 0.05$, very different from that of bond percolation. For bond percolation on the bcc network, Monte-Carlo simulations indicate (Arbabi and Sahimi, 1993) that $f/ve \simeq 2.1 \pm 0.2$, which is close to the critical exponent of conductivity of random percolation networks, $\mu \simeq 2.00 \pm 0.04$. Superelastic percolation networks with with CFs have also been studied by various techniques. For bond percolation on the triangular network the most accurate estimate of T (Arbabi and Sahimi, 1993) is $T/\nu_e \simeq 0.92 \pm 0.02$, while for bond percolation on a bcc network (Arbabi and Sahimi, 1993), $T/\nu_e \simeq 0.80 \pm 0.03$. We should point out that these estimates of f and T were obtained with regular lattices. It has been shown (Moukarzel and Duxbury, 1995; Jacob and Thorpe, 1995, 1996) that rigidity percolation on random lattices behaves quite differently than on the regular lattices. It is not yet clear whether f and T in random lattices will be different from the above estimates.

Bond percolation in CF percolation networks has also been studied by an EMA. For a d-dimensional network of coordination number Z, the effective force constant α^e is given (Feng *et al.*, 1985) by

$$\int_0^\infty \frac{\alpha^e - \alpha}{\alpha + \alpha^e(Z/2d - 1)} \psi(\alpha)\, d\alpha = 0, \tag{141}$$

which is very similar to Eq. (43) for scalar percolation, where $\psi(\alpha)$ is the distribution of the force constant α (note that αe_{ij} can be interpreted as the force constant of the bond i–j, so that a distribution for e_{ij} implies a distribution for α). From the effective force constant α^e, one can calculate the elastic moduli of the network. For example, for the triangular network the shear modulus is given by $4\alpha^e/\sqrt{3}$. It is not difficult to see that Eq. (141) predicts that

$$p^B_{ce} = 2d/Z. \tag{142}$$

According to (142), the average coordination number of a d-dimensional CF network at p_{ce} is given by $\langle Z \rangle = p^B_{ce} Z = 2d$, independent of the coordination number of the network itself. This implies that the coordination number of a d-dimensional CF network must be greater than $2d$ in order for it to have nonzero elastic moduli, thus explaining why the study of this model on the simple cubic lattices is meaningless. The same is true for the hexagonal and the diamond lattices. Equation (142) can also be derived by a constraint-counting argument (Feng *et al.*, 1985). When p is small, the CF network consists of disconnected pieces (floppy regions) and hence has many zero-frequency modes whose number is given by the number of degrees of freedom, $N_d = Nd$, minus the number of constraints, $N_c = ZNp/2$, where N

is the number of nodes in the lattice. Thus, the fraction of zero-frequency modes is given by $(Nd - ZNp/2)/Nd = 1 - Zp/2d$, which vanishes at $p = p_{\mathrm{ce}}^{\mathrm{B}} = 2d/Z$, identical with Eq. (142).

Equation (142) predicts that for the triangular network $p_{\mathrm{ce}}^{\mathrm{B}} = 2/3 \simeq 0.666$, which should be compared with the numerical estimate $p_{\mathrm{ce}}^{\mathrm{B}} \simeq 0.642$ given above. For the bcc lattice Eq. (142) predicts $p_{\mathrm{ce}}^{\mathrm{B}} = 3/4 = 0.75$, compared with the numerical estimate $p_{\mathrm{ce}}^{\mathrm{B}} \simeq 0.737$. Thus, unlike the EMA for percolation conductivity, Eq. (43), the performance of the EMA for rigidity percolation improves as the dimensionality of the system increases. Equation (141) also predicts that the critical exponent of the elastic moduli is $f = 1$, which does not agree with its numerical estimates. However, except for a very small region near $p_{\mathrm{ce}}^{\mathrm{B}}$, the predictions of Eq. (141) are in very good agreement with numerical simulation results.

6.2 Bond-Bending Models

One main shortcoming of CF percolation networks is that their percolation thresholds p_{ce} are much large than those of scalar percolation p_{c}. Thus, for $p_{\mathrm{c}} \le p \le p_{\mathrm{ce}}$, where p is the fraction of the intact springs, an EPN with only central forces is geometrically connected, but its elastic moduli are all zero, which is unphysical. Another shortcoming of CF percolation networks is that the significance of a straight-bond chain in transmitting elastic forces in them is ambiguous, because in a nonlinear model the straight bonds could buckle under compression but not under extension.

A more general vector percolation model with both central and bond-bending (or angle-changing) forces is free of such shortcomings. One of the main advantages of the bond-bending (BB) model is that its percolation threshold can be the same as that of scalar percolation, if the appropriate microscopic force laws between the sites of the network are used, and hence the model can be used for investigating mechanics of disordered solids such as polymers, ceramics, and powders. In general, the elastic energy of any bond-bending model is given (Kantor and Webman, 1984) by

$$\mathscr{H} = \frac{\alpha}{2}\sum_{\langle ij\rangle}[(\boldsymbol{u}_i - \boldsymbol{u}_j)\cdot \boldsymbol{R}_{ij}]^2 e_{ij} + \frac{\gamma}{2}\sum_{\langle jik\rangle}(\delta\theta_{jik})^2 e_{ij}e_{ik}, \tag{143}$$

where α and γ are the central and BB force constants, respectively. Here $\langle jik\rangle$ indicates that the sum is over all triplets in which the bonds j–i and i–k form an angle whose vertex is at i. The first term in Eq. (143) represents the usual contribution of the CFs, while the second term is due to BB forces. The precise form of $\delta\theta_{jik}$ depends on the microscopic details of the model. If bending of the bonds that make 180° with one another (*i.e.*, collinear bonds) is not allowed, then

$$\delta\theta_{jik} = (\boldsymbol{u}_i - \boldsymbol{u}_j)\cdot \boldsymbol{R}_{ik} + (\boldsymbol{u}_i - \boldsymbol{u}_k)\cdot \boldsymbol{R}_{ij}. \tag{144}$$

We refer to this particular version of the model as the Kirkwood–Keating (KK) model. Kirkwood (1939) used this model to study vibrational properties of rod-like molecules, while Keating (1966) studied the elastic properties of covalent crystals with essentially the same model (but not in the context of percolation). If bending of the collinear bonds is allowed, then

$$\delta\theta_{jik} = \begin{cases} (\boldsymbol{u}_{ij}\times\boldsymbol{R}_{ij} - \boldsymbol{u}_{ik}\times\boldsymbol{R}_{ik})\cdot(\boldsymbol{R}_{ij}\times\boldsymbol{R}_{ik})/|\boldsymbol{R}_{ij}\times\boldsymbol{R}_{ik}|, \\ \qquad \boldsymbol{R}_{ij} \text{ not parallel to } \boldsymbol{R}_{ik}, \\ |(\boldsymbol{u}_{ij}+\boldsymbol{u}_{ik})\times\boldsymbol{R}_{ij}|, \\ \qquad \boldsymbol{R}_{ij} \text{ parallel to } \boldsymbol{R}_{ik}, \end{cases} \tag{145}$$

where $\boldsymbol{u}_{ij} = \boldsymbol{u}_i - \boldsymbol{u}_j$. For all 2D systems, Eq. (145) simplifies to

$$\delta\theta_{jik} = (\boldsymbol{u}_i - \boldsymbol{u}_j)\times \boldsymbol{R}_{ij} - (\boldsymbol{u}_i - \boldsymbol{u}_k)\times \boldsymbol{R}_{ik}. \tag{146}$$

We refer to this as the BB model. For most materials to which the KK or the BB models are applicable, one has $\gamma/\alpha \le 0.3$.

Phillips and Thorpe (1985) used a mean-field theory to predict that the bond percolation threshold $p_{\mathrm{ckk}}^{\mathrm{B}}$ of a d-dimensional KK model with the coordination number Z is given by

$$p_{\text{cck}}^{\text{B}} \simeq \frac{1}{Z}\frac{d^2+d}{2d-1}. \qquad (147)$$

On the other hand, as mentioned in Sec. 1.2, for scalar percolation one has

$$p_{\text{c}}^{\text{B}} \simeq \frac{1}{Z}\frac{d}{d-1}. \qquad (148)$$

Thus, for 2D systems, $p_{\text{ckk}}^{\text{B}} = p_{\text{c}}^{\text{B}} \simeq 2/Z$, and simulations have confirmed that the percolation threshold of the KK model in 2D is the same as that of the scalar percolation. However for 3D systems Eq. (147) predicts that

$$p_{\text{ckk}}^{\text{B}} \simeq 2.4/Z, \qquad (149)$$

so that the average coordination number of the network at the percolation threshold should be about 2.4. On the other hand, Eq. (148) yields $p_{\text{c}}^{\text{B}} \simeq 1.5/Z$. Equation (149) was confirmed by numerical simulations (He and Thorpe, 1985). The BB model in d dimensions, on the other hand, has the same percolation threshold as p_{c} if each site of the network interacts with at least $d(d-1)/2$ of its nearest-neighbors. Therefore, by using suitable forms of $\mathscr{H}$ one obtains EPNs whose percolation thresholds are the same as p_{c}, a desirable property as far as many practical applications are concerned.

The critical exponents f and T have also been estimated for the BB models by a variety of techniques. In 2D the most accurate estimate of f was obtained by a transfer-matrix method (Zabolitzky *et al.*, 1986), while in 3D f was estimated (Arbabi and Sahimi, 1988) by large-scale Monte-Carlo simulations. The numerical results are listed in Table 4. Moreover, Sahimi (1986a), and later Roux (1986), proposed that

$$f = \mu + 2\nu, \qquad (150)$$

where μ is the critical exponent of the conductivity of percolation networks. The predictions of Eq. (150) are in excellent agreement with the numerical results given above, and thus it is likely to be exact. The origin of Eq. (150) is clear: elasticity introduces two extra factors of ξ_p, and therefore one must have, elastic moduli/conductivity $\sim \xi_p^2$, which results in Eq. (150).

The 2D and 3D superelastic BB models have been studied extensively. Such models were first proposed by Sahimi and Goddard (1985) for modeling the divergence of the viscosity η of a gelling solution near and below the gel point (see below). In addition to their relevance to modelling viscoelastic properties of gel polymers, SEPNs can be thought of as a model of random reinforcement of disordered materials. The most accurate estimates of the critical exponent T for BB models were also obtained (Arbabi and Sahimi, 1990; Sahimi and Arbabi, 1993) by large-scale Monte-Carlo simulations, and are also listed in Table 4. These estimates are somewhat smaller than the corresponding values for the exponent s of conductor–superconductor mixtures defined by Eq. (9). It has been proposed (Arbabi and Sahimi, 1990; Sahimi and Arbabi, 1993) that

$$T = \nu - \frac{\beta}{2}. \qquad (151)$$

The predictions of Eq. (151) agree with the numerical estimates of T.

The BB models have also been studied with an EMA (Schwartz *et al.*, 1985; Mall and Russel, 1987). The general form of the EMA for this case is similar to Eqs. (43) and (141). It

Table 4. Values of the critical exponents of scalar and vector percolation in d dimensions. Values of f and T for the central-force model refer to bond percolation, while those of μ and s are independent of the model.

d	μ/ν	s/ν	f/ν	T/ν	Model
2	0.9745 ± 0.0015	0.9745 ± 0.0015	2.97 ± 0.03	0.92 ± 0.03	Bond bending
	—	—	2.95 ± 0.25	0.92 ± 0.02	Central force
3	2.27 ± 0.01	0.835 ± 0.005	4.3 ± 0.1	0.74 ± 0.04	Bond bending
	—	—	2.1 ± 0.1	0.80 ± 0.03	Central force

predicts that $p_c^B = 2/Z$, the same as that of scalar percolation. The numerical predictions of the EMA for the BB models in 2D are also accurate, except very near p_c.

We should mention two other related models. One is the beam model (Roux and Guyon, 1985) in which each bond is a beam whose elastic behavior is governed by three material-dependent constants, $a_1 = l/E_{\mathrm{Y}}S$, $a_2 = l/E_{\mathrm{s}}S$, and $a_3 = l^3/E_{\mathrm{Y}}I$, where E_{Y} and E_{s} are the Young and shear moduli, S is the cross section of the beam, and I is the moment of inertia for flexion. Each site of the network is characterized by a displacement vector $\boldsymbol{u}_i$ and a rotational angle θ_i. If a site is rotated, the beams bend accordingly, and thus the local momenta are taken into account. Consider, for example, a square network. For a horizontal beam that connects sites i and j one has a longitudinal force F_{lj} acting at j, $F_{lj} = \alpha_1(u_{ix} - u_{jx})$, a shear force $F_{sj} = \alpha_2(u_{iy} - u_{jy}) + \alpha_2 l(\theta_i + \theta_j)/2$, and a flexural torque $\tau_j = \alpha_2 l(u_{iy} - u_{jy} + l\theta_j)/2 + \alpha_3 l^2(\theta_i - \theta_j)$, where $\alpha_1 = 1/a_1$, $\alpha_2 = 1/(a_2 + a_3/12)$, and $\alpha_3 = \alpha_2(a_2/a_3 + 1/3)$. In a similar way, the analogous equations for the vertical direction are written down. In mechanical equilibrium the sums of all forces and of all torques acting on a site must be zero, giving rise, in the continuum limit, to the classical Cosserat equations. The percolation threshold of this model is of course the same as that of scalar percolation. Numerical simulations also indicated that the scaling properties of this model are identical with those of the BB model.

The second model is the so-called granular or disk model (Schwartz *et al.*, 1984) which has been used for studying vibrational properties of granular rock, such as sandstone. The elastic energy of the system is given by

$$\begin{aligned}\mathscr{H} = \frac{1}{2}\sum_{\langle ij\rangle} e_{ij}\{&\alpha[(\boldsymbol{u}_i - \boldsymbol{u}_j)\cdot \boldsymbol{R}_{ij}]^2 \\ &+ \gamma\{\boldsymbol{R}_{ij} \times [\boldsymbol{R}_{ij} \times (\boldsymbol{u}_i - \boldsymbol{u}_j)] \\ &+ R(\theta_i + \theta_j)\boldsymbol{z} \times \boldsymbol{R}_{ij}\}^2 \\ &+ \delta(\theta_i - \theta_j)^2\}, \qquad (152)\end{aligned}$$

where R is the radius of the disks, δ is the elastic constant associated with the restoring torque that is necessary when two disks counterrotate, and $\boldsymbol{z}$ is a unit vector normal to the plane of the disks. The rest of the notation is the same as before. With such couplings, any relative displacements or rotations of two neighboring disks can be done at a cost to the energy $\mathscr{H}$ of the system. Therefore, the percolation threshold of this system is the same as that of scalar percolation. In terms of a lattice model, the granular model is essentially equivalent to the beam model described above. Numerical studies indicate that the scaling properties of the elastic moduli of this model are the same as those of the BB model. Therefore, the BB model is the simplest elastic percolation model that possesses two important and fundamental properties that most models of heterogeneous materials must have: a rotationally invariant elastic energy, and a percolation threshold that is identical with that of scalar percolation. We summarize in Table 4 the currently accepted estimates of the various critical exponents for both rigidity percolation and the BB model.

Let us now discuss applications of EPNs and SEPNs to modelling of various properties of composite solids and gel polymers (the application to glasses is discussed separately).

6.3 Elastic Properties of Composite Solids

Deptuck *et al.* (1985) measured the Young's modulus of a sintered, submicrometer powder that was described in Sec. 2.1. Their measurements indicated that the Young's modulus of the powder obeys scaling law (136) with $f \simeq 3.8$, in excellent agreement with the numerical estimate (see Table 4) of the BB model in 3D. Allen *et al.* (1988) carried out dynamical measurements of the shear modulus of a model 2D percolation lattice, by exciting small torsional linear oscillations on a cylindrical screen as links were cut to approach p_c. They obtained $f \simeq 3.6 \pm 0.2$, relatively close to $f \simeq 3.96$ in 2D. Measurements of the elastic moduli of 2D composites were also carried out by Benguigui (1986), Lobb and Forrster (1987), and Sofo *et al.* (1987). Benguigui's experiments were done with sheets of metal in which holes had been punched; he obtained $f \simeq 5.0 \pm 0.5$, consistent with the prediction of Halperin *et al.* (1985) and Feng *et al.* (1987) that the critical exponent f for such 2D percolating continua should be larger than the corresponding value for lattice systems by about 3/2 (hence, $f \simeq 3.96 + 1.5 = 5.5$). Measurements of Lobb and Forrester (1987) were also carried out with metal sheets into which holes had been punched. They obtained $f \simeq 4.95 \pm 1.1$, again consistent with Halperin *et al.*'s prediction. Sofo *et al.* (1987) used randomly holed metallized Mylar and obtained $f \simeq 5.3 \pm 0.7$, in even better agreement with the prediction of Halperin *et al.* (1985).

On the other hand, Benguigui and Ron (1993) constructed a mixture of a very soft material, in their case a gel, and a very rigid material, which was alumina and zirconia, and measured the Young's modulus of the mixture as the volume fraction of the rigid materials approached p_c, the percolation threshold of the rigid component. They found that the modulus diverges at p_c, and that near the percolation threshold the Young's modulus of the mixture obeys scaling law (140) with $T \simeq 0.66 \pm 0.04$, in excellent agreement with the value of superelasticity exponent in 3D (see Table 4). Thus, there remains no doubt that elastic and other mechanical properties of disordered solids can be described by EPNs and SEPNs. Elastic percolation networks have also been used for modeling wave propagation in porous media, for modelling fracture of rock at large length scales (Sahimi *et al.*, 1993), and for explaining the spatial distribution (Sahimi *et al.*, 1993) and dynamics (Sahimi and Arbabi, 1996) of earthquakes.

An important characteristic of any solid is its Poisson ratio $\mathscr{P}$. For a 2D isotropic solid $\mathscr{P}$ is given by

$$\mathscr{P} = 1 - 2E_s/E_t, \tag{153}$$

where E_s and E_t are the shear and tensile moduli, respectively. For a 3D isotropic solid the corresponding equation is

$$\mathscr{P} = \frac{3(E_b/E_s) - 2}{2 + 6(E_b/E_s)}, \tag{154}$$

where E_b is the bulk modulus of the solid. The Poisson ratio is a measure of the strain in the transverse direction that results from a stress applied longitudinally. In most materials the experimentally measured $\mathscr{P}$ is positive, which corresponds to materials that shrink transversely when stretched longitudinally. The definition of $\mathscr{P}$ for an anisotropic solid is arbitrary. Theoretically (Landau and Lifshitz, 1959) one can have highly compressible isotropic materials with Poisson ratios as low as -1, and more generally one has $-1 \leq \mathscr{P} \leq 1/2$. For anisotropic materials one has the general bound $|\mathscr{P}| \leq \sqrt{E_{yM}/E_{ym}}$, where E_{yM} and E_{ym} are the major and minor orthotropic Young's moduli.

The elastic percolation models discussed here can also possess negative values of the Poisson ratio. On the experimental side, there are some manufactured foams (Lakes, 1987) that are isotropic and their Poisson ratio is as low as -0.5. There are also many anisotropic materials, such as microporous poly(tetrafluoroethylene) (Evans and Caddack, 1989), microporous ultrahigh-molecular-weight polyethylene (Alderson and Evans, 1992) and iron pyrites, pyrolitic graphite, hexagonal metals, and fiber-reinforced composites, that have large negative Poisson ratios, as low as -1.2, regardless of how $\mathscr{P}$ is defined. Of course, 3D elastic percolation models on all regular lattices are also anisotropic. Thus, negative Poisson ratios, as demonstrated by elastic percolation models and by many real materials, should not be considered as unphysical and, in fact, they may point to the possibility of designing a new class of materials with interesting, unusual, and useful properties. For example, they would have enhanced flexural rigidity and plane strain-fracture toughness, but lower bulk modulus.

6.4 Elastic and Viscoelastic Properties of Gel Polymers

Another class of materials to which elastic and superelastic percolation models are applicable comprises gel polymers. To compare experimental results for the scaling properties of the elasticity of gels with the predictions of EPNs, we divide the gel polymers into two groups. In the first group are what we call physical gels, in the formation of which chemical reactions play no role. Two examples are gelation of silica particles in NaCl solutions and in pure water (Gauthier-Manuel *et al.*, 1988) and silica aerogels (Woignier *et al.*, 1988). The attachment of the particles in such gels is by relatively weak association. The BB forces are important in such gels since touching particles that form long chains, when deformed, roll on top of one another and this motion, together with the displacement of the centers of any three mutually touching particles, creates forces that are equivalent to the BB forces. Experimental measurements (Gauthier-Manuel *et al.*, 1988; Woignier *et al.*, 1988) of f for such gels confirmed this: f was found to be about 3.8, in excellent agreement with the critical exponent f of the 3D BB model (see Table 4).

In the second group are what we call chemical gels, which are the usual branched polymers are formed by a chemical reaction between the monomers. In most chemical gels the BB forces are usually not important and the only important force between the monomers seems to be the central (stretching) forces. There are numerous experimental measurements of f for such gels. Examples include measurement of f for hydrolyzed polyacrylamide (Allain and Salomé, 1987b, 1990), tetraethylorthosilicate reactions (Hodgson and Amis, 1990; Takahashi *et al.*, 1994), gelatin solutions (Djabourov *et al.*, 1988), polycondensation of polyoxypropylated trimethylolpropane with hexamethylenediisocyanate (Durand *et al.*, 1987), and several other measurements (Gauthier-Manuel and Guyon, 1980; Adam *et al.*, 1981; Tokita *et al.*, 1984). These measurements all yielded a value of f in the range 1.9–2.2, which does not agree with that of the BB model, but agrees nicely with the exponent of the 3D CF percolation (see Table 4).

A value of f in the range 1.9–2.2 can also be interpreted by another percolation model. Alexander (1984) argued that in some gels and rubbers that are under internal or external stress, there are terms in the elastic energy of the system that are similar to the Born model described by

$$\mathscr{H} = \frac{1+\mathscr{P}}{1-\mathscr{P}} \sum_{ij} [(\boldsymbol{u}_i - \boldsymbol{u}_j) \cdot \boldsymbol{R}_{ij}]^2 e_{ij} + \frac{1-3\mathscr{P}}{4(1-\mathscr{P})} \sum_{ij} (\boldsymbol{u}_i - \boldsymbol{u}_j)^2, \qquad (155)$$

where all the notations are as before. In 3D the critical exponent of this system is $f = \mu \simeq 2.0$, because near p_c the contribution of the second term on the right-hand side of Eq. (155), which is a purely scalar term, dominates that of the first term, which is due to the central forces. However, Eq. (155) has the unphysical feature that it is not rotationally invariant. Moreover, because rubbers and gels differ from the Born model in several important ways, such as the presence of nonlinear terms in their elastic energy and the possibility of negative as well as positive Born coefficients, it is not clear that the result $f \simeq \mu$ is applicable to such materials.

We should mention that there are some chemical gels in which the BB forces seem to be important, and thus their scaling behavior may be described by the BB model. Examples include the measurements of Adam *et al.* (1985) for polycondensation, $f \simeq 3.3 \pm 0.5$, and those of Martin *et al.* (1988) and Adolf *et al.* (1990) for gels made from 89 wt% of the diglycidyl ether of bisphenol A cured with 11 wt% of diethanolamine, which yielded $f \simeq 3.3 \pm 0.3$. These values are much closer to $f \simeq 3.75$ for the 3D BB model than to $f \simeq 2.1$ for the 3D CF model. We must also point out that in some polymers entropic effects are important (leading to the formation of long chains and entanglement), whereas in the elastic percolation models described here such effects have not been taken into account (the elastic energy of the EPNs considered here is enthalpic). It is not clear that if the entropic effects are taken into account (a difficult task), f would remain the same as the one that one finds with the BB models. Daoud and Coniglio (1981) and Martin *et al.* (1988) suggested that for such cases

$$f = \nu d. \qquad (156)$$

In 3D Eq. (156) predicts $f \simeq 2.64$, quite different from the exponents of the CF and BB models. Recent measurements of the shear modulus of an end-linking gel polymer by Takahashi *et al.* (1994) yielded $f \simeq 2.7$, in very good agreement with Eq. (156).

Numerous experimental measurements indicate that the viscosity η of a gelling solution below and near the gel point obeys the power law

$$\eta \sim (\phi_c - \phi)^{-k}, \qquad (157)$$

where ϕ is the gel fraction and ϕ_c its value at the gel point, which is a percolation threshold. To explain the experimental data on the scaling behavior of η near the gel point, it was proposed (Arbabi and Sahimi, 1990; Sahimi and Arbabi, 1993) that the scaling properties of η near the gel point are analogous to those of the shear modulus of a SEPN near p_c. This analogy was made simply because both quantities diverge at p_c (the gel point). However, even the analogy between η and the shear modulus of an SEPN is not nearly enough to explain the scaling of η near the gel point, because experimental data indicate that the value of k is either in the range 0.6–0.9 (see, for example, Adam *et al.*, 1979, 1985; Allain and Salomé, 1987a; Durand *et al.*, 1987), or in the range 1.3–1.5 (see, for example, Djabourov *et al.*, 1988; Martin *et al.*, 1988, Martin and Wilcoxon, 1988), whereas the shear modulus of a 3D SEPN is characterized by a *unique* value of T. The reason for having two distinct values of k is (Arbabi and Sahimi, 1990; Sahimi and Arbabi, 1993) that the dynamics of the two solutions that yield the two distinct values of k are totally different. In one case, the system is presumably close to the Zimm limit in which there is little or no polymer diffusion in the reaction bath, because there are strong hydrodynamic interactions between the monomers, and also between polymers of various sizes. Hence, a SEPN, which is a static system with fixed rigid clusters, may be suitable for simulating the Zimm regime. Indeed, the estimate $T \simeq 0.65$ for 3D SEPNs supports the idea that those gelling solutions whose value of k is in the range 0.6–0.9 are in fact close to the Zimm regime and can be described by a *static* SEPN.

On the other hand, the gelling solution can also be near the Rouse regime in which there are no hydrodynamic interactions between the polymers of various sizes, and therefore the polymers can diffuse essentially freely in the reaction bath. To simulate this regime a dynamic superelastic percolation model was proposed (Arbabi and Sahimi, 1990; Sahimi and Arbabi, 1993) in which each cluster of the totally rigid bonds represents a polymer. The soft bonds (those for which the elastic constant e_{ij} is finite) represent the liquid (solution) medium in which the rigid clusters move randomly, with equal probability, in any direction of the network. This simulates the diffusion of the polymers in the reaction bath. Two rigid clusters cannot overlap, but they can temporarily join and form a larger cluster, which can be broken up again at a later time. It was shown (Arbabi and Sahimi, 1990; Sahimi and Arbabi, 1993) that the shear modulus of this dynamic SEPN diverges with an exponent T' given by

$$T' = 2\nu - \beta, \tag{158}$$

which in 3D predicts that $T' \simeq 1.35$, supporting the idea that the gelling solutions whose values of k are in the range 1.3–1.5 are close to the Rouse limit, and can be described by a *dynamic* SEPN.

6.5 Structural Properties of Branched Polymers and Gels

After a polymer is formed by a chemical reaction, the experimentalist usually analyzes its structure by diluting it in a good solvent. Such branched polymers in a dilute solution of a good solvent may swell and have a radius larger than their extent at the end of the chemical reaction. Thus, it is important to consider both typical polymers and the swollen ones. Consider first a swollen branched polymer in a good solvent whose radius is larger than the correlation length. The structural properties of such branched polymers are described by *lattice animals*, which are percolation clusters below p_c whose radii are larger than the percolation correlation length ξ_p. However, the scaling properties of lattice animals are different from those of percolation clusters (Lubensky and Isaacson, 1978; Family and Coniglio, 1980). For example, their fractal dimension D_A is quite different from D_F, the fractal dimension of the sample-spanning percolation clusters at p_c. In fact, Parisi and Sourlas (1981) showed that in 3D, $D_A = 2$ exactly, quite different from $D_F \simeq 2.52$.

One way of checking this prediction is by small-angle scattering. The intensity $I(q)$ of scattering at an angle θ_s is related to the magnitude of the scattering vector, $q = 4\pi\sin(\theta_s/2)/\lambda$ (λ is the wavelength of radiation), by

$$I(q) \sim q^{-D_A}. \tag{159}$$

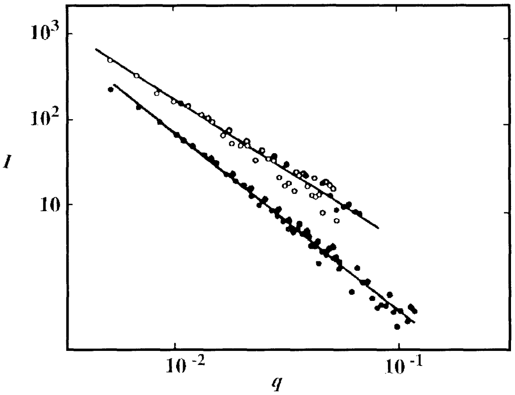

FIG. 19. SANS data for branched polymers. The upper curve is for a polydisperse polymer solution, while the lower curve is for a single polymer in a dilute good solvent (after Bouchaud *et al.*, 1986).

Bouchaud *et al.* (1986) carried out small-angle neutron-scattering (SANS) experiments on a monodisperse polyurethane sample and measured the scattered intensity as a function of q. Figure 19 presents their results, from which one obtains $D_A = 1.98 \pm 0.03$, in excellent agreement with the Parisi–Sourlas prediction, $D_A = 2$. In real applications, however, polymer solutions are almost always polydisperse and contain polymers of all sizes with radii smaller or larger than ξ_p. Thus, one needs to define *average* properties, where the averaging is taken over the polymer size distribution. For example, an average polymer radius $\langle R \rangle$ is used to define an *effective* fractal dimension for all the branched polymers in the solution through the relation $n \sim \langle R \rangle^{D_E}$, where n is the average number of the monomers. Daoud *et al.* (1984) showed that for a polydisperse polymer in a dilute solution of a good solvent

$$D_E = D_A(3 - \tau). \qquad (160)$$

Thus, Eq. (160) mixes the animal fractal dimension D_A with the percolation exponent τ defined by Eq. (15). Thus, one should have $D_E \simeq 1.64$ for 3D polymers. Bouchaud *et al.* (1986) synthesized a natural polydisperse polyurethane sample and carried out SANS experiments on a dilute solution of it. Figure 19 also shows their results, from which one obtains $D_E \simeq 1.6 \pm 0.05$, in good agreement with the theoretical prediction of 1.64. For related experiments see Adam *et al.* (1985), who carried out static light-scattering experiments in dilute polydisperse polyurethane solutions; Leibler and Schosseler (1985), who measured the average radius of polystyrene, crosslinked by irradiation by elastic light scattering; Patton *et al.* (1989), who performed both quasielastic and elastic light scattering experiments on branched polyesters; and Dubois and Cabane (1989), who used a silica gel, a physical (rather than chemical) gel, all of whom found evidence supporting the theoretical predictions.

Note that Eq. (160) can also be used for estimating the percolation exponent τ, since D_E and D_A can be measured directly from the small-angle experiments. Indeed, using the experimental values for D_E and D_A, one obtains $\tau \simeq 2.2$, in excellent agreement with the percolation prediction of 2.18 (see Table 3). In their experiments with irradiated polystyrene solution in cyclopentane, Leibler and Schosseler (1985) coupled gel permeation chromatography and light scattering and obtained the polymer size distribution, which provides a direct means of measuring τ, using Eq. (15). They obtained $\tau \simeq 2.3 \pm 0.1$, consistent with the percolation prediction. Lapp *et al.* (1989) further checked this result by doing similar experiments in a system made by chemical end-linking of polydimethylsiloxane, and Patton *et al.* (1989) did the same in a system in which polyester was made by bulk condensation polymerization. The results of both groups were consistent with the percolation prediction for τ. Note that since the fractal dimension D_F is related to τ by

$$D_F = d/(\tau - 1), \qquad (161)$$

these results also imply that $D_F \simeq 2.5$, in agreement with the percolation prediction, $D_F \simeq 2.52$. For other experiments confirming the applicability of percolation theory to describing the structure of branched polymers and gels see Adam *et al.* (1985), who performed static light-scattering measurements on a polyurethane sol; Candau *et al.* (1985), who carried out their experiments on polystyrene systems crosslinked with di(vinyl benzene); Schmidt and Burchard (1981), who carried out anionic copolymerization of di(vinyl benzene) with styrene and obtained branched polymers and gels and used light scattering to measure various properties of interest; and Trappe *et al.* (1992). More recent theoretical developments in this area include the work of Lucena *et al.* (1994) who introduced models of branched polymers that seem different from those of lattice animals discussed above. Bunde *et al.* (1995) studied this model extensively, and showed that the branched polymers that are generated by this model are similar to percolation clusters (*i.e.*, gels) rather than lattice animals. However, no experimental verification of this result is yet available.

7. APPLICATION TO GLASS FORMATION

In an attempt to explain the strong glass-forming propensity of some chalcogenide systems, Phillips (1979) proposed for the first time that covalent bonding in glasses can be optimized when the average coordination number $\langle Z\rangle$ of the 3D covalent network in mechanical equilibrium is about 2.4. This idea was significantly refined by Thorpe (1983), who established the connection between this phenomenon and a vector percolation problem. According to the Phillips–Thorpe (PT) ideas, in covalent networks for $\langle Z\rangle < 2.4$, the number N_f of interatomic (central and BB) forces per atom that act as constraints (thus $N_f = N_c$, where N_c is the number of constraints) is less than the network dimensionality $d = 3$, which is the same as the number of degrees of freedom N_d per atom. Under a shearing force such networks easily deform and possess a finite number of zero-frequency modes $f_m = N_d - N_c$. When $\langle Z\rangle > 2.4$, N_c is larger than N_d, and thus such networks are macroscopically rigid and possess nonzero elastic moduli. Hence, when $\langle Z\rangle = 2.4$, one has $N_c = N_d$ and therefore $f_m = 0$, which represents the vector percolation threshold of the system. Two crucial points should be noted here. First, the arguments leading to $\langle Z\rangle \simeq 2.4$ are all mean-field type of reasoning. However, computer simulations of He and Thorpe (1985) confirmed that this mean-field estimate is highly accurate. Secondly, $\langle Z\rangle \simeq 2.4$, which agrees with Eq. (149), represents the average coordination number of 3D networks at the percolation threshold of the KK model.

There have been many experimental tests of these ideas, the first of which was probably provided by Bresser *et al.* (1986). They used binary Ge_xSe_{1-x} glasses, which are perhaps the simplest of such materials. The coordination numbers of Ge and Se are 4 and 2, respectively, over the composition range $0 < x < 1/3$, and thus the average coordination number of the network is $\langle Z\rangle = 2(x+1)$. Therefore, with $\langle Z\rangle \simeq 2.4$, one has $x_c \simeq 0.2$. Bresser *et al.* (1986) used such binary glasses in the composition range $0 < x < 1/3$ using ^{129}I Mössbauer emission spectroscopy, and presented strong evidence that $x_c \simeq 0.23 \pm 0.02$. The Mössbauer-site intensity ratio I_B/I_A indicates dramatic threshold behavior. At $x = 0$ (*i.e.*, *g*-Se) only B sites are observed, and thus I_B/I_A is infinite. For $0 < x < 0.15$, I_B/I_A decreases with increasing x, reaching a minimum around $x \simeq 0.15$, but as $x_c \simeq 0.23$ is approached this ratio increases and reaches a maximum. Beyond x_c the ratio I_B/I_A decreases monotonically with x again. The molar volumes V_m of Ge_xSe_{1-x} also indicate a threshold behavior. For $0 < x < 1/3$ the molar volume decreases monotonically with x, reaching its minimum at $x_c \simeq 0.23 \pm 0.02$, beyond which it increases again monotonically as x does. Note that $x_c \simeq 0.23 \pm 0.02$ agrees nicely with the PT estimate $x_c = 0.2$, corresponding to an average coordination number of about 2.4.

Further experimental evidence of the applicability of the PT ideas was provided by Halfpap and Lindsay (1986), who measured the elastic moduli C_{11} and C_{44} of the Ge–As–Se glasses over a wide range of composition. The coordination number of As is 3, and therefore if the glass has the composition $Ge_xAs_ySe_{1-x-y}$, then its average coordination number is $\langle Z\rangle = 4x + 3y + 2(1-x-y) = 2x + y + 2$. Thus, varying x and y allows one to obtain glasses over a wide range of compositions and test the applicability of vector percolation to glass formation. Despite different local structures of the glasses that are obtained when x and y are varied, measurements of Halfpap and Lindsay (1986) indicated that at $\langle Z\rangle \simeq 2.4$ there is a dramatic increase in the elastic moduli C_{11} and C_{44}; an example is shown in Fig. 20. Further

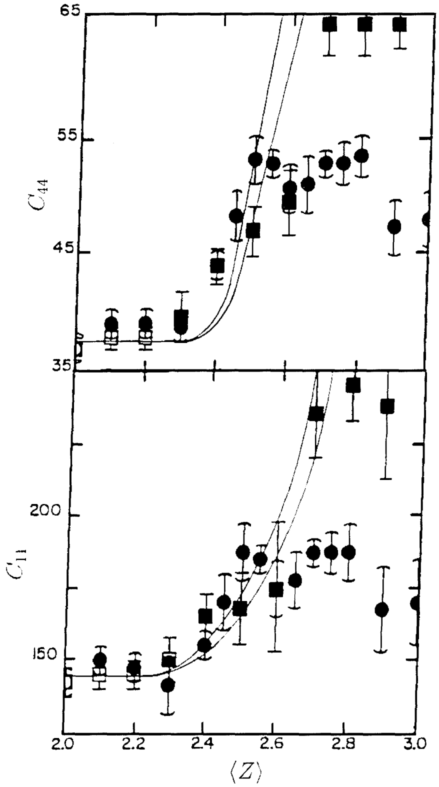

FIG. 20. Threshold behavior of the elastic moduli (in kbar; 1 bar = 10^5 Pa) of glasses versus the average coordination number $\langle Z\rangle$. Circles and squares correspond, respectively, to high- and low-As series of glasses. The theoretical curves on the left are for amorphous Ge, while those on the right are for crystalline Ge (after Halfpap and Lindsay, 1986).

evidence for the applicability of the PT ideas was provided by the experimental data of Mahadevan and Giridhar (1989), who also measured the elastic moduli C_{11} and C_{44} of various glasses formed with As, Ge, S, Sb, Se and Te, and found essentially the same behavior that had been found by Halfpap and Lindsay (1986). Finally, Feng *et al.* (1997) presented Raman-scattering data for $\mathrm{Ge}_x X_{1-x}$ glasses (X = S or Se) that indicated that there is a stiffness threshold at a mean coordination number $\langle Z\rangle \simeq 2.46 \pm 0.01$, in close agreement with the PT ideas. For related experimental works see Yun *et al.* (1989), Tatsumisago *et al.* (1990), and Böhmer and Angell (1992). Grest and Cohen (1983) give a review of older works that attempted to establish a connection between glass transition and percolation.

8. APPLICATION TO VIBRATIONS AND DENSITY OF STATES OF MATERIALS

An important property of materials is $N(\omega)$, their vibrational density of states, which is used for estimating their specific heat and thermal conductivity. $N(\omega)\,d\omega$ is the number of vibrational modes with frequencies between ω and $\omega + d\omega$. On the basis of the similarity between the Fourier transform of the equation of motion for a system of Hookeian springs,

$$-\omega^2 \tilde{\boldsymbol{u}}_i = \sum_{\langle ij\rangle} e_{ij}[(\tilde{\boldsymbol{u}}_j - \tilde{\boldsymbol{u}}_i)\cdot \boldsymbol{R}_{ij}], \qquad (162)$$

and the Laplace transform of the discretized diffusion equation,

$$\lambda \hat{P}_i(\lambda) = \sum_{\langle ij\rangle} W_{ij}(\hat{P}_j - \hat{P}_i) \qquad (163)$$

where $P_i(t)$ is the probability of finding a diffusing particle at site i at time t and W_{ij} is the transition rate, *i.e.*, the probability per unit time that the diffusing particle jumps from i to j, Alexander *et al.* (1978) suggested that

$$N(\omega) = -2\omega\, \mathrm{Im}\langle \hat{P}_0(-\omega^2)\rangle/\pi, \qquad (164)$$

where Im denotes the imaginary part of the complex number. It is then straightforward to show that

$$N(\omega) \sim \omega^{d-1}. \qquad (165)$$

Equation (165) is valid at low frequencies (*i.e.*, long wavelengths or large length scales over which the system is homogeneous) such that $\omega < \omega_{\mathrm{co}}$, where ω_{co} is the cutoff or crossover frequency. Vibrational states in homogeneous systems are usually called phonons, which are weakly localized.

If the network is fractal, *e.g.*, a percolation network at p_c or at length scales $L < \xi_p$, then Eq. (165) is no longer valid. The density of states of fractal networks was first discussed by Alexander and Orbach (1982) and Rammal and Toulouse (1983), who argued that in this case

$$N(\omega) \sim \omega^{D_S - 1}, \tag{166}$$

where D_S is the spectral or fracton dimension, already mentioned in Sec. 4.4. For percolation networks

$$D_S = 2\frac{D_F}{D_W} = 2\frac{\nu d - \beta}{2\nu + \mu - \beta}. \tag{167}$$

Equation (165) is valid as long as the scalar contributions to the elastic energy of the material dominate the vectorial contributions (as in, for example, the Born model). However, as we discussed above, the nature of the forces that are exerted on the particles of the network and their contributions to the elastic energy are most important. Hence, if we wish to take into account the vectorial nature of the vibrational density of states, then we are forced to introduce a new quantity D_{ES}, which is called the *elastic* or *flexural* spectral dimension and is defined by replacing in Eq. (167) the conductivity exponent μ by f, the critical exponent of the elastic moduli, so that (Webman and Grest, 1985)

$$D_{ES} = 2\frac{\nu d - \beta}{2\nu + f - \beta}. \tag{168}$$

Accordingly, we are also forced to have two different types of densities of states for vibrations of fractal networks. One is $N(\omega)$, the density of states when the scalar contributions to the elastic energy of the system dominate all other contributions, for which Eq. (166) is valid. The second type is what we call the *vectorial* or *elastic* density of states $N_e(\omega)$, which is the case when the vectorial contributions, such as those of the central or BB forces, dominate the elastic energy. In this case, in analogy with Eq. (166), the density of states is given by

$$N_e(\omega) \sim \omega^{D_{ES} - 1}. \tag{169}$$

Both Eqs. (166) and (169) are valid for high frequencies (*i.e.*, short wavelengths or length scales) such that $\omega > \omega_{co}$. Vibrational states on fractal structures, expressed by Eqs. (166) and (167), are called *fractons* (phonons on fractals!). Such vibrational states are localized as long as D_S or D_{ES} is less than 2 (Rammal and Toulouse, 1983). Using values of the critical exponents given in Tables 3 and 4, we see that while $D_S \simeq 4/3$ for all $d \geq 2$, D_{ES} varies continuously with d and is *less than 1*.

The crossover between Eqs. (165) and (166) is similar to the crossover between normal and anomalous diffusion that occurs at a time scale t_{co} given by Eq. (98), which corresponds, in the Laplace transform space, to a crossover value of $1/\lambda_{co}$, and since $\omega_{co}^2 \sim \lambda_{co}$, we obtain

$$\omega_{co} \sim (p - p_c)^{\nu + (\mu - \beta)/2} \sim (p - p_c)^{\nu D_W/2}$$

$$\sim \xi_p^{-D_W/2} \sim \xi_p^{-D_F/D_S}. \tag{170}$$

For an L^d system such that $L < \xi_p$, Eq. (170) is equivalent to

$$\omega_{co} \sim L^{-D_W/2} \sim L^{-D_F/D_S}, \tag{171}$$

so that as L increases (but $L/\xi_p \ll 1$), the cutoff or crossover frequency decreases. Alternatively, we can convert Eq. (171) to an equation for a cutoff length scale L_{co} at which a crossover between Eqs. (165) and (166) takes place:

$$L_{co} \sim \omega_{co}^{-D_S/D_F}. \tag{172}$$

These results can be written in a unified scaling form

$$N(\omega) \sim \omega^{D_S - 1} h(\omega/\omega_{co}), \tag{173}$$

where $h(x)$ is a scaling function with the properties that $h(x) \sim x^{d - D_S}$ for $x \ll 1$, and $h(x) \sim$ const. for $x \gg 1$. This also implies that for $L > \xi_p$ we have

$$N(\omega) \sim (p - p_c)^{\nu D_W (D_S - d)/2} \omega^{d-1} \sim \omega_{co}^{D_S - d} \omega^{d-1}. \tag{174}$$

We note here that $N(\omega)$ can also be calculated by an EMA (Sahimi, 1984; Derrida *et al.*, 1984a). The results are $N(\omega) \sim \omega_{co}^{-d/2} \omega^{d-1}$ for the phonon regime and $N(\omega) =$ const. for the fracton regime.

The difference between Eqs. (166) and (169) is significant. Recall that for both 2D and 3D percolation networks at $p_c, D_S \simeq 4/3$, and hence

$$N(\omega) \sim \omega^{1/3}, \tag{175}$$

implying that the medium is mechanically stable [since $N(\omega) \to 0$ as $\omega \to 0$]. Equation (175) is valid for materials in which the scalar contributions dominate their elastic energy. On the other hand, if we use the value of f for 3D BB models, $f \simeq 3.75$, we obtain $D_{ES} \simeq 0.87$, so that

$$N_e(\omega) \sim \omega^{-0.13}. \tag{176}$$

That is, as ω decreases (as the length scales increase) there are a large number of vibrating modes, implying that such systems cannot become too large, because if they do they lose their mechanical stability, and therefore have to restructure themselves into a more stable structure. This type of density of states should be observed in materials in which the contributions of the BB forces dominate their elastic energy.

Feng (1985) argued that in a percolation network in which both the central and BB forces are present, another length scale L_{bb}, in addition to ξ_p, is important, which, according to him, is given by

$$L_{bb} \sim \sqrt{\gamma/\alpha}, \tag{177}$$

where α and γ are, respectively, the central and BB force constants defined by Eq. (143). In effect, L_{bb} is the length scale below which the motion due to central forces is energetically more favorable and above which the BB forces dominate. If $L_{bb} > \xi_p$, then at low frequencies Eq. (165) and at higher frequencies Eq. (166) governs the density of states, with a crossover at ω_{co}. However, if $L_{bb} < \xi_p$, then at low frequencies one is in the phonon regime until a characteristic frequency ω_{bb} is reached, at which there is a crossover from Eq. (165) to Eq. (169). When the higher frequency ω_{co} is reached, there is a second crossover from Eq. (169) to (166). It is not difficult to guess that [see Eq. (171)]

$$\omega_{bb} \sim \xi_p^{-D_F/D_{ES}}. \tag{178}$$

For a review of computer simulation efforts for confirming these predictions see Nakayama *et al.* (1994). Here we discuss a few experimental verifications of the above theoretical predictions.

Most of the experimental studies involved aerogels, which are highly porous solid materials that have a very tenuous structure. Their porosity can be as high as 99%, and for this reason they often have very unusual and unique properties and a wide range of applications, ranging from catalyst supports to thermal insulators and radiators. Among all aerogels silica aerogels have received the widest attention. They appear to have the structure of percolation networks, the evidence for which comes from two different directions. One is the work of Woignier *et al.* (1988) who measured the Young's modulus of silica aerogels as a function of density and volume fraction; their work was already discussed in Sec. 6.4. The other evidence comes from measurements of the fractal dimension of the gel by SANS using Eq. (162). Vacher *et al.* (1988) presented extensive SANS data from which they obtained $D_F \simeq 2.45$, very close to $D_F \simeq 2.52$ for 3D sample-spanning percolation clusters (see Table 3). Therefore, at least one class of silica aerogels have a structure which is more or less similar to that of the percolation cluster at p_c.

Tsujimi *et al.* (1988) carried out very low-frequency depolarized Raman-scattering measurements on fractal silica aerogels. If $I(\omega)$ is the total scattering intensity at frequency ω, then it can be shown that

$$I(\omega)/N(\omega) \sim \omega^{-2(1-2\gamma/D_W)}, \tag{17}$$

where D_W is the fractal dimension of the random walk discussed in Sec. 3.3. Measurements by Tsujimi *et al.* yielded $\gamma > 1$, indicating apparent superlocalization of the vibrational modes (see Sec. 4.4). Another bit of experimental evidence for the above results is provided by verifying the scaling law for the density of states, Eq. (166) or (169). One way of doing this is by plotting the crossover or cutoff frequency ω_{co} as a function of q, the magnitude of the scattering vector. Since q is inversely proportional to the length scale L, Eq. (171) tells us that

$$\omega_{co} \sim q^{D_F/D_S}, \tag{180}$$

so that such a plot should yield $\omega_{\rm co} \sim q^{1.88}$, if silica aerogels are percolation fractals and $D_{\rm S} \simeq 4/3$. Indeed, Vacher *et al.* (1989) presented data obtained with Brillouin scattering of visible light, which indicated that $\omega_{\rm co} \sim q^{1.9}$, in very good agreement with the theoretical prediction. The density of states itself can be measured directly by various methods, and the experiments of Schaefer *et al.* (1990) yielded $D_{\rm S} \simeq 1.22 \pm 0.14$, again consistent with the theoretical expectation.

9. APPLICATION TO LOCALIZATION: QUANTUM PERCOLATION

Electronic transport in disordered media that was discussed in Secs. 2 and 4 is considered classical, because in those systems conduction ceases only when the volume fraction of the conducting component is below the percolation threshold. Anderson localization has motivated the development of a variant of percolation theory, namely, quantum percolation, in which disorder is brought about by a distribution of the matrix elements of a tight-binding representation of the Hamiltonian. As its name suggests, quantum percolation is the quantum counterpart of the classical percolation theory discussed so far, and has proven to be useful in the understanding of wave propagation through a disordered heterogeneous medium and certain modes of electronic transport in metal–insulator composites. For example, as discussed in Sec. 2, if the volume fraction of the nonmetallic component of a metal–insulator composite is large enough, the medium is in the dielectric regime, in which the conduction of charge carriers is *via* thermally activated hopping. Even when the metallic component is sample-spanning, one may not observe the expected metallic behavior if the temperature of the system is low enough.

Similar to rigidity percolation discussed in Sec. 6.1, in quantum percolation the formation of a sample-spanning cluster is not enough for ensuring the existence of a nonzero quantum transmittance. Moreover, as discussed in Sec. 1.3, in classical percolation the dead-end bonds or sites play no important role in flow and transport through the system, whereas in quantum transport (percolation) such bonds or sites do play an important role. When a quantum particle encounters an unoccupied bond or site, scattering takes place, giving rise to the important phenomenon of coherent backscattering (see, for example, Khemel'nitskii, 1984). For large enough scattering strength the classical diffusivity vanishes and electrons become trapped, even if a sample-spanning cluster exists for their transport. This immediately implies that the quantum percolation threshold $p_{\rm cq}$ is *larger than* $p_{\rm c}$, its classical counterpart, and numerical simulations as well theoretical works confirm this.

As is well known, Anderson (1958) proposed that, in addition to the extended states, the electronic states in heterogeneous media may be localized, if the strength of the heterogeneities is strong enough. Such heterogeneities can be morphological, and thus quantum percolation can help one understand the Anderson transition. The study of this localization usually starts with the following tight-binding Hamiltonian (or one of its variants):

$$\mathscr{H} = \sum_i \varepsilon_i a_i^\dagger a_i + \sum_i \sum_j V_{ij} a_i^\dagger a_j. \tag{181}$$

The diagonal site energy terms ε_i are distributed uniformly in the interval $[-W/2, W/2]$. If i and j are nearest neighbors, then $V_{ij} = V$; otherwise $V_{ij} = 0$. Edwards and Thouless (1972) extended the ideas of Anderson by suggesting that the conductance of a piece of a disordered medium depends on the sensitivity of its energy levels to the changes in the boundary conditions. Suppose that $\delta\mathscr{E}$ is the energy difference between the eigenstates, and $\Delta\mathscr{E}$ is the change in the energy levels as the result of changing the boundary conditions from periodic to antiperiodic. Then, it can be shown that $\Delta\mathscr{E}/\delta\mathscr{E}$ is equal to the dimensionless conductivity of the sample. These ideas were further refined by Abrahams *et al.* (1979), who related the energy levels of a system with volume $2L^d$ with those of a system with volume L^d, in order to quantify the perturbations caused by a change in the boundary conditions. They defined a quantity β given by

$$\beta = \frac{d \log G}{d \log L}, \tag{182}$$

and assumed that it is a function of the conductance G alone; $\beta(G)$ turns out to be the relevant scaling function for the Anderson transition. If $\beta(G) > 0$, then $G \to \infty$ as $L \to \infty$, implying that all the states are extended with a continuous spectrum. However, if $\beta(G) < 0$, then $G \to 0$ as $L \to \infty$, which means that the system is insensitive to boundary perturbations, and thus all the states all localized. This scaling theory also suggests that in a disordered medium with $d \leq 2$ all the states are localized, while for $d \geq 3$ they are all extended, depending on the strength of disorder, and therefore $d = 2$ is the lower critical dimension of the problem. This means, in the context of quantum percolation, that for $d \leq 2$ one has to have $p_{\mathrm{cq}} = 1$, whereas for $d \geq 3$ one must have $0 < p_{\mathrm{cq}} < 1$. Numerical studies of quantum percolation do confirm this (in $d = 1$ there is no difference between the quantum and classical percolation). Therefore, let us discuss these studies briefly.

9.1 Numerical Studies of Quantum Percolation

Unlike classical percolation for which one does not need any Hamiltonian, the study of quantum percolation requires a Hamiltonian. The simplest model is one in which the Hamiltonian is given by Eq. (181), and the site energies ε_i are distributed according to a binary distribution:

$$\psi(\varepsilon_i) = p\delta(\varepsilon_i - \varepsilon_{\mathrm{A}}) + (1-p)\delta(\varepsilon_i - \varepsilon_{\mathrm{B}}). \tag{183}$$

Consider the limit $\varepsilon_{\mathrm{B}} \to \infty$. In this case, an electron initially on a site A may propagate across the sample if it can find a continuous path of the A sites or bonds. This is the necessary condition for quantum percolation (Kirkpatrick and Eggarter, 1972). However, a quantum percolation model, as defined by Eqs. (181) and (183), differs from the Anderson model in several aspects. In the latter case disorder is introduced by assuming that the site energies are distributed randomly, whereas in the former case disorder is of binary type. Moreover, the density of states for the quantum percolation model consists of split bands (see, for example, Soukoulis and Grest, 1992) with a central spike and a dip around it where the states are localized. Thus, in this model the Anderson transition can occur only through the merging of at least two pairs of mobility edges, which is different from the usual Anderson model. There are also certain difficulties associated with the moments of the distribution of ε (Odagaki, 1980), which we do not discuss here. Despite such differences, quantum percolation has proven to be very useful for understanding Anderson localization.

Similar to the classical percolation, analytical studies of quantum percolation are very difficult, and thus many numerical methods have been developed for studying quantum percolation. Some of these methods are similar to those developed for the classical percolation. For example, renormalization-group methods, paralleling those for the classical percolation (see Sec. 1.9.3), have been developed for quantum percolation, beginning with the work of Odagaki and Chang (1984) and Root and Skinner (1986). The latter authors also defined a correlation length $\xi_q(p)$ for quantum percolation:

$$\xi_q(p) = \left\langle \sum_j P_{ij} r_{ij} \right\rangle, \tag{184}$$

where the average is taken over all the occupied sites i and all the configurations for a given p. Here P_{ij} is the time-averaged probability that an initial state $|i\rangle$ evolves into state $|j\rangle$; $\xi_q(p)$ diverges as p approaches p_{cq}:

$$\xi_q \sim (p - p_{\mathrm{cq}})^{-\nu_{\mathrm{q}}}, \tag{185}$$

where ν_q is the analog of ν for the classical percolation. Renormalization-group methods for quantum percolation involve the usual errors that are associated with such methods. They are more difficult than those for the classical percolation, but become more accurate as the size of the renormalization cell increases.

Another method of studying quantum percolation is by series expansion and Padé approximation (Shapir *et al.*, 1982; Meir *et al.*, 1986, 1989; Harris and Meir, 1987). Similar to the classical percolation, this method uses the fact that at p_{cq} certain quantities diverge. For example, in classical percolation the mean cluster size diverges as p_{c} is approached. For quantum percolation, one can study a variety of quantities. For example, Meir *et al.* (1989) studied

$$\mathscr{T}(\mathscr{E}) = \int \mathscr{T}(r, \mathscr{E})\mathrm{d}^d r, \tag{186}$$

where $\mathscr{T}(r, \mathscr{E})$ is the average transmittance of a wave with energy $\mathscr{E}$ between two points separated by a distance r. For a localized state one expects to have

$$\mathscr{T}(r, \mathscr{E}) \sim \xi_{\mathrm{q}}^{\gamma_{\mathrm{q}}+d} \sim (p - p_{\mathrm{cq}})^{-\nu_{\mathrm{q}}(\gamma_{\mathrm{q}}+d)}, \tag{187}$$

where γ_{q} is the associated exponent. While this method yielded reasonable results for $d \geq 3$, the results for $d = 2$ were not conclusive. Another method used to study quantum percolation is the slice recursion method, which has been used widely for localization problems, including quantum percolation (Taylor and MacKinnon, 1989). In this method one calculates the Lyapunov exponent, which is the inverse of the localization correlation length ξ_{l}, and by developing a suitable scaling function for it one finds the associated critical exponents. There are several other numerical methods for studying quantum percolation, which are discussed in detail by Mookerjee *et al.* (1995).

Summarizing, the most accurate numerical analysis of quantum percolation indicates that in two dimensions all the states are localized, in agreement with the scaling theory of Abrahams *et al.* (1979), and thus $p_{\mathrm{cq}} = 1$. In $d = 3$ the most recent work (Stadler *et al.*, 1996) indicates that $\nu_{\mathrm{q}} \simeq 1.6$, and on a simple cubic lattice, $p_{\mathrm{cq}} \simeq 0.44$, which, as expected, is larger than the classical percolation threshold $p_{\mathrm{c}} \simeq 0.311$ (see Table 2).

9.2 Crossover Between Anderson Localization and Percolation

The crossover between percolation and Anderson localization, which is relevant to the conductivity and the onset of superconductivity in thin metal–insulator films, is also an important issue. Deutscher *et al.* (1985) introduced two parameters, $z = \xi_{\mathrm{l}}/\xi_p$, where ξ_{l} is the localization correlation length which diverges as $(p - p_{\mathrm{c}})^{-\nu_l}$, and $w = R_0 e^2/L\hbar$, where R_0 is the resistivity of the sample at a minimum length scale L over which it can be defined, $\hbar$ is Planck's constant, and e is the electron's charge. Using the ideas of Abrahams *et al.* (1979) regarding the location of Anderson localization (see above), Deutscher *et al.* (1985) showed that $z = w^{\nu/(\mu-\nu)}(p - p_{\mathrm{c}})^{-\nu_{\mathrm{l}}}$, and proposed the following scenario for the crossover.

1. If $z \ll 1$, then classical percolation dominates and the resistance R of the sample is given by the usual scaling law [Eq. (8)], $R \sim (p - p_{\mathrm{c}})^{-\mu}$.
2. If $z \gg 1$, then localization effects are dominant and $R \sim (p - p_{\mathrm{c}})^{-\nu_{\mathrm{l}}}$.

Deutscher *et al.* (1985) showed that this scenario is completely consistent with the experimental data.

GLOSSARY

Accessible Fraction: The fraction of the microscopic elements of a disordered medium that can be reached from two opposite external surfaces of the medium.

Anomalous Diffusion: A diffusion process in which the mean square displacement of the diffusants varies slower than linearly with the process time.

Backbone: The current- or flow-carrying part of a disordered (percolation) medium.

Capillary Pressure: The difference between the pressures at two points, one on each side of an interface between two immiscible fluids.

Drainage: Displacement of a wetting fluid by a nonwetting fluid in a porous medium.

Effective-Medium Approximation: The idea that a disordered medium may be represented by an ordered medium whose properties mimic those of the disordered medium. These properties are calculated in a self-consistent manner.

Fractals: A word to describe objects with a noninteger dimensionality. Such objects are exactly or statistically scale invariant. This means that there is no length scale associated with the objects, and thus they appear self-similar under magnification.

Fractons: Vibrational modes on fractal objects. Such modes are localized on most fractal structures.

Hysteresis: If a system does not come back to its original state as a control parameter is varied in a cyclic manner, the system is said to show hysteresis. An example is capillary pressure in porous media discussed in this article.

Imbibition: Displacement of a nonwetting fluid by a wetting fluid in a porous medium.

Porosimetry: A method for obtaining the pore size distribution of a porous medium by injecting mercury into the pore space and retracting it, and measuring the pressures that are needed during this process.

Renormalization Group: The group formed by the set of operators used to coarsen a system up to a length scale.

Rigidity Percolation: A percolation model in which each bond of a lattice is a Hookeian spring. The mere connectivity of the springs and their formation of a sample-spanning cluster is not enough for percolation of stress or strain in the lattice.

Scaling Laws: The equations that various properties of a disordered medium follow near its critical point, such as the percolation threshold. Such equations are often in the form of power laws, characterized by critical exponents.

Superlocalization: A quantum state in a disordered medium in which all the wave functions decay with the distance r as $\exp(-r^{\gamma})$ with $\gamma > 1$. In the usual Anderson localization $\gamma = 1$.

Universality: The idea that certain quantities, such as the critical exponents, are independent of microscopic details of a system, and depend only on its dimensionality.

Vector Percolation: A percolation model in which each bond of a lattice is an elastic element, such as a spring or beam. Thus, vector percolation describes transport of vectorial properties in disordered media, such as transport of stress or strain.

Further Reading

The Works Cited represent a very small fraction of the vast literature on percolation theory and its applications. Most papers that deal with percolation problems appear in *Physical Review B, Physical Review E, Physical Review Letters, Journal of Physics A* and *Journal of Statistical Physics*. For a simple but extensive discussion of theoretical foundations of percolation theory, see Stauffer and Aharony (1992). Bunde and Havlin (1996) and Hughes (1996) provide more theoretical discussion of percolation theory. For extensive discussions of various applications of percolation theory see Sahimi (1994). A comprehensive review of electrical and dielectrical properties of composite solids is given by Clerc *et al.* (1990). Porous-media problems are extenstively discussed in Sahimi (1993b, 1995). Anomalous diffusion in disordered media is discussed exhaustively by Havlin and Ben-Avraham (1987). Very detailed discussions of hopping conductivity are given by Shklovskii and Efros (1984), and by Böttger and Bryskin (1985). Applications of percolation theory to modeling of elastic and viscoelastic properties of composites, polymers, ceramics, and glasses, as well as nonlinear composites, are discussed extensively by Sahimi (1998). Localization and quantum percolation are reviewed by Lee and Ramakrishnan (1985), Kramer and MacKinnon (1993) and Belitz and Kirkpatrick (1994).

INTRODUCTION: HISTORICAL SURVEY

A periodic surface is a surface that moves onto itself under a unit translation in one, two or three coordinate directions, similarly as in the periodic arrangement of atoms in regular crystals. The most interesting are triply periodic surfaces, which are periodic in all three directions forming structures that have various crystallographic symmetries. Here we mostly concentrate on smooth surfaces with cubic symmetry.

The paradigm structures for all periodic surfaces are minimal periodic surfaces. Such surfaces have zero mean curvature at every point of the surface, as was shown by Meusnier (Nitsche, 1989) and Laplace in the XVIII century. The simple patch of the minimal surface can be visualized in a simple experiment of Plateau (Belgian physicist, XIX century): use a soap solution and dip a metal frame (not necessarily planar) in it. The film that forms on the frame will adopt the shape such as to minimize the surface free energy, *i.e.*, as to minimize the area of the surface (hence the name minimal surface).

The first periodic (in one direction only) minimal surface discovered in 1776 (Hoffman, 1996) was a helicoid: the surface swept out by a horizontal line rotating at a constant rate as it moves at a constant speed up a vertical axis. The next example (periodic in two directions) was discovered in 1830 by Herman Scherk. The first triply periodic minimal surface was discovered by Herman Schwarz in 1865. The revival of interest in periodic surfaces was due to the observation (Luzzati and Spegt, 1967; Luzzati *et al.*, 1968a,b,c) that bilayers of lipids in water solutions form triply periodic surfaces under suitable thermodynamic conditions, and the discovery of new triply periodic minimal surfaces (among them the gyroid phase) by the mathematician Schoen (1970). If we draw a surface through the middle of a triply periodic lipid bilayer it follows from geometrical con-

straints that it must be a triply periodic minimal surface (Charvolin and Sadoc, 1987).

The self-assembled structures formed by lipids or surfactants in water solutions are used nowadays as templates for the three-dimensional polymerization reaction leading to mesoporous sieves (Davis, 1993), contact lenses (Anderson and Ström, 1991), or bulk catalysts, and this adds a technological dimension to the study of periodic surfaces. The formation of periodic surfaces in etioplast in plants and the usage of periodic surfaces for the crystallization of high–molecular-weight membrane proteins (de Kruijff, 1997) shows that these surfaces are related to biological problems. After the discovery of various structures formed by carbon—*i.e.*, wires and fullerenes—it has been also shown theoretically that the carbon atoms can be arranged to form triply periodic surfaces (Terrones and Mackay, 1993; Hyde and O'Keeffe, 1996). In ionic crystals the points at which the electrostatic potential is constant form a periodic surface; its symmetry can be determined by the symmetry-adapted distribution of charges (von Schnering and Nesper, 1987). It has also been shown that there is a very strong connection between chemical structures and periodic surfaces (Klinowski *et al.*, 1996; Mackay and Klinowski, 1986).

1. TYPES OF PERIODIC SURFACES

Triply periodic surfaces can be nodal (Mackay, 1993, 1994, 1995; von Schnering and Nesper 1991), equipotential surfaces (von Schnering and Nesper, 1987; Mackay, 1988), and minimal surfaces. They are described below in terms of their geometrical properties and generating equations.

Surfaces are characterized locally by the mean (H) and Gaussian (K) curvature: K and H can be calculated according to $H = \frac{1}{2}(1/R_1 + 1/R_2)$, $K = 1/R_1R_2$, where R_1 and R_2 are principal radii of curvature (Fig. 1). From the point of view of physics, especially important are those of constant mean curvature, since they are widespread in nature. A soap film spanned on a wire frame is a surface with zero mean curvature, and a soap bubble is a surface of constant mean curvature. The curvature of the surface is related to thermodynamic quantities by the Poisson–Laplace equation $H = \Delta P/2\sigma$, where H is the mean curvature at the interface of two homogeneous media, ΔP is the pressure difference across the interface, and σ is the surface tension. The notion of curvature was used to develop the effective Hamiltonian (Canham, 1970; Helfrich, 1973)

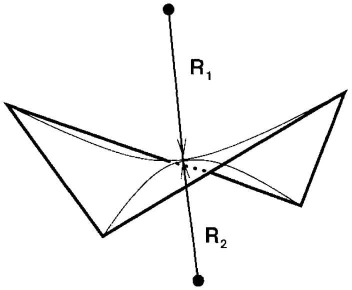

FIG. 1. Piece of surface with nonpositive Gaussian curvature. R_1 and R_2 are the principal radii. The Gaussian (K) and the mean (H) curvatures are expressed in terms of the principal radii as follows: $H = 1/2R_1 + 1/2R_2$, $K = 1/R_1R_2$. If $R_1 = -R_2$, at every point, the surface is called minimal. This implies that K is nonpositive at every point.

$$\mathscr{H} = \kappa \int dS(H - H_0)^2 + \bar{\kappa} \int dS\,K, \qquad (1)$$

where κ and $\bar{\kappa}$ are bending and Gaussian rigidities, H is the mean curvature, H_0 is the spontaneous curvature, and K is the Gaussian curvature. The integration is over the entire surface. The effective Hamiltonian has been successfully used in studies of lipid membranes (Lipowsky, 1993; Gompper and Schick, 1994).

Every triply periodic surface can be characterized by genus, an integer number that describes the number of holes or handles in the surface. The genus of a surface is related to its local properties by the Gauss–Bonnet theorem:

$$\int dS\,K = 2\pi\chi = 4\pi(1 - g), \qquad (2)$$

where K is the Gaussian curvature, χ is the Euler–Poincaré characteristic, and g is the genus. It is possible that different surfaces have the same genus. The genera for the best known triply periodic surfaces, reported for a translational unit cell, are 3 for the Schwarz (P), 5 for

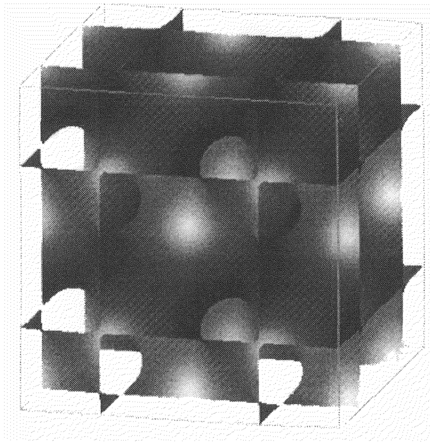

FIG. 2. Schwarz's minimal surface *D*.

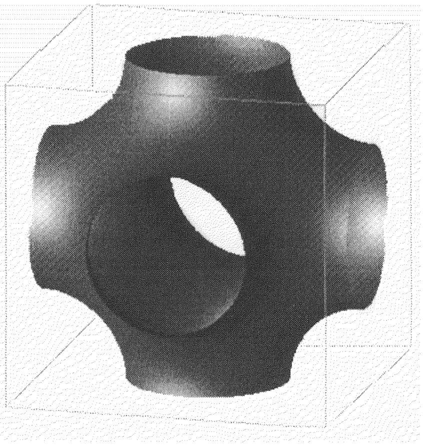

FIG. 4. Schwarz's minimal surface *P*.

the Schoen (G) and 9 for the Schwarz (D) surfaces (see Figs. 2–4). Please note that the value of the genera for P, D, and G is the same for a lattice fundamental region (different from the unit cell) (Anderson *et al.*, 1990). The latter fact should be expected on the basis of the local isometry of these surfaces.

Periodic surfaces can also be characterized by distribution of normal vectors. In the case of polymerized surfactant membranes, such a distribution is accessible experimentally *via* ^{2}H NMR technique (Anderson, 1990b; Góźdź and Hołyst, 1997). An example of the normal vector distribution for the P, D and G surfaces is given in Fig. 5.

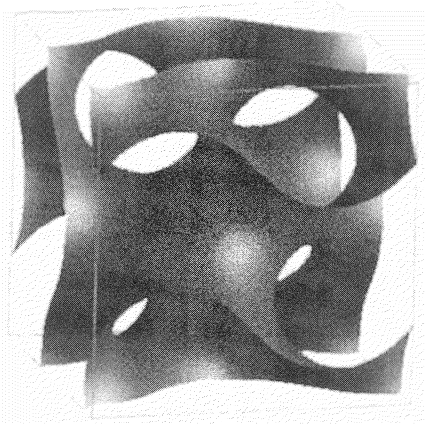

FIG. 3. Schoen's minimal surface *G*.

1.1 Minimal and Constant–Mean-Curvature Surfaces

Triply periodic minimal surfaces (TPMS) are surfaces of constant mean curvature equal to zero. The name "minimal" comes from the fact that the surface spanned on a frame has

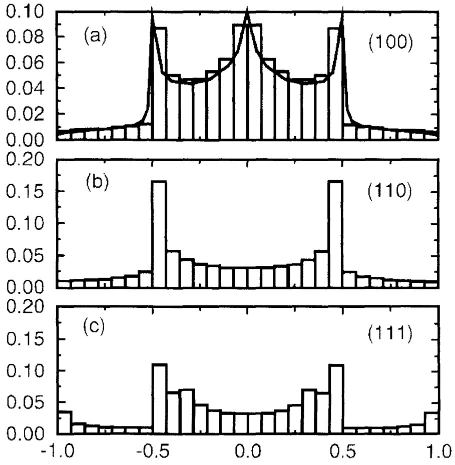

FIG. 5. The normalized NMR distribution function for *P*, *D*, and *G* surfaces (same for all) calculated numerically (Góźdź and Hołyst, 1997) and analytically (Anderson, 1990b) for the following directions of the magnetic field $\boldsymbol{B}$: (a) (100); the solid line shows the results of analytic calculations (Anderson, 1990b). (b) (110). (c) (111). $x = [3\cos^2(\theta_{nB}) - 1]/2$. Here θ_{nB} is the angle between the normal to the surface and the magnetic field. For a sphere this distribution (given for simplicity in θ_{nB}) is $f(\theta_{nB}) = 0.5\sin(\theta_{nB})$.

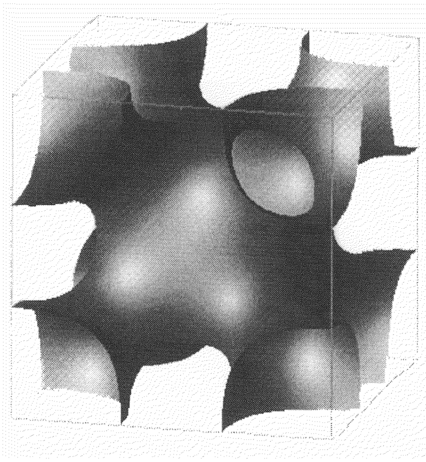

FIG. 6. Schoen's minimal surface *I-WP*.

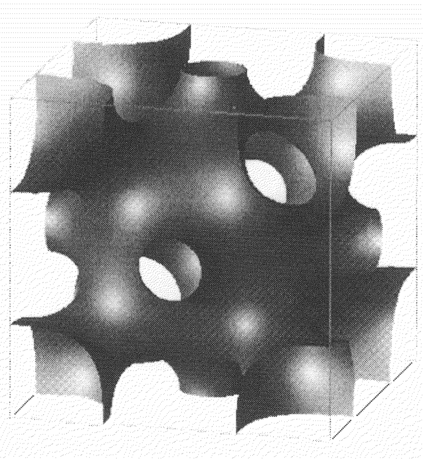

FIG. 7. Schoen's minimal surface *O-CT*0.

the lowest, "minimal" surface area if it is the surface of zero mean curvature. TPMS are infinite and are not bounded by a frame, but the mean curvature for these surfaces is zero at every point on the surface. That is why they are called "minimal". The condition of zero mean curvature implies that the Gaussian curvature is nonpositive at every point. The points where the Gaussian curvature is zero are called the flat points. These points are isolated.

Most of the TPMS divide the volume into two equal subvolumes (balanced surfaces; Fischer and Koch, 1986, 1996) (*P*, *D*, and *G* are the most prominent examples). There are also TPMS that divide volume into unequal subvolumes (unbalanced surfaces) (*I-WP*, *O-CT*0); see Figs. 6 and 7.

TPMS are described locally by the Enneper–Weierstrass equations (Schoen 1970; Terrones, 1990):

$$x = \tau \operatorname{Re} \int_{\omega_0}^{\omega_1} \mathrm{d}\omega \, e^{i\theta} R(\omega)(1-\omega^2),$$

$$y = \tau \operatorname{Re} \int_{\omega_0}^{\omega_1} \mathrm{d}\omega \, e^{i\theta} R(\omega) i(1+\omega^2), \tag{3}$$

$$z = \tau \operatorname{Re} \int_{\omega_0}^{\omega_1} \mathrm{d}\omega \, e^{i\theta} R(\omega) 2\omega,$$

where Re denotes the real part of the complex integral and integration is carried on an arbitrary path from ω_0 to ω_1 in the complex plane. The Enneper–Weierstrass equations guarantee that the surface is minimal but not necessarily embedded, *i.e.*, free of self-intersections. $R(\omega)$ is called the Weierstrass function and is characteristic for a given minimal surface. The parameter τ sets the length scale. The angle θ is called the Bonnet angle. The transformation that results from the change of θ is called the Bonnet transformation. Surfaces related by Bonnet transformation are called associate. The Bonnet transformation is isometric and conformal: all the lengths and angles are preserved. The surface is only bent without stretching. The surfaces related by Bonnet angle equal to 90° are called adjoint or conjugate surfaces, since they are described by adjoined (conjugate) complex functions. *D*, *P*, and *G* are associate surfaces with the Weierstrass function $R(\omega) = (1 - 14\omega^4 + \omega^8)^{-1/2}$. The Bonnet angles are respectively $\theta = 0°, 90°, 38.015°$ (Schoen, 1970). *P* and *D* are adjoint surfaces.

The properties of the TPMS follow uniquely from the Weierstrass function $R(\omega)$ (Terrones, 1990). $R(\omega)$ is known only for a few TPMS of simple topology. It is possible to construct $R(\omega)$ if there exists a surface patch from which the whole TPMS can be generated by reflection or rotation of the patch boundary, provided the surface belongs to the so-called regular class (Fogden, 1990, 1992; Fogden *et al.*, 1993; Fogden and Haeberlein, 1994;

Cvijović and Klinowski, 1992a,b,c). Not every surface has this property.

TPMS can be also constructed by the conjugate-surface method invented by Schoen (1970) (see also Karcher, 1989; Karcher and Polthier, 1996). The idea is to convert the free-boundary problem to the Plateau problem by using a Bonnet transformation and solve the simpler Plateau problem next. The method has been applied to prove the existence of many conjectured TPMS (Karcher, 1989) and to generate new examples by so called handle insertion (Schoen, 1970; Karcher and Polthier 1996). The conjugate-surface method has been applied to low-genus simple surfaces, but in principle can be used to generate high-genus surfaces.

The analysis of the crystallographic-group rotational symmetries led to the discovery of several new TPMS (Fisher and Koch, 1986, 1996; Koch and Fischer 1988). They deduced a number of group–subgroup pairs of space groups compatible with TPMS. Similar analysis has been done in the Fourier space (Sheng, 1994; Sheng and Elser 1994), leading to the discovery of a new minimal surface. The Fourier space is especially convenient in studies of symmetries of TPMS (Mermin, 1992).

TPMS belong to the broader class of periodic surfaces of nonzero constant mean curvature (CMC). The existence of periodic CMC surfaces was proven in 1970 (Lawson, 1970) for two doubly periodic surfaces of hexagonal and square symmetry. The first triply periodic CMC surfaces were calculated numerically for *P*, *D*, *I-WP* *F-RD*, *C*(*P*), and S'-S'' surfaces (Anderson *et al.*, 1990). The proof of existence was given by Karcher (1989) by the solution of the analogous Plateau problem in S^3. Recently numerical calculations have been done, using the Surface Evolver program (Brakke, 1992), for the *G* surface (Grosse–Brauckmann, 1997).

The Surface Evolver presents a convenient way of generating minimal and CMC surfaces. It minimizes the integral

$$\int (H - H_0)^2 \mathrm{d}S \tag{4}$$

for a discretized surface, *i.e.*, a surface given as a set of triangles.

1.2 Zero-potential and Equipotential Surfaces

Periodic equipotential surfaces are the level surfaces of the electric potential field generated by a periodic, discrete distribution of point charges in the space. The potential $\Omega(\boldsymbol{r})$ at a point $\boldsymbol{r} = (x, y, z)$ is defined according to

$$\Omega(\boldsymbol{r}) = \sum_{i,j,k}^{\infty} q(i,j,k)|\boldsymbol{r} - (i,j,k)|^{-1}, \tag{5}$$

where $q(i,j,k)$ is a point charge at the lattice site (i,j,k).

It turns out that many surfaces $\Omega(\boldsymbol{r}) = 0$ defined for charge distributions characteristic for ionic crystals of chemical compounds have very similar topology to TPMS (von Schnering and Nesper, 1991). The zero-potential surface for the CsCl ionic crystal charge distribution shares the same topology as the Schwarz *P* TPMS. However, analysis of the mean curvature shows that periodic equipotential surfaces are not TPMS (Barnes *et al.*, 1990).

1.3 Nodal Surfaces

Nodal surfaces are defined by $\Psi(\boldsymbol{r}) = 0$, for $\Psi(\boldsymbol{r})$ given by the following Fourier series (Mackay, 1993; Klinowski *et al.*, 1996):

$$\Psi(\boldsymbol{r}) = \sum_{\boldsymbol{k}} F(\boldsymbol{k}) \cos[2\pi \boldsymbol{k} \cdot \boldsymbol{r} - \alpha(\boldsymbol{k})], \tag{6}$$

where $\boldsymbol{k}$ describes the reciprocal lattice vectors for a given lattice, $\alpha(\boldsymbol{k})$ is a phase shift, and $F(\boldsymbol{k})$ is an amplitude associated with a given $\boldsymbol{k}$ vector.

Periodic surfaces can be approximated in terms of nodal surfaces. The quality of approximation depends on the number of terms in the Fourier series. The topology of a surface is in some simple cases already well reproduced by a series containing only the first terms in the expansion. Several such surfaces have been tabulated (von Schnering and Nesper, 1991). For example, the simplest approximations for *P*, *D*, and *G* surfaces based on Eq. (6) are respectively

$$\cos(X) + \cos(Y) + \cos(Z) = 0,$$

$$\cos(X)\cos(Y)\cos(Z) + \sin(X)\sin(Y)\sin(Z)$$
$$= 0,$$

$$\sin(X)\cos(Y) + \sin(Y)\cos(Z) + \cos(X)\sin(Z) = 0, \tag{7}$$

where $X = 2\pi x$, $Y = 2\pi y$, $Z = 2\pi z$.

Although nodal surfaces are neither minimal nor of constant mean curvature, they can be used as an *Ansatz* for such surfaces (Lambert *et al.*, 1996). The huge advantage of nodal surfaces is that they are described by simple mathematical equations. This fact makes them easily accessible to a broad range of scientists.

2. EXPERIMENTAL OBSERVATIONS OF PERIODIC SURFACES

Scattering techniques applied to a solution of water and lipids (Luzzati *et al.*, 1968a,b,c; Luzatti and Spegt, 1967) demonstrated the existence of a periodic bilayer of lipids dividing the water into two disjoint continuous subvolumes, forming a bicontinuous structure. Apart from scattering techniques, the single most effective probe of bicontinuous structures is the pulsed-gradient NMR self-diffusion technique, which can provide the self-diffusion rates of all the components in the cubic structure (Lindman *et al.*, 1989), providing a direct check on the continuity and extension of the region occupied by the components. If any of the components of the system is closed inside the micelle, then its effective diffusion constant (measured as a mean squared displacement divided by time) goes to zero, whereas for one in the continuous structure the effective diffusion coefficient is nonzero. Also TEM (transmission electron microscopy) micrographs often play a crucial role in the identification of bicontinuous structures (Thomas *et al.*, 1986).

2.1 Diffusion on Surfaces

For any closed surface the effective diffusion coefficient is zero. For a cylindrical surface the effective diffusion constant would be $\frac{1}{3}D_0$ (D_0 is the local diffusion coefficient), because of the reduction of the available spatial dimensions from 3 to 1. Analogously for the plane we find that the diffusion constant is $\frac{2}{3}D_0$. The coefficient in front of D_0 is known as an obstruction factor. It can be shown exactly that the diffusion coefficient for any minimal periodic surface of cubic symmetry is $\frac{2}{3}D_0$ (Anderson and Wennerström 1990), which also sets an upper limit for the diffusion constant on any surface. Actually for any surface of small mean curvature the value of the diffusion constant would be close to the value for the minimal surface. For the diffusion of a surfactant on a surface of constant mean curvature one can use the approximate formula given by Anderson and Wennerström (1990),

$$D = D_0[2/3 - \mu(v - v_0)^2], \tag{8}$$

where μ is a constant specific for a given symmetry and/or topology and v is the volume fraction occupied by one of the subvolumes, while v_0 is the volume fraction of this subvolume for the minimal surface of the same symmetry and topology as the surface studied. For balanced TPMS [*e.g.*, *G*, *D*, *P*, and *C*(*P*)], $v_0 = \frac{1}{2}$. For unbalanced TPMS (*e.g.*, *I-WP* and *F-RD*), v_0 differs from $\frac{1}{2}$ by about 6%. The constant $\mu = 1.8$ for the *P* family for monolayers and $\mu = 1.8/4 = 0.45$ for the bilayers. We note that additional study of the diffusion of water in the subvolume yields information about the hydration of water molecules at the polar periodic surface. Short-time diffusion of water should yield additional information about the surface area *S* of the periodic surface per unit volume, since the diffusion constant for short times *t* is (Mitra *et al.*, 1992)

$$\frac{D(t)}{D_0} = 1 - \frac{4}{9\sqrt{\pi}}\sqrt{D_0 t}S. \tag{9}$$

A detailed comparison of the theoretical calculation and experimental observations for various periodic surfaces is given by Anderson and Wennerström (1990). The typical diffusion constant D_0 for surfactant or phospolipids in bilayers is usually between 2×10^{-7} and $5 \times 10^{-8}\,\mathrm{cm^2\,s^{-1}}$; for comparison the diffusion of water is $2 \times 10^{-5}\,\mathrm{cm^2\,s^{-1}}$.

2.2 Amphiphilic Solutions

In an ordered mixture of water and surfactant or lipid, diffusion measurements provide direct information about the bicontinuity of the structure and therefore about the existence of a periodic surface. X-ray scattering provides information about the symmetry of the structure and therefore discerns between different periodic surfaces: the set of reflections for the *P* surface (*Im*3*m* symmetry) indexes to $\sqrt{2} : \sqrt{4} : \sqrt{6} : \sqrt{10} : \sqrt{12} : \sqrt{14} : \sqrt{16}$; that of the *D* surface (*Pn*3*m* symmetry), to $\sqrt{2} : \sqrt{3} : \sqrt{4} : \sqrt{6} : \sqrt{8} : \sqrt{9} : \sqrt{10}$; and that of the *G* surface (*Ia*3*d* symmetry), to $\sqrt{6} : \sqrt{8} : \sqrt{14} : \sqrt{16} : \sqrt{20} : \sqrt{22} : \sqrt{24}$ (Henry and Lonsdale, 1952). Finally measurements of the surface area inside the cubic cell can yield partial information about the topology of the structure. One can expect a small unit cell and a small surface area per side of the unit cell in structures of simple topology (Barois *et al.*, 1990) and large values for structures of complex topology. Typically the surface area per side of the cubic cell is between 2 and 4 for simple topology surfaces such as *P*, *D*, *G*, *I-WP*, *O-CT*0, etc., while it can be larger than 7 for complex-topology surfaces (Góźdź and Hołyst, 1996c).

In binary mixtures of water and surfactants or lipids the most commonly observed periodic structure is the gyroid phase, existing usually on the phase diagram between the hexagonal and lamellar mesophases. This structure has been observed in a very large number of systems (Luzzati *et al.*, 1968a,b,c; Arvidson *et al.*, 1985; Larsson, 1989; Clerck *et al.*, 1990, Turner *et al.*, 1992, Landh, 1994) and in computer simulations of the systems (Larson, 1996). The gyroid phase is found at rather high surfactant concentrations, usually much above 50% by weight. The similarities of various phase diagrams suggest that the transitions are driven mainly by the packing constraints, entropies and energies of mixing, and conformations of surfactant chain (Larson, 1996; SOLUBILITY AND MIXING IN FLUIDS).

Other cubic phases even at very low concentration of surfactants can be found in ternary mixtures (with water and oil) (Anderson and Wennerström, 1990; Barois *et al.*, 1990). For the system didodecyldimethylammonium bromide, water, and styrene, periodic surfaces are found over the huge range of water fractions from 11 to over 80%. Also in the system clear evidence for the *G* to *D* to *P* transition is found both in the mentioned experiments and in theory (Ciach, 1996).

The phase transitions between surfaces of different topology are accompanied by thermally excited topological fluctuations in the form of passages between the surfaces, as observed in computer simulations (Larson, 1992, 1996; Gompper and Kraus, 1994; Hołyst and Góźdź, 1997). Each passage changes the Euler characteristics by -2; thus this quantity is the direct measure of the number of passages in the system. The passages should be expected close to phase boundaries.

2.3 Copolymers

A diblock *AB* copolymer consists of two chemically distinct homopolymers *A* and *B* bound together by a covalent bound. The immiscibility (see SOLUBILITY AND MIXING IN FLUIDS) of *A* and *B* monomers drives the system towards ordered structures, such as to minimize the contacts between different monomers. The system separates into *A*-rich and *B*-rich domains, with the covalent bond resting at the interface between the domains. The typical structures formed are lamellar and hexagonal structures, where the domains are planar or cylindrical. Between the hexagonal and lamellar phases the gyroid phase (similarly as in lipid solutions) has been observed in x-ray experiments (Schultz *et al.*, 1994; Hajduk *et al.*, 1994; Föster *et al.*, 1994), where a periodic surface of topology and symmetry of the *G* surface is formed between *A*-rich and *B*-rich domains. It is worth mentioning that the first report on the observation of a periodic surface in block copolymers (starblocks) was done in 1986 (Thomas *et al.*, 1986), but the correct identification of the gyroid structure for the starblocks was done in 1995 (Hajduk *et al.*, 1995).

The gyroid phase for diblock copolymers exists in a narrow window of diblock copolymer [polyisopropene (PI)–polystyrene (PS)] composition v_{PI} (polyisoprene volume fraction) between 35 and 40% (Föster *et al.*, 1994). The gyroid phase exhibits pronounced metastability when cooled below the transition to lamellar or hexagonal phases. The theory also predicts the existence of the gyroid phase in the diblock copolymer system (Matsen and Bates, 1996).

Multiply continuous structures were observed in an *ABC* linear triblock copolymer system (Mogi *et al.*, 1992). In this structure two periodic surfaces of *D* symmetry and topology separate a volume into three disjointed subvolumes *A*-rich, *B*-rich, and *C*-rich, therefore the name ordered tricontinuous double-diamond structure.

2.4 Chemical Structures

The periodic zero-potential surfaces (POPS) occur most naturally in ionic crystals, where we have a periodic distribution of charges (von Schnering and Nesper, 1987). Although POPS are not minimal surfaces (Mackay and Klinowski, 1986; Barnes *et al.*, 1990), they may resemble them closely (Klinowski *et al.*, 1996).

The cesium chloride CsCl structure has the same topology and symmetry as the *P* Schwarz surface and is called the P^* surface to distinguish it from the *P* minimal surface. The aluminosilicates of the zeolite sodalite ($Na_4Al_3Si_{12}O_{26}Cl$) form a P^* surface, similarly as does the perovskite structure ($CaTiO_3$).

The D^* surface can be found in the zeolite structure of faujasite ($M^{1}_{57}Al_{57}Si_{135}O^{[53]}_{384}$) (Andersson *et al.*, 1984), similar to the cubic Laves phase $MgCu_2$.

Finally Y^{**}, the analog of the *G* surface, is found in compounds with the garnet structure $Ca_3[Al_2Si_3O_{12}]$, materials important for their applications as optoelectric color displays and magnetic bubble memory. Y^{**} is also found in the compound Ta_6Cl_{15}. A detailed description is given by von Schnering and Nesper (1987).

Mackay and Terrones (1991) predicted that a new type of ordered graphite foams, related to fullerenes, with topology similar to periodic surfaces may be found. These new structures are constructed by introducing seven- or eight-membered rings of carbon atoms into sheets of six-membered rings, thus giving saddle-shape surfaces. In fact such structures should be more stable than fullerene C_{60} (Terrones and Mackay, 1993) mainly because the 120° bond angles in ordinary graphite are almost preserved in the seven-membered and eight-membered carbon rings. In this way *P*, *D*, *G*, and *I-WP* surfaces were constructed of energies lower than the C_{60} form of carbon. The saddle and splay moduli (Helfrich, 1973) for these structures are respectively 190 kT and −65 kT (Hyde and O'Keeffe, 1996), making the graphite surfaces an order of magnitude stiffer than bilayers of an amphiphilic system (Chung and Caffrey, 1994).

2.5 Periodic Surfaces in Living Matter

Chroloplasts are organelles involved in photosynthesis, presenting a complex system of parallel bilayers. When a plant is grown for several days in the absence of light, the lamellar structure of chloroplast transforms into a periodic surface of the same topology and symmetry as the *P* Schwarz surface (also called a prolamellar body or etioplast), although it is not a minimal surface (Günning, 1965; Bouligand, 1990).

The cell membranes in a living organism—*e.g.*, endoplasmic reticulum (where cell proteins and lipids are synthesized)—are known to have a complex three-dimensional morphology, which, as shown by Landh (1995), is the same as for the triply periodic minimal surfaces. Three fundamental structures identified so far in cellular organelles are the gyroid *G* Schoen surface and the *D* and *P* Schwarz surfaces. The partition of space by the surface in the cell organelle enables the cell to control the concentration of various molecules and their transport across the bilayers. There are indications that multiply continuous structures exist in the mitochondria of the very large cone cells in tree shrews (Samorajski *et al.*, 1966).

The skeleton elements of sea stars, sea urchins, or sea cucumbers are monocrystals of a magnesium-rich calcite, each crystal being limited not by a planar surface but by a surface of the topology of the *P* surface (Nissen, 1969).

We note that it is possible using the mathematical modeling of periodic surfaces to represent the DNA helicoidal structure by a singly periodic surface (Jacob, 1997).

3. FUNCTIONAL GENERATION OF PERIODIC SURFACES

Periodic surfaces can be generated as minima of a free-energy functional. Here we present the functional used to generate periodic structures and discuss the methods of minimization (in real and Fourier space) and the resulting solutions of the minimization problem.

3.1 Landau–Ginzburg Model

In studies of microemulsion and ordered phases that appear in systems containing surfactants, the following Landau–Ginzburg functional was proposed (Teubner and Strey, 1987; Gompper and Schick 1990):

$$\mathscr{F}[\phi(\boldsymbol{r})] = \int \mathrm{d}^3 r(|\Delta\phi(\boldsymbol{r})|^2 + g(\phi(\boldsymbol{r}))|\nabla\phi(\boldsymbol{r})|^2 + f(\phi(\boldsymbol{r}))). \tag{10}$$

The functions $g(\phi(\boldsymbol{r}))$, $f(\phi(\boldsymbol{r}))$ are given by

$$g(\phi(\boldsymbol{r})) = g_2\phi(\boldsymbol{r})^2 + g_0, \tag{11}$$

$$f(\phi(\boldsymbol{r})) = [\phi(\boldsymbol{r})^2 - 1]^2[\phi(\boldsymbol{r})^2 + f_0]. \tag{12}$$

The values of the field $\phi(\boldsymbol{r})$ are proportional to the difference in oil and water concentrations and are negative for water and positive for oil regions or *vice versa*. The sign is just a matter of convention. The surface

$$\phi(\boldsymbol{r}) = 0 \tag{13}$$

describes the interface between oil and water. The function $f(\phi(\boldsymbol{r}))$ is the bulk free energy. The surfactant degrees of freedom are considered as being integrated out and the surfactant properties enter the functional (10) through the form of the functions $g(\phi(\boldsymbol{r}))$ and $f(\phi(\boldsymbol{r}))$. The functional (10) can be also used to model binary mixtures of water and surfactants. In such a case the negative values of $\phi(\boldsymbol{r})$ are interpreted as the interior part of a bicontinuous phase and the positive as the exterior part of the phase (or *vice versa*).

The function $f(\phi(\boldsymbol{r}))$ has by construction three minima, which guarantees three-phase coexistence, *i.e.*, oil, water, and a microemulsion. The minima for oil-rich and water-rich phases are of equal depth, which makes the system symmetric. Varying the parameter f_0 makes the middle phase (microemulsion) more or less stable with respect to the two bulk phases. The phase diagram for the functional (10) contains homogeneous oil and water phases, microemulsion, and a lamellar phase (Gompper and Zschoke, 1992).

3.2 Minimization Procedure in Real and Fourier Space

In real space, the functional (10) is discretized first on the cubic lattice to find its minima. Thus the functional $\mathscr{F}[\phi(\boldsymbol{r})]$ becomes a function $F(\{\phi_{i,j,k}\})$ of N^3 variables, where $L = (N-1)h$ is the linear dimension of the cubic lattice, h is the lattice spacing and $\{\phi_{i,j,k}\}$ stands for the set of all variables of the function. Each variable $\phi_{i,j,k}$ represents the value of the field $\phi(\boldsymbol{r})$ at the point $\boldsymbol{r} = (i,j,k)h$ and $i,j,k = 1,\ldots,N$.

The periodicity is incorporated into the functional (10) by the boundary conditions $\phi_{1,j,k} = \phi_{N,j,k}$, $\phi_{2,j,k} = \phi_{N+1,j,k}$, $\phi_{3,j,k} = \phi_{N+2,j,k}$ $\phi_{0,j,k} = \phi_{N-1,j,k}$, and $\phi_{-1,j,k} = \phi_{N-2,j,k}$ and similarly in the y and z directions. The points outside the unit cell, given by the periodic boundary conditions, enter the functional through the calculation of derivatives of points at the boundary and near the boundary of the lattice, *i.e.*, when at least one of the indices i,j,k is equal to $1, 2, N-1$, or N.

The symmetry of the structure is imposed on the field $\phi(\boldsymbol{r})$ by building the field inside a unit cell of a smaller polyhedron, replicating it by reflections, translations, and rotations (Góźdź and Hołyst, 1996c).

In Fourier space $\phi(\boldsymbol{r})$ for periodic structures is represented by the Fourier series

$$\phi(\boldsymbol{r}) = A_0 + \sum_i \sum_{\boldsymbol{k}^i} [A_i \cos(\boldsymbol{k}^i \cdot \boldsymbol{r}) + B_i \sin(\boldsymbol{k}^i \cdot \boldsymbol{r})] \tag{14}$$

where $\boldsymbol{k}^i$ are the reciprocal lattice vectors in the ith shell and A_i and B_i are the amplitudes of the ith shell. Here the shell means a set of reciprocal lattice vectors of the same length related to each other by the symmetry operations characteristic for a given lattice. The approximation by the Fourier series ensures that the function $\phi(\boldsymbol{r})$ is continuous at the unit-cell boundaries. Next, the functional (10) is minimized with respect to the amplitudes A_i and

B_i. As a result one gets the nodal surface given by the equation $\phi(\mathbf{r}) = 0$. The quality of approximation is better the larger the number of shells included.

From the computational point of view the Fourier-space approach requires fewer variables to be minimized for, but the speed of calculations is significantly decreased by the evaluation of a trigonometric function, which is computationally expensive.

3.3 High-Genus Periodic Surfaces

High-genus surfaces are easily generated by functional minimization in real space. It is enough to set a larger value for the unit cell than the value for a low-genus surface of the same symmetry and to start minimization from an arbitrary configuration. The minimization will lead to the high-genus surface with the mean curvature close to zero (Góźdź and Hołyst, 1996a,b,c). The high-genus surfaces are most easily generated for the values of parameters f_0 and g_0 in (10) taken near the boundary between lamellar and microemulsion phases. Other methods present great difficulties in generating high-genus periodic minimal surfaces.

Here a few examples of high-genus surfaces of different symmetry are presented The structure *SCN*1, Fig. 8, has the symmetry of the Schwarz *P* surface; the structure *CD*, Fig. 9, has the symmetry of double diamond *D* surface; and the structure *GX*5, Fig. 10, has the symmetry of the gyroid *G* surface. All these surfaces are balanced. The genus for *SCN*1 is 43; for *CD*, 73; and for *GX*5, 157.

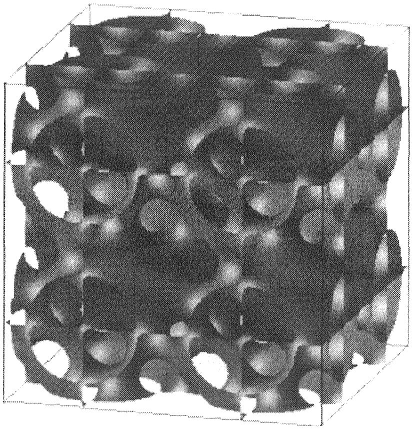

FIG. 9. High-genus surface *CD* of the same symmetry as the *D* surface.

3.4 Multiply Continuous Structures

Multiply continuous structures were discovered during functional generation of periodic surfaces (Góźdź and Hołyst, 1996a,c). The possibility of the existence of multiply continuous structures has so far never been discussed with respect to ternary mixtures of oil, water, and a surfactant, although it has

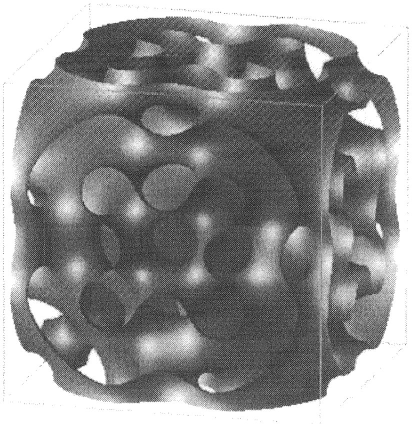

FIG. 8. High-genus surface *SCN*1 of the same symmetry as the *P* surface.

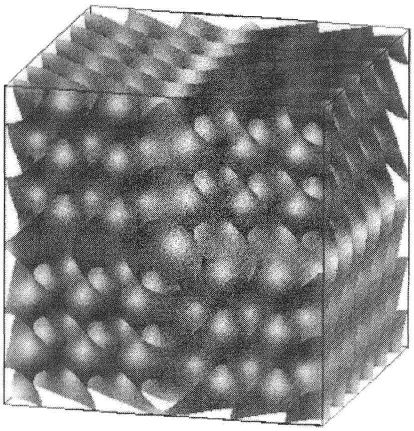

FIG. 10. High-genus surface *GX*5 of the same symmetry as the *G* surface.

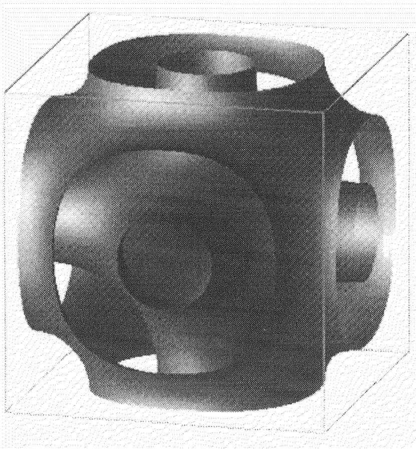

FIG. 11. Triply continuous structure of the same symmetry as the *P* surface.

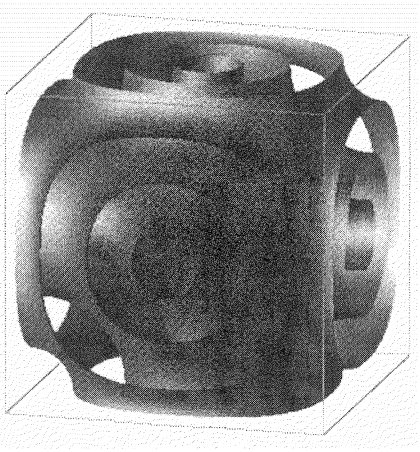

FIG. 12. Quadruply continuous structure of the same symmetry as the *P* surface.

been observed in the *ABC* diblock copolymers (Mogi *et al.*, 1992). In the bicontinuous structure a single surface separates the volume into two disjoint subvolumes. In multiply continuous phases there is more than one periodic surface, which disconnects the volume into three or more disjoint subvolumes. The multiply continuous structures are most easily generated for the values of parameters f_0 and g_0 in (10) taken near the boundary between lamellar and water (oil) phases and for a bigger unit cell length, $L = (N - 1)h$, than the length of structures of low genus. The experimental results do not rule out the existence of such structures (Gompper and Schick, 1994).

We present here multiply continuous structures of the simple cubic phase symmetry (*SCL*1, *SCL*2, Figs. 11 and 12) and of the gyroid phase symmetry (*GL*2, Fig. 13). The *SCL*1 structure is triply continuous, *SCL*2 is quadruply continuous, and *GL*2 is sextuply continuous. It is remarkable that the volume fraction of oil and water is 0.5 for all these structures. The genera for all surfaces in a given structure are the same.

The *SCL*1 surface is especially interesting. Although the outer and the inner surfaces look different, they have the same surface area. In fact they are built from the same piece of the surface.

The *SCL*2 structure is composed of three different embedded periodic surfaces. The middle surface is the Schwarz minimal surface *P*. Similarly, the middle surface in the *GL*2 structure is the Schoen minimal surface *G*.

The existence of a structure such as *GL*2 suggests that one can generate arbitrary *n*-uply continuous structures. In the functional method it is only necessary to set the cell length sufficiently large.

4. APPLICATIONS

Although the periodic structures formed by lipids, surfactants, and soaps in water sol-

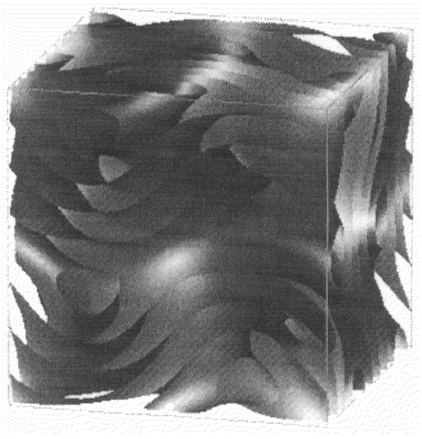

FIG. 13. Sextuply continuous structure of the same symmetry as the *G* surface.

utions have been known since 1967 (Luzatti and Spegt, 1967), the practical applications started in the 1990s. The discovery that an organic periodic surface can be used as a template for organic or inorganic polymerization reactions where the final product is an ordered mesoporous material of well defined pore sizes and shapes—*e.g.*, mesoporous silica (Kresge *et al.*, 1992) or hydrogels used as contact lenses (Anderson and Ström, 1991)—brought the subject of periodic surfaces into the realm of technology.

4.1 Mesoporous Sieves and Catalysts

The mesoporous silica structures are prepared in a water–surfactant system (Kresge *et al.*, 1992). After polymerization of the silica oligomers the surfactant can be burned and the inorganic sieve emerges. The sieves are remarkable since they have pore sizes ranging from 20 Å to hundreds of angstroms; the pores have well defined shape and size; the structure is ordered over a micron length scale. The process is complicated and still not fully understood (Cheng *et al.*, 1995). Monnier *et al.* (1993) describe the process as follows: there is a multidentate binding of anionic silicate oligomers to the cationic surfactant, the polymerization takes place in the interfacial region, and there is a charge-density matching between the surfactant and the silicate. The synthesis can be carried out under conditions in which silicate alone does not condense (at *p*H from 12 to 14 and silicate concentration between 0.5% and 5%) and/or at a small concentration of surfactant (Monnier *et al.*, 1993; Attard *et al.*, 1995). They point out that under certain conditions formation of the ordered structure results from the interplay between the silica and the surfactants. The formation of the ordered structure at high temperature is fast in comparison with the polymerization reaction; the polymerized silica mesostructure obtained in this two-stage process is more stable than the one obtained at low temperature. The polymerization of silicate at the interface is favored because the surfactant partially screens the charges and the concentration of silicate species is high in this region. There is an indication that the silicate and the polymerization process may take part in the ordering process, especially when the polymerization is fast enough. Apart from the lamellar and hexagonal microstructures, the bicontinuous gyroid structure is formed. In the system of CTA/SiO_2 for a high fraction of both components a single infinite silicate sheet separates the surfactant into two equal and disconnected subvolumes. The midplane of the silicate sheet is the minimal gyroid periodic surface.

The surfaces formed by surfactants can also be used as templates for inorganic oxide crystallization (Archibald and Mann, 1993), and presumably nature uses them in biomineralization processes.

The coating of mesoporous silicates with sulfur compunds can be achieved and the coated powder can be used as an effective agent for water purification (Feng *et al.*, 1997).

4.2 Soft Contact Lenses

The periodic surfaces formed by amphiphilic molecules can also be used as templates for the polymerization reaction, leading to the formation of material that can be used for the production of contact lenses (Anderson and Ström, 1991; Anderson, 1987, 1990a). For example, a water solution of hydrophilic monomers such as 2-hydroxyethylmethacrylate (HEMA) mixed with a surfactant in the right proportions self assembles into a triply periodic structure, in which monomers and surfactants form a periodic surface. Next, the polymerization is initiated by, *e.g.*, ultraviolet light, heat, an electron beam, electroinitiation, or redox initiation. After polymerization the surfactant is removed (*e.g.*, electrophoretically) and the mesoporous rigid structure is created. These structures have three properties important for contact lenses. First of all they have a very regular pore structure, unlike the conventional hydrogels where the pore structure is very irregular. The pore sizes can be made large enough to allow the passage of high–molecular-weight proteins through the lens into the eye. They can have a large water content, allowing for the rapid permeability of oxygen, which is an exponential function of the water concentration in hydrogel. Finally, despite large pores (which can be selected in a range 20–400 Å), the structure can have still a large shear modulus, unlike the simple hydrogel typically used as a contact-lens material. In a simple hydrogel at equilibrium swollen by a solvent, the shear modulus G_s is given by (Flory 1953)

$$G_s = -RT\frac{\ln(1-\phi_m)+\phi_m+\chi\phi_m^2}{v_1(\phi_m^{1/3}-\phi_m)}, \tag{15}$$

where ϕ_m is the volume fraction of monomers, v_1 is the molar volume of the solvent, χ is the Flory–Huggins interaction parameter between the solvent and the monomer molecules, T is the temperature, and R is the gas constant. A simple estimate for poly-*cis*-1,4-butadiene shows that when the solvent (water) content increases from 52 to 82% the shear modulus decreases from 1.35×10^7 to 2.56×10^5 dyn cm^{-2} (*i.e.*, fifty-fold). This can be compared with the mesoporous material made on the surfactant template for which the decrease would be only 50%, because in this case the strength of the material is only a linear function of the pore size.

In the simple hydrogel the large pore size usually means a strong decrease in the cross-linking density. On the other hand, in the mesoporous material prepared on a periodic surface the average distance between the monomers is independent of the pore size.

4.3 Crystallization of Membrane Proteins on Periodic Surfaces

The prediction of the biological function of a given protein is based on its known structure. This in turn can be deduced from the x-ray spectra, NMR spectra (Thompson *et al.*, 1992), or electron microscopy (Unwin, 1993). In the case of x-ray spectra one has to prepare a crystal of a given protein. The high-molecular-weight membrane proteins that are responsible for many biological functions—such as active transport through the membrane, signal transduction, charge separation, energy conversion, and catalysis of vital reactions—have anisotropic shape and hydrophobic surfaces. This is a serious obstacle in producing well-ordered three-dimensional crystals suitable for x-ray analysis. The natural environment of membrane proteins is the lipid bilayer that forms the membrane. In solutions the proteins lose their integrity, denaturate, or aggregate. However, if the protein removed from the bilayer is put back, it regains stability (Page *et al.*, 1988). The idea for obtaining crystals of membrane proteins is to use the cubic phases consisting of water and the periodic lipid bilayer as hosts for polymerization of membrane proteins (Landau and Rosenbusch, 1997). In this experiment monoolein or monopalmitolein forms a periodic surface that incorporates bacteriorhodopsin, a membrane protein extracted from the purple patches of *Halobacterium halobium*. Nucleation starts at the surface, and the crystal grows while the proteins diffuse along the bilayer to the nucleation site. As the crystal grows the lipid surface recedes, so that no lipidic components are incorporated into the growing crystal. The structure of the crystal depends on the structure of the bilayer. For monoolein it was a hexagonal crystal, while in the case of monopalmitolein it formed a rhombic crystal. The periodicity and continuity of the lipid surface is crucial; when the lipids form a micellar solution—that is, the lipid surface forms closed structures—the crystals could not be grown. The crystallization process takes about 14 d to obtain crystals of sizes $0.1 \times 0.1 \times 0.03\,\text{mm}^3$, and the current resolution of x-ray spectroscopy is 2 Å.

This method seems to be very promising for the routine crystallization of labile membrane proteins.

GLOSSARY

Amphiphilic Molecule: A molecule that consist of two parts, one hydrophobic and one hydrophilic (examples: soap molecules, detergents, lipids, and phospholipids).

Bicontinuous Structure: A structure consisiting of two disjoint continuous subvolumes, separated by a continuous (*i.e.*, not closed) surface.

Diblock Copolymer: Two linear polymers consisting of different repeated units joined by a covalent bond at the ends.

Euler Characteristic: $\chi = 2(1-g)$, where g is genus.

Gaussian Curvature: The inverse of the product of two principal radii of curvature. For a sphere of radius R it is equal to $1/R^2$. For an infinite cylinder it is 0.

Genus: Number of holes in a closed surface. The genus of a sphere is 0; for a torus it is 1; and for a pretzel it is 2.

Hydrophilic: Having strong affinity towards water ("water loving").

Hydrophobic: Opposite to hydrophilic ("water hating").

Mean Curvature: One half of the sum of the inverse of two principal radii of curvature. For a sphere of radius R it is $1/R$. For a cylinder of the same radius it is $1/2R$.

Mesoporous Material: A porous material with pore sizes intermediate between the microscopic scale (*i.e.*, angstroms) and the macroscopic scale (*i.e.*, thousands of angstroms).

Micellar Solution: A solution of, *e.g.*, water and surfactant where the surfactant molecules form a closed structure—spherelike, disklike, or rodlike. The bilayer surface is closed in this case in contrast to the periodic surfaces.

Periodic Surface: A surface that moves onto itself under a unit translation in one, two, or three coordinate directions.

Polymer: A molecule of high molecular weight consisting of repeated units (monomers or mers).

INTRODUCTION

A quantum computer is a device that can arbitrarily manipulate the quantum state of a part of itself. The field of quantum computation is largely a body of theoretical promises for some impressively fast algorithms that could be executed on quantum computers. However, since the first significant algorithm was proposed in 1994 (Shor, 1994) experimental progress has been rapid with several schemes yielding two– (Turchette *et al.*, 1995; Monroe *et al.*, 1995) and three–quantum-bit manipulations (Gershenfeld and Chuang, 1997). At the writing of this article it does not seem unreasonable to expect that small quantum computers capable of manipulating the quantum states of five or six two-level systems will be available within around five years. In addition, with the discovery of quantum error-correction schemes (Shor, 1995), such machines have the promise of providing long-term storage of quantum information and possibly allowing the ability to manipulate many more bits. It is still too early to tell whether the promises of rapid computation are achievable, nor is it yet well understood how broad a class of problems could be significantly speeded up by quantum computers.

Quantum computers were first discussed by Benioff (1980, 1981, 1982) in the context of simulating classical Turing machines (very elementary conventional computers) with quantum unitary evolution. Feynman (1982, 1986) considered the converse question of how well classical computers can simulate quantum systems. It was concluded that classical computers invariably suffer from an exponential slowdown in trying to simulate quantum systems, but that quantum systems could, in principle, simulate each other without this slowdown. It was Deutsch (1985a, 1985b), however, who first suggested that quantum superposition might allow quantum evolution to perform many classical computations in parallel.

To demonstrate where such capabilities may lie hidden, we review an elementary quantum mechanical experiment. The two-slit experiment is prototypic for observing one key feature of quantum mechanics: a source emits photons, electrons, or other particles that arrive at a pair of slits. These particles undergo unitary evolution and finally measurement. We see an interference pattern, with both slits open, which wholly vanishes if either slit is covered. In some sense, each particle passes through both slits in parallel. If such unitary evolution were to represent a calculation (or an operation within a calculation) then the quantum system would be performing computations in parallel. In some sense this quantum parallelism comes for free without our having to construct many copies of the "processing

unit." The output of this system would be given by the constructive interference among the parallel computations.

In this article we give a tutorial on how quantum mechanics can be used to improve computation. We concentrate on the only known algorithm that demonstrates an exponential speedup relative to the best known classical algorithms. Our challenge: solving a problem that is exponentially difficult for a conventional computer—that of factoring a large number. As a prelude, we review the standard tools of computation, universal gates and machines. These ideas are then applied first to classical, dissipationless computers and then to quantum computers. A schematic model of a quantum computer is described as well as some of the subtleties in its programming. The Shor algorithm (Shor, 1994; Ekert and Jozsa, 1996) for efficiently factoring numbers on a quantum computer is presented in two parts: the quantum procedure within the algorithm and the classical algorithm that calls the quantum procedure. The mathematical structure within the factoring problem is discussed, making it clear what contribution the quantum computer makes to the calculation. The complexity of the Shor algorithm is compared with that of factoring on conventional machines, and its relevance to public-key cryptography is noted. In addition, we discuss the experimental status of the field and also quantum error correction, which may in the long run help solve some of the most pressing difficulties. We conclude with an outlook as to the feasibility and prospects for quantum computation in the coming years.

1. COMPUTING AT THE ATOMIC SCALE

Quantum computers will perform computations at the atomic scale (DiVincenzo, 1995b). We might ask at this point how close conventional computations are to this scale already. Figure 1 shows a survey made by Keyes (1988): the number of dopant impurities in the bases of bipolar transistors used for digital logic against the year. This plot may be thought of as showing the number of electrons required to store a single bit of information.

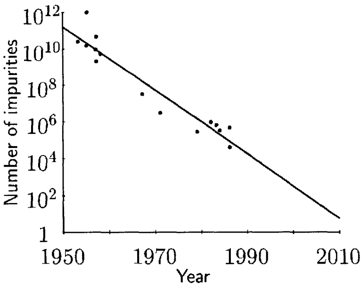

FIG. 1. Number of dopant impurities involved in logic in bipolar transistors versus year. (From Keyes, 1998; copyright 1988 by International Business Machines Corporation, reprinted with permission.)

An extrapolation of the plot suggests that we might be within reach of the atomic-scale computations within the next two decades.

Another way of viewing this plot is perhaps even more relevant for the development of quantum computation: conventional computers have been improving in speed and miniaturization at an exponential rate since their earliest days. Clearly there is a bound to our ability to miniaturize conventional electronics, and we will likely be touching that limit within the next 20 years. The question is raised: can we continue to expect to see an exponential improvement in performance 20 and more years from now? As we approach some of the physical limits to conventional computational construction we may begin to see a slowdown of this exponential rate. A detailed study of quantum computation may help us understand the fundamental physical limitations upon computation, conventional or otherwise.

2. REVERSIBLE COMPUTATION

What are the difficulties in trying to build a classical computing machine on such a small scale? One of the biggest problems with the program of miniaturizing conventional computers is the difficulty of dissipated heat. As early as 1961 Landauer studied the physical limitations placed on computation from dissipation (Landauer, 1961). Surprisingly, he was able to show that all but one operation required in computation could be performed in a reversible manner, thus dissipating no heat! The first condition for any deterministic device to be reversible is that its input and output be uniquely retrievable from each other. This is called logical reversibility. If, in addition to being logically reversible, a device can actually run backwards then it is called physically reversible and the second law of thermodynamics guarantees that it dissipates no heat.

The work on classical, reversible computation laid the foundation for the development of quantum mechanical computers. On a quantum computer, programs are executed by unitary evolution of an input that is given by the state of the system. Since all unitary operators U are invertible with $U^{-1} = U^{\dagger}$, we can always "uncompute" (reverse) a computation on a quantum computer.

3. CLASSICAL UNIVERSAL MACHINES AND LOGIC GATES

We now review the basic logic elements used in computation and explain how conventional computers may be used for any "reasonable" computation. A reasonable computation is one that may be written in terms of some (possibly large) Boolean expression, and any Boolean expression may be constructed out of a fixed set of logic gates. Such a set (*e.g.*, AND, OR, and NOT) is called universal. In fact we can get by with only two gates, such as AND and NOT or OR and NOT. Alternatively, we may replace some of these primitive gates by others, such as the exclusive-OR (called XOR or often controlled-NOT); then AND and XOR form a universal set. The truth tables for these gates are displayed in Table 1. Any machine that can build up arbitrary combinations of logic gates from a universal set is then a universal computer. Further, which universal set of gates is chosen makes little difference: a theorem by Muller (1956) states that the complexity of the simplest circuits needed to compute any reasonable Boolean function is affected by at most a constant multiplicative factor.

Which of the above gates is reversible? Since AND, OR, and XOR are many-to-one operations, information is lost and they are not, as they stand, logically reversible. Before we discuss how these logic gates may be made reversible we consider some nonstandard gates that we shall require.

Table 1. Truth table defining the operation of some simple logic gates. Each row shows two input values A and B and the corresponding output values for gates AND, OR, and XOR. The output for the NOT gate is shown only for input B.

A	B	AND	OR	XOR	NOT B
0	0	0	0	0	1
0	1	0	1	1	0
1	0	0	1	1	1
1	1	1	1	0	0

3.1 FANOUT and ERASE

Although the above gates are sufficient for the mathematics of logic, they are not sufficient to build a machine. A useful computer will also require the FANOUT and ERASE gates (Fig. 2).

First consider the FANOUT gate: is it reversible? Certainly no information has been destroyed, and so it is at least logically reversible. Landauer (1961) showed that it could also be physically reversible. Let us describe a simple model for FANOUT based on Bennett's (1988) scheme for a reversible measurement (Fig. 3). [We note, however, that the concepts involved in this scheme come from Toffoli (1980) and Fredkin and Toffoli (1982).] Here a dark ball is used to determine the presence or absence of a second (light) ball inside a trap. The trap consists of a set of mirrors and may be thought of as a one-bit memory register. If the trap is occupied then the dark ball is reflected and leaves along direction M (with the

(a) FANOUT (b) ERASE

FIG. 2. Two nonstandard gates that are required to build a computer, in addition to a universal set of logic gates: (a) the FANOUT gate, which duplicates an input A; and (b) the ERASE gate, which deletes its input.

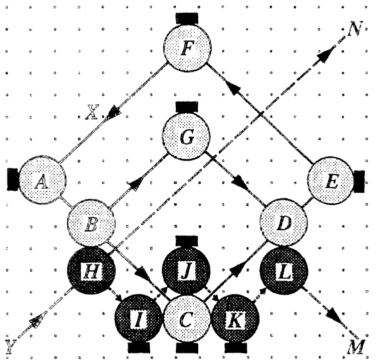

FIG. 3. A reversible measurement of the existence of a (light) ball in a trap of mirrors (dark rectangles). A (dark) ball enters the trap from *Y*. In the absence of a light ball in the trap the dark ball will follow the path *HN*. In presence of a light ball (timed to start at *X*) the dark ball will deflect the light one from its unhindered trajectory *ABCDEF* to *ABGDEF* and will follow the path *HIJKLM* itself. (From Bennett, 1998; copyright 1988 by International Business Machines Corporation, reprinted with permission.)

light ball continuing along its original trajectory); otherwise it passes unhindered towards *N*. Upon leaving the trap, the dark ball's direction is used to populate, or not, another trap.

Let us now consider the ERASE operation, required to "clean out" the computer's memory periodically. One type of erasure can be performed reversibly: if we have a backup copy of some information, we can erase further copies by uncomputing the FANOUT gate. The difficulty arises when we wish to erase our last copy, referred to here as the primitive ERASE.

Consider a single bit represented by a pair of equally probable classical states of some particle. To erase the information about the particle's state we must irreversibly compress phase-space by a factor of two. If we allowed this compressed phase space to expand, at temperature *T*, to its original size, we could obtain an amount of work equal to $k_B T \ln 2$ (where k_B is Boltzmann's constant). Landauer (1961) concluded, on the basis of simple models and more general arguments about the compression of phase space, that the erasure of a bit of information at temperature *T* requires the dissipation of at least $k_B T \ln 2$ heat (a result known as Landauer's principle).

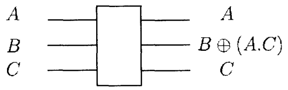

FIG. 4. Three-input, three-output universal reversible Toffoli gate. This gate is clearly reversible since a second application of it retrieves the original input.

3.2 Computation without ERASE

Fortunately, the primitive ERASE is not absolutely essential in computation. To see why, consider what is required to compute arbitrary functions using reversible logic (where the primitive ERASE is forbidden). Landauer showed how any function $f(a)$ could be made one-to-one by keeping a copy of the input:

$$f : a \rightarrow (a, f(a)). \tag{1}$$

Here the bold parentheses represent an ordered set of values, in this case, two. Extra "slots" will be added (or removed) as required in our discussion below.

How can this trick be used to perform reversible logic? One solution, known as the Toffoli gate (Toffoli, 1980; Fredkin and Toffoli 1982; Landauer 1961), is shown in Fig. 4. The output of this gate may be decomposed into various gates:

$$B \oplus (A \cdot C) = \begin{cases} A \cdot C, & \text{for } B = 0 \quad \text{(AND)}, \\ A \oplus B, & \text{for } C = 1 \quad \text{(XOR)}, \\ \bar{A}, & \text{for } B = C = 1 \quad \text{(NOT)}, \\ A, & \text{for } B \neq C = 1 \quad \text{(FANOUT)}, \end{cases} \tag{2}$$

where $A \cdot B$ represents an AND gate, $A \oplus B$ represents an XOR gate, and $\bar{A}$ represents a NOT gate. We see that this gate is universal, because it performs AND, XOR, NOT, or FANOUT depending on its inputs. A combination of many such gates could then be used for any computation and would still be reversible.

As noted by Landauer, this procedure leads to an immediate problem because of the absence of the primitive ERASE. The more gates we employ, the more "junk" bits we accumulate: at each gate we must save input bits in order to preserve reversibility. In other words a computer built out of reversible logic instead of conventional, irreversible logic gates would behave like

$$f : a \to (a, j(a), f(a)), \tag{3}$$

with many extra junk bits $j(a)$.

Bennett (1973 and 1989; Li *et al.*, 1997) solved this problem by showing that the junk bits could be reversibly erased at intermediate steps with minimal run-time and memory costs. The spirit of Bennett's solution may be understood in terms of the following procedure:

$$f : a \to (a, j(a), f(a)) \tag{4a}$$

$$\text{FANOUT} : (a, j(a), f(a)) \to (a, j(a), f(a), f(a)) \tag{4b}$$

$$f^{\dagger} : (a, j(a), f(a), f(a)) \to (a, f(a)), \tag{4c}$$

where $f^{\dagger}$ denotes uncomputing f, as opposed to computing f^{-1}. First, f is computed, producing both junk bits and the desired output. Then the FANOUT gate is applied to duplicate the output. Finally, we uncompute the original function f by running its computation backwards. This procedure removes the junk bits and the original output. The duplicate, however, remains!

This completes our discussion of the construction of classical, reversible computers. We have found that reversibility does not bar the logical design of computing machines. Before mapping these ideas to quantum systems, however, we introduce some elementary quantum mechanical notation.

4. ELEMENTARY QUANTUM NOTATION

A simple quantum system is the two-level spin-$\frac{1}{2}$ particle. Its basis states, spin down $|\downarrow\rangle$ and spin up $|\uparrow\rangle$, may be relabeled to represent binary zero and one, *i.e.*, $|0\rangle$ and $|1\rangle$, respectively. The state of a single such particle is described by the wave function $\psi = \alpha|0\rangle + \beta|1\rangle$, *i.e.*, a linear superposition among any of the possible "classical" states of the system. The squares of the complex coefficients $|\alpha|^2$ and $|\beta|^2$ represent the probabilities for finding the particle in the corresponding states. Generalizing this to a set of k spin-$\frac{1}{2}$ particles we find that there are now 2^k basis states (quantum mechanical vectors that span a Hilbert space) corresponding, say, to the 2^k possible bit strings of length k. Freely moving between decimal, binary, and spin labels then we might write, for example for $k = 5$, a state $|25\rangle = |11001\rangle = |\uparrow\uparrow\downarrow\downarrow\uparrow\rangle$.

The dimensionality of the Hilbert space grows exponentially with k. In some very real sense quantum computations make use of this enormous size latent in even the smallest systems.

5. LOGIC GATES FOR QUANTUM BITS

In this section we describe how arbitrary logic gates may be constructed for quantum bits. We start by considering various one-bit unitary operations and a single two-bit one—the XOR operation. Combinations of these are sufficient to construct a Toffoli gate for quantum bits or, indeed, *any* unitary operation on a finite number of bits.

Start with a single quantum bit. If we represent the states $|\downarrow\rangle$ and $|\uparrow\rangle$ (*i.e.*, $|0\rangle$ and $|1\rangle$) as the vectors $\binom{1}{0}$ and $\binom{0}{1}$, respectively, then the most general unitary transformation corresponds to a 2×2 matrix of the form

$$U_\theta \equiv \begin{pmatrix} e^{i(\delta+\sigma/2+\tau/2)}\cos(\theta/2) & e^{i(\delta+\sigma/2-\tau/2)}\sin(\theta/2) \\ -e^{i(\delta-\sigma/2+\tau/2)}\sin(\theta/2) & e^{i(\delta-\sigma/2-\tau/2)}\cos(\theta/2) \end{pmatrix}, \tag{5}$$

where we typically take $\delta = \sigma = \tau = 0$ (Barenco *et al.*, 1995a). Using this operator we can flip bits via

$$U_\pi|0\rangle = -|1\rangle, \quad \text{and} \quad U_\pi|1\rangle = |0\rangle. \tag{6}$$

FIG. 5. Schematic of the quantum circuit diagram for a one-bit gate. The line represents a single quantum bit (such as a spin-$\frac{1}{2}$ particle). Initially, this bit has a state described by $|A\rangle$; after it has "passed" through this circuit it comes out in the state $U_\theta|A\rangle$.

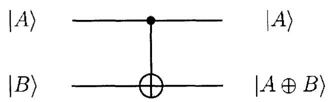

FIG. 6. Quantum circuit diagram for an XOR gate. The lower bit $|B\rangle$ is flipped whenever the upper bit $|A\rangle$ is set.

The extraneous sign represents a phase factor that does not affect the logical operation of the gates and may be removed if we wish, now or at a later stage. Such one-bit computations are illustrated schematically as a quantum circuit in Fig. 5 (Barenco *et al.*, 1995a; DiVincenzo 1995a).

Another important one-bit gate is $U_{-\pi/2}$, which maps a spin-down particle to an equal superposition of down and up:

$$U_{-\pi/2}|0\rangle = \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle). \tag{7}$$

Consider a string of k spin-$\frac{1}{2}$ particles initially spin-down. If we apply this gate independently to each particle we obtain a superposition of every possible bit string of length k:

$$|0\rangle \rightarrow \frac{1}{\sqrt{q}}\sum_{a=0}^{q-1}|a\rangle, \tag{8}$$

where $q = 2^k$. Our computer is now in a superposition of an exponentially large number of integers a from 0 to $2^k - 1$. Suppose further that we could construct a unitary operation that maps a pair of bit strings $|a;0\rangle$ into the pair $|a;f(a)\rangle$ for some function $f(a)$. Then such a unitary operator acting on the superposition of states

$$\frac{1}{\sqrt{q}}\sum_{a=0}^{q-1}|a;0\rangle \rightarrow \frac{1}{\sqrt{q}}\sum_{a=0}^{q-1}|a;f(a)\rangle, \tag{9}$$

would compute $f(a)$ in parallel an exponentially large number of times for the various inputs a. This follows from the linearity of quantum mechanics.

To see how such unitary operators may be constructed from a few elementary ones we must also consider the XOR gate (Barenco *et al.*, 1995a; DiVincenzo 1995a). Writing the two-particle basis states as the vectors

$$|00\rangle = \begin{pmatrix}1\\0\\0\\0\end{pmatrix}, \qquad |01\rangle = \begin{pmatrix}0\\1\\0\\0\end{pmatrix}, \tag{10a}$$

$$|10\rangle = \begin{pmatrix}0\\0\\1\\0\end{pmatrix}, \qquad |11\rangle = \begin{pmatrix}0\\0\\0\\1\end{pmatrix}, \tag{10b}$$

we may represent the XOR gate as a unitary operator

$$U_{\mathrm{XOR}} = \begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&0&1\\0&0&1&0\end{pmatrix}. \tag{11}$$

Here the first particle acts as a conditional gate to flip the state of the second particle. It is easy to check that the state of the second particle corresponds to the action of the XOR gate given in Table 1. The quantum circuit for an XOR gate is illustrated in Fig. 6. This circuit is equivalent to the elementary instruction

$$\texttt{if } (|A\rangle = \texttt{1})\ |B\rangle = \mathrm{NOT}\ |B\rangle \tag{12}$$

which may be thought of as example of quantum computer code (suggest by DiVincenzo at the 1995 Quantum Computation, Villa Gualino Workshop). The ket brackets $|\ \rangle$ are reminders that we are dealing with quantum rather than classical bits. The XOR gate allows us to move information around, as is

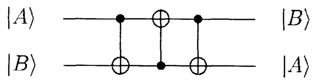

FIG. 7. Circuit for swapping a pair of bits.

illustrated in Fig. 7.

How do we construct the Toffoli gate? One major problem with this gate is that it requires three bits in and three out. Quantum mechanically, this seems to correspond to a scattering process involving three-particle collisions (Deutsch, 1989) calling for a (possibly) unreasonable control of the particles. Fortunately, the Toffoli gate may be constructed by two-particle scattering processes alone (DiVincenzo, 1995a; Barenco *et al.*, 1995b; Sleator and Weinfurter, 1995; Deutsch *et al.*, 1995; Lloyd, 1995). In particular, we show a construction here involving the XOR gate and some one-bit gates U_θ (Fig. 8) (Barenco *et al.*, 1995a). Not only is the XOR sufficient for all logic operations on a quantum computer, but it can be used to construct arbitrary unitary transformations on any finite set of bits. Numerous proposals for producing such gates have been considered (Ekert and Jozsa 1996; DiVincenzo 1995b), and we discuss some promising experimental results in the next section.

6. LOGIC GATES IN THE LABORATORY

In this section we briefly review two recent experiments that demonstrate conditional dynamics of a type that is promising for constructing quantum logic gates (Turchette *et al.*, 1995; Monroe *et al.*, 1995). These two results appeared back to back in the same issue of *Physical Review Letters*.

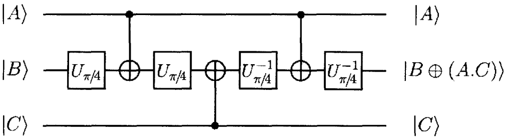

FIG. 8. Toffoli gate built from two-bit XOR gates plus some one-bit gates (Barenco *et al.*, 1995a). This circuit introduces some extra signs in the unitary matrix U_{XOR}, which may be removed at a later stage.

The first experiment, by Turchette *et al.* (1995), demonstrated that the phase of a weak coherent optical field could be controlled by the intensity of a second coherent field at a slightly different frequency. The chief result is that such a high nonlinear susceptibility was achieved that a large phase shift (up to 16°) was produced by a change in intensity corresponding to a single photon in the second field. The coupling between the optical fields was obtained using the hyperfine level structure of cesium. A stream of Cs atoms was dropped through an optical cavity, which effectively restrained the atomic decay modes to the cavity modes. This allowed the atoms to couple strongly to the optical fields passing through the cavity with minimal incoherent emission into free space. Since coherent instead of single-photon states were used in this experiment, however, there could be no direct demonstration of the coherence retained in the final state of the optical fields. In this scheme a qubit would need to be represented by single-photon states rather than weak coherent states, but that does not appear to be a great difficulty.

The second experiment, by Monroe *et al.* (1995), involved a direct demonstration of an XOR gate in a radio-frequency ion trap (also known as a Paul trap). Here the lowest vibrational excitation of a single $^9\mathrm{Be}^+$ ion in the trap and its hyperfine state represented the two qubits. A pair of off-resonant laser beams were used to drive stimulated Raman transitions between the basis states of these two qubits. The XOR gate was executed using three laser pulses, as had been suggested by Cirac and Zoller (1995). The coherence of the qubits in this system was reported to have survived for around to 10–20 XOR operations (Thompson, 1996).

Cirac and Zoller had suggested using a linear ion trap to hold a set of ions in a well localized manner by mutual electrostatic repulsion. Each ion would be "addressed" separately by its own laser. By tuning the lasers shining on individual ions to the appropriate levels, either single-qubit operations could be performed or the internal ionic state could be transferred to that of the lowest two vibrational modes of the trap. In this way two-qubit gates could be simulated between even noncontiguous ions via their interactions with the trap's vibrational modes. This ability significantly reduces the complexity of elementary operations over other proposals (Lloyd, 1993). The fact that this theoretical proposal was implemented within a few months, though in a slightly modified form, suggests that few-qubit processors could become a reality within a relatively short period of time. In Sec. 13 we discuss the short-term prospects for such machines.

In quantum computation we normally aim at having the qubits couple maximally to each other and minimally to the outside world. This lessens the actions of environment-induced decoherence. From this perspective the latter scheme, involving ion traps, appears more nearly ideal. However, there is another class of quantum logic processor, which aims at communicating quantum information between various, possibly distantly, separated subsystems. This might allow for the combining of smaller quantum computers into larger ones operating on more qubits through combination. It is likely also to be important for the area of quantum communication and potential technologies that few-bit quantum logic processors might enable. For such tasks the former scheme involving "flying" qubits appears a more likely direction. It is possible that a mature quantum computation technology would have components incorporating the positive aspects of both the above schemes.

7. MODEL QUANTUM COMPUTER AND QUANTUM CODE

In this section we describe a simple abstract model for a quantum computer based on a classical computer instructing a machine to manipulate a set of spins. This model has some intrinsic limitations that make designing algorithms in a high-level language somewhat tricky. We discuss some of the rules for writing such quantum computer code as a high-level language and give an example.

Consider the following model for the operation of a quantum computer. Several thousand spin-$\frac{1}{2}$ particles (or two-level systems) are initially in some well defined state, such as spin down. A classical machine takes single spins or pairs of spins and entangles them (performing an elementary one-bit operation U_θ or the two-bit XOR gate); see Figs. 9(a), 9(b), and 9(c). These stages are repeated on different pairs of spins according to the instructions of a conventional computer program. Since the spins are entangled, we must not look at the spins at intermediate stages. We must keep the quantum superposition intact. Furthermore, nothing else may interfere with the spins that could destroy their orientation or interrupt their unitary evolution. Once this well-defined cycle of manipulation is complete the orientations of the spins are measured [Fig. 9(d)]. This set of measured orientations is the output of the computation.

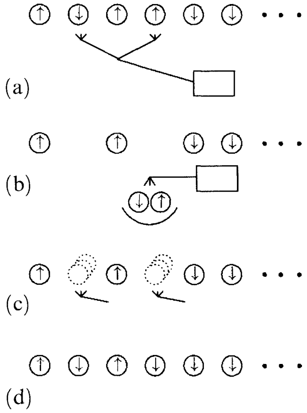

FIG. 9. Model quantum computer as pictured by Shor (presented at the 1994 Quantum Computation, Villa Gualino Workshop). Initially all particles are spin-down. In stage (a) a classical machine takes a single or pair of spins and in stage (b) it performs a selected one-bit or two-bit operation; in stage (c) the "entangled" particles are returned to their original locations. These three stages are repeated many times in accord with the instructions given by an ordinary classical computer. When this cycle is complete stage (d) consists of measuring the state of the particles (leaving them is some particular bit string); this bit string is the result of the computation.

Given this paradigm for a quantum computer, what might its high-level language (its computer code) look like? The most serious difficulty that must be dealt with is that the quantum information is manipulated by a conventional computer in a completely blind manner—without any access to the values of this quantum information. This means that the program cannot utilize "shortcuts" conditional on the value of a quantum variable (or register or bit). For example, loops must be iterated through exactly the same number of times independent of the values of the quantum variables. Similarly, conditional branches around large pieces of code must be broken down into repeated conditions for each step. In addition, each instruction performed upon the quantum bits must be logically reversible. Thus, ordinary assignments of a value to a variable, such as `|a⟩ = n`, are not legal and must instead be performed as increments on an initially zeroed variable, such as `|a⟩ = |a⟩ + n`.

An example of such code that could run on this machine might look like this (suggested by DiVincenzo at the *1995 Quantum Computation, Villa Gualino Workshop*):

```
   do 10 k = 1, worstdiv
   |a⟩ = |a⟩ - n
   if ( |a⟩ >=0 ) |q⟩ = |q⟩ + 1
10 continue
   do 20 k = 1, worstdiv
   if ( k > |q⟩ ) |a⟩ = |a⟩ + n
20 continue
```

This code fragment could be used to calculate the quotient and the remainder, placed in `|q⟩` and `|a⟩`, respectively, for the division of `|a⟩` by `n`; the constant `worstdiv` is the worst-case number of times the loop must be traversed. Here `|q⟩` is initially zero. Each instruction here is either a conventional computer instruction or one involving some quantum variables. The former are direct instructions for the external computer, while the latter must be interpreted as a sequence of manipulations to be performed upon the quantum bits. As it stands, this code is *not* reversible (neither is it very efficient); e.g., the label `10` gives no specification of which routes might be used to get to it. It can, however, be easily rewritten.

8. QUANTUM PARALLELISM: PERIOD OF A SEQUENCE

We now have sufficient ingredients to understand how a quantum computer can perform logical operations and compute just like an ordinary computer. In this section we describe an algorithm that makes use of the quantum parallelism that we have hinted at already: finding the period of a long sequence.

Consider the sequence

$$f(0), f(1), \ldots, f(q-1), \tag{13}$$

where $q \equiv 2^k$; we shall use quantum parallelism to find its period. We start with a set of initially spin-down particles, which we group into two sets (two quantum registers, or quantum variables):

$$|0;0\rangle = |\downarrow, \downarrow, \ldots; \downarrow, \downarrow, \ldots\rangle, \tag{14}$$

the first set having k bits, the next having sufficient for our needs. (In fact other registers are required, but by applying Bennett's solution to space management they may be suppressed in our discussion here.) On each bit of the first register we perform the $U_{-\pi/2}$ one-bit operation, yielding a superposition of every possible bit-string of length k in this register:

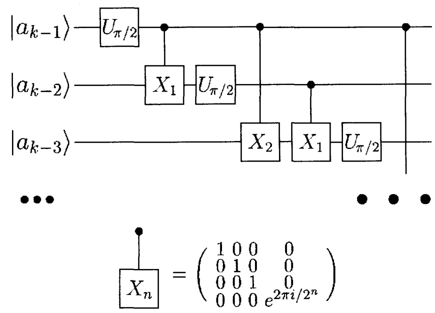
$$\rightarrow \frac{1}{\sqrt{q}} \sum_{a=0}^{q-1} |a;0\rangle. \tag{15}$$

The next stage is to break down the computation corresponding to the function $f(a)$ into a set of one-bit and two-bit unitary operations. The sequence of operations is designed to map the state $|a;0\rangle$ to the state $|a; f(a)\rangle$ for any input a. Now we see that the number of bits required for this second register must be at least sufficient to store the longest result $f(a)$ for any of these computations. When, however, this sequence of operations is applied to our exponentially large superposition, instead of the single input, we obtain

$$\rightarrow \frac{1}{\sqrt{q}} \sum_{a=0}^{q-1} |a; f(a)\rangle. \tag{16}$$

An exponentially large amount of computation has been performed essentially for free.

The final computational step, like the first, is again a purely quantum mechanical one.



$|a_{k-1}\rangle$
$|a_{k-2}\rangle$
$|a_{k-3}\rangle$
$U_{\pi/2}$
X_1
X_2
X_n
$= \begin{pmatrix} 1\,0\,0 & 0 \\ 0\,1\,0 & 0 \\ 0\,0\,1 & 0 \\ 0\,0\,0 & e^{2\pi i/2^n} \end{pmatrix}$

FIG. 10. Circuit for the quantum Fourier transform of the variable $|a_{k-1} \ldots a_1 a_0\rangle$ using Coppersmith's (1994; Cleve 1994; DiVincenzo 1995b) fast Fourier-transform approach. The two-bit "X_n" gate may itself be decomposed into various one-bit and XOR gates (Barenco *et al.*, 1995a).

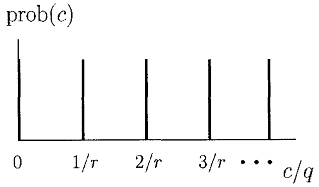


FIG. 11. Idealized plot of the probability of each result prob(c) *versus* c/q. Constructive interference produces narrow peaks at multiples of the inverse period of the sequence $1/r$. (The discrete approximation means that the peaks will actually have a nonzero width.)

Consider a discrete "quantum" Fourier transform on the first register

$$|a\rangle \rightarrow \frac{1}{\sqrt{q}} \sum_{c=0}^{q-1} e^{2\pi iac/q} |c\rangle. \tag{17}$$

It is easy to see that this is reversible via the inverse transform, and indeed it is readily verified to be unitary. Further, an efficient way to compute this transform with one-bit and two-bit gates has been described by Coppersmith (1994; Cleve 1994; DiVincenzo 1995b) (Fig. 10).

When this quantum Fourier transform is applied to our superposition, we obtain

$$\rightarrow \frac{1}{q} \sum_{a=0}^{q-1} \sum_{c=0}^{q-1} e^{2\pi iac/q} |c; f(a)\rangle. \tag{18}$$

The computation is now complete and we retrieve the output from the quantum computer by measuring the state of all spins in the first register (the first k bits). Indeed, once the Fourier transform has been performed the second register may even be discarded (Chuang *et al.*, 1996).

What will the output look like? Suppose $f(a)$ has period r so that $f(a+r) = f(a)$. The sum over a will yield constructive interference from the coefficients $e^{2\pi iac/q}$ only when c/q is a multiple of the reciprocal period $1/r$. (In fact, we must be careful that the discrete Fourier transform yields sufficient resolution to extract the multiple of the inverse period from c/q. This is always possible provided the number of bits k in the first quantum register satisfies $r^2 \leq q = 2^k$.) All other values of c/q will produce destructive interference to a greater or lesser extent. Thus, the probability distribution for finding the first register with various values is shown schematically by Fig. 11.

One complete run of the quantum computer yields a random value of c/q underneath one of the peaks in the probability of each result prob(c). That is, we obtain a random multiple of the inverse period. To extract the period itself we need only repeat this quantum computation roughly $\log\log(r/k)$ times in order to have a high probability for at least one of the multiples to be relatively prime to the period r—uniquely determining it (Shor 1994). Thus, this algorithm yields only a probabilistic result. Fortunately, we can make this probability as high as we like.

All the above work may appear a little anticlimactic. We have gone to a lot of trouble to design a quantum computer to find the period of a sequence. The point is, however, that the sequence is calculated in parallel and is exponentially long—even for a small value of, say, $k = 270$ bits in the first register, the quantum computer has calculated and stored more results than there are particles in the universe.

This algorithm for finding the period of an exponentially long sequence on a quantum computer lies at the heart of efficiently factoring numbers. We first proceed to review the computational difficulty of factoring for conventional computers. Then we discuss the implications this computational difficulty has had for the secure transmission of private information via public key cryptosystems. We then follow these discussions with Shor's (1994) new result for efficient factoring.

9. THE COMPLEXITY OF FACTORING

How can we quantify the difficulty of solving a problem with a conventional computer? Surely once the computer program is written and debugged we may simply let it run and wait for the answer. But this brings us to the crux of the difficulty. For a given problem how long must we expect to wait for the solution? When more carefully phrased this becomes the simplest measure of computational difficulty of an algorithm, yielding the "algorithmic complexity" of the problem.

To be more specific, without getting into technicalities, let us consider the problem of factoring a number N into its prime factors (*e.g.*, the number 51 688 may be decomposed as $2^3 \times 7 \times 13 \times 71$). A convenient way to quantify how quickly a particular algorithm may solve this, or any, problem is to ask how the number of steps to complete the algorithm scales with the size of the "input" the algorithm is fed. For the factoring problem, this input is just the number N we wish to factor; hence the length of the input is $\log N$. (The base of the logarithm is determined by our numbering system. Thus a base of 2 gives the length in binary; a base of 10 in decimal. For example, the number 51 688 requires 16 binary digits, but only five decimal digits, to specify it.) "Reasonable" algorithms are ones that scale as some small-degree polynomial in the input size (with a degree of perhaps 2 or 3). One famous example of a fast algorithm is the fast Fourier transform, which requires roughly $O(M \log_2 M)$ steps to perform the discrete Fourier transform of M points (so for a fixed precision the input scales as M); by contrast, a conceptually simpler algorithm equivalent to matrix multiplication would require $O(M^2)$ computational steps (Press *et al.*, 1988). This modest improvement from a quadratic to a roughly linear complexity has made many image-processing applications possible with even quite modest computers.

On conventional computers the best known factoring algorithm runs in $O(\exp[(64/9)^{1/3} \times (\ln N)^{1/3} (\ln \ln N)^{2/3}])$ steps (Odlyzko, 1995). This algorithm, therefore, scales exponentially with the input size $\log N$. For instance, in 1994 a 129-digit number (known as RSA129; Rivest *et al.*, 1978) was successfully factored using this algorithm on approximately 1600 workstations scattered around the world; the entire factorization took eight months (Atkins *et al.*, 1995). Using this to estimate the prefactor of the above exponential scaling, we find that it would take roughly 800 000 years to factor a 250-digit number with the same computer power; similarly, a 1000-digit number would require 10^{25} years (significantly longer than the age of the universe). This difficulty is, however, almost certainly exaggerated since it takes no account of the constant improvement in factoring algorithms and the constant speedup of computer hardware. In fact, both of these components have shown a more or less exponential improvement over the last few decades (Odlyzko, 1995), with each contributing roughly equally to the increased computational power. The difficulty of factoring large numbers is crucial for public-key cryptosystems, such as ones used by banks. There, such codes rely on the difficulty of factoring numbers with around 250 digits.

10. SECURITY AND RSA

Cryptography as a discipline aims at minimizing the affect of the dishonest. One such situation is the need for secure communication between two parties across an insecure channel. The sender encrypts a plain-text message with an encryption key yielding the cypher text. The message is sent across an insecure medium where, we must assume, an eavesdropper may have access. The receiver takes the cypher text and uses a decryption algorithm to restore the plaintext. If we assume that the eavesdropper has access to the decryption algorithm, then the receiver must have something in addition to ensure the security of the transmitted message; this is the decryption key. According to Shannon's information theory the cypher text must contain some information about the plain-text message unless the decryption key is at least as long as the message itself (Goldreich, 1995). Such a perfect cipher was invented in 1917, and is known as the Vernam cipher or one-time pad; it requires a key equal in size to the plain-text message. Thus, for perfect security we have the problem of distributing the key itself, which must be done over a secure channel such as by trusted courier. In many situations, such as banking transactions where the volume of information is very large, this is unreasonable.

An understanding of computational complexity allows us to "circumvent" the restriction of Shannon's theory. A pseudorandom-number generator can be used to generate a long almost random key from a much smaller secret key. If the lack of randomness cannot be discovered except through an unreasonable amount of computational effort by the eavesdropper then we have a secure encryption system. An excellent example of such a scheme is the U.S. Data Encryption Standard (DES), which uses a 56-bit key (Press *et al.*, 1988). One estimate of the security of DES suggests that for around one million dollars a special-purpose machine could be built to try all 2^{56} keys in a few hours, though security can be easily enhanced by multiple application and a larger effective key (Odlyzko, 1994). Clearly short keys reduce the burden of key distribution amongst single pairs of users, but for n users $n(n-1)/2$ keys would be required to allow any pair to communicate securely. This becomes unwieldy for commercial applications where millions of users may be involved.

Another approach, also based on computational complexity, is known as public-key encryption. The most popular scheme, and one used in may commercial applications, is RSA encryption (Rivest *et al.*, 1978). A person wishing to receive secret communications simply publishes a pair of numbers (N, e) that form the public key. Encryption involves converting the message to numerical data and dividing it into blocks of numbers m_j each smaller than N. Each block m_j of the message is then encrypted by its modular exponentiation

$$c_j \equiv m_j{}^e (\operatorname{mod} N), \tag{19}$$

where mod N represents modulo arithmetic (the expression is computed and only the remainder after division by N is retained). The encrypted blocks c_j are then transmitted to the receiver via a public channel. Thus, RSA (and any other public key scheme) efficiently solves the key distribution problem.

Decryption by the receiver requires knowing the inverse operation, *i.e.*, knowing the d such that

$$m_j \equiv c_j{}^d (\operatorname{mod} N), \tag{20}$$

reconstructs the original message m_j from the encrypted data c_j. The size of N makes the direct determination of d too difficult. Instead, d is constructed along with the public key pair (N, e) in an efficient manner. This construction involves choosing $N = pq$ as the product of a pair of comparably sized primes, with e relatively prime to both $p-1$ and $q-1$, and solving the much simpler problem

$$ed \equiv 1 (\operatorname{mod} p-1) \tag{21a}$$

$$ed \equiv 1 (\operatorname{mod} q-1). \tag{21b}$$

It is important to note that the best algorithms for finding d proceed by first factoring N; thus the security of RSA relies on the assumed difficulty of factoring (Schneier, 1994).

11. SHOR'S RESULT: FACTORING NUMBERS

Recently, an algorithm was developed by Shor (1994; Beckman *et al.*, 1996) of AT&T for factoring numbers on a quantum computer that runs in $O((\log N)^3)$ steps. This is cubic in the input size, so that factoring a 250-digit number with such an algorithm would require only a few billion steps. The implication is that public-key cryptosystems based on factoring may be breakable. In this section we give the classical portion of Shor's algorithm, which relates factoring to finding the period of an exponentially long sequence and hence makes the problem tractable for a quantum computer.

We wish to factor the number N. It will be sufficient to find even a single factor, since then we can reduce the problem to a simpler one. First, select a number x. Euclid's algorithm (see Appendix) could be used to compute efficiently the common factors between N and x, hence reducing our problem. We therefore assume that these numbers are co-prime. Next, consider the sequence formed by the function $f(a) = x^a (\bmod N)$. This sequence has the form

$$\begin{array}{l} 1, x, \ldots, x^{r-1}, \quad x^r, x^{r+1}, \ldots \\ \underbrace{1, x, \ldots, x^{r-1},}_{r\ \text{terms}} \quad \underbrace{1, x, \ldots,}_{r\ \text{terms}} \quad \underbrace{1, x, \ldots}_{r\ \text{terms}} \end{array} \tag{22}$$

Here the top row is just the sequence of powers $\{x^a\}$; the bottom row is the same sequence written in modulo arithmetic, namely $\{x^a (\bmod N)\}$. The number r is just the first nontrivial power where $x^r \equiv 1 (\bmod N)$. A close look at this sequence shows that it has a periodic structure with period r. Using standard algorithms this period would not be readily accessible for a long sequence. However, with the quantum computer algorithm described in Sec. 8 it could be calculated efficiently. This possibility opens up a novel way to find the factors of N, as we shall now describe.

Let us suppose that we have obtained the period r by the above quantum computer algorithm. [Note that since the period r is not known beforehand, we require $N^2 \leq q = 2^k$ for the Fourier transform step to yield sufficient resolution (Shor, 1994; Ekert and Jozsa, 1996)]. If now this period is even we may proceed with our factoring algorithm. If not, we must select another x and start again. A randomly chosen x will yield a suitably even period r 50% of the time, and so not too many trials will be needed (Shor, 1994; Ekert and Jozsa, 1996).

Having chosen an x so that the sequence $\{x^a (\bmod N)\}$ has an even period r, we rewrite the expression $x^r \equiv 1 (\bmod N)$ as the difference of two squares:

$$(x^{r/2})^2 - 1 \equiv 0 \ (\bmod N). \tag{23}$$

Expressing the left-hand-side as a product between a sum and difference we obtain

$$(x^{r/2} + 1)(x^{r/2} - 1) \equiv 0 \ (\bmod N). \tag{24}$$

This says that the product of the two terms on the left is a multiple of the number N we wish to factor. Thus, either one or the other of these terms must have a factor in common with N. The final step in the algorithm then is to calculate the greatest common divisor of these terms individually with N (see the Appendix for an efficient classical algorithm); any nontrivial common divisor will be a factor we have sought. This completes our search.

As an example, consider the number $N = 91$. Choosing $x = 3$ we find that the sequence $3^a (\bmod 91)$ has the form:

$$\begin{array}{l} a : 0, 1, 2, 3, 4, 5, 6, 7, \ldots \\ 3^a : 1, 3, 9, 27, 81, 243, 729, 2187, \ldots \\ 3^a (\bmod 91) : 1, 3, 9, 27, 81, 61, 1, 3, \ldots . \end{array} \tag{25}$$

A quantum computer could calculate the period in parallel; however, it is sufficient here to see by eye that this sequence has a period of $r = 6$ (since it is even we may proceed with the algorithm). Rearranging the expression $3^6 \equiv 1 (\bmod 91)$ as discussed above we conclude that $28 \times 26 \equiv 0 (\bmod 91)$. This implies that either $\gcd(28, 91)$ or $\gcd(26, 91)$ will be a nontrivial factor of 91 (where gcd is the greatest common divisor function). In fact, in this case, the two terms yield different factors, 7 and 13, respectively. This completes the prime factorization of 91 yielding $91 = 7 \times 13$.

12. QUANTUM ERROR CORRECTION

Building a quantum computer is a daunting task. Even within apparently small atomic-scale systems, quantum computation runs on the enormous size of Hilbert space. Quantum computation involves building a trajectory from a standard initial state to a complex final state. The main difficulty is keeping to this trajectory. To fail is to be lost in Hilbert space. The largest problem is hypersensitivity to perturbations, shifting the computational trajectory randomly from its path. Such perturbations come from an unintentional coupling to external noise (Unruh, 1995). In this section we briefly touch on quantum error correction and fault-tolerant computing, both introduced by Shor (1995, 1996), which promise to alleviate greatly the problem associated with un-

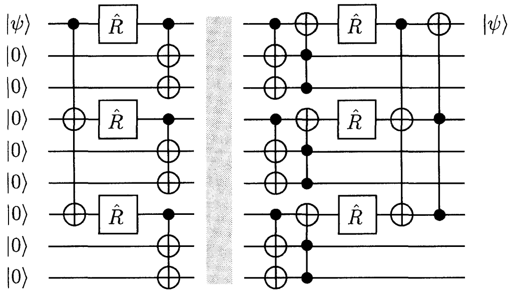

FIG. 12. Schematic of Shor's (1995) original error-correction scheme to protect one qubit in a nine-qubit code against arbitrary one-qubit decoherence. The unprotected qubit enters as qubit 1 from the left. Its error protection encoded state is just to the left of the shaded region. This region represents an arbitrary one-qubit error that may be introduced through coupling to the environment. To recover the original qubit one performs the remainder of the circuit to the right of the decoherence. (The text describes the new circuit elements.)

wanted perturbations.

In straight quantum error correction the state of a fragile quantum system is encoded into a quantum system having more degrees of freedom. By choosing the mapping to a suitable subspace of the larger system, a limited class of errors that occur on this larger space may be corrected. In Fig. 12 we see a circuit for Shor's original scheme. [Since then much work has been done in the last year (Steane, 1996, 1997a, 1997b; Calderbank and Shor, 1996; Calderbank *et al.*, 1997; Laflamme *et al.*, 1996; Knill and Laflamme, 1997; Gottesman, 1996, to cite just a few).] The unprotected single qubit $|\psi\rangle$ is processed by the left half of the circuit shown in Fig. 12 until just before the shaded region. The resulting combined nine-qubit state represents the now error-protected encoded state. Any single-qubit error (represented by the shaded region) on this encoded state may now be "undone" by sending the state through the decoding and correcting circuit shown to the right of the shaded region.

We have introduced three new circuit elements in Fig. 12, which we now explain. The first three-qubit gate involves a single control qubit (at the heavy dot) from qubit 1 to qubits 4 and 7. This gate is a shorthand notation for a pair of XOR gates (or controlled-NOT gates) between gates 1 and 4 and gates 1 and 7. The second new three-qubit gate involves two control qubits (see, for example, the last gate in the decoding circuit). This is a Toffoli gate with the condition to flip qubit 1 given by the logical AND of qubits 4 and 7 (recall that these logical operations occur separately for each branch of the wave function). (In this circuit a Toffoli gate without extraneous phases is required.) Finally, the single-qubit gate labeled $\hat{R}$ is defined by

$$\hat{R}|0\rangle = (|0\rangle + |1\rangle)/\sqrt{2}, \tag{26a}$$

$$\hat{R}|1\rangle = (|0\rangle - |1\rangle)/\sqrt{2}, \tag{26b}$$

which is a variation of the operation $\hat{U}_{-\pi/2}$ discussed earlier.

The above scheme and its variations allow for the long-term storage of quantum information. Unfortunately, they require that the encoding and decoding circuitry operate without error. Further, the above circuitry only slows the rate of decoherence, but does not eliminate its effect. By contrast, fault-tolerant quantum computation can get around these problems and, in principle, allows for unlimited quantum computation provided a threshold in accuracy for each elementary gate's operation in the presence of decoherence can be surpassed. Fault-tolerant computation involves a redesign of the error-correction and computation circuitry so as to allow for the imperfect operation of individual gates or for a decoherence event during computation. The future success of quantum computation will almost certainly rely on these techniques and upon our ability to determine theoretically, and experimentally surpass, the threshold (see Shor, 1996; DiVincenzo and Shor, 1996; Plenio *et al.*, 1997; Aharonov and Ben-Or, 1996; Steane, 1997d; Zalka, 1996; Gottesman, 1997).

13. PROSPECTS

We now describe the likely prospects for quantum computation. In this article we have discussed a single algorithm yielding an exponential speedup over conventional methods: effectively the calculation of the period of a long sequence. To date this is the only algorithm displaying such a speedup. This algorithm was applied to a traditional computer-science problem, factoring, only by recognizing a deeper structure within that problem. This requirement appears to be a general one: quantum parallelism will only yield an exponential speedup in problems whose structure avoids the need to try exponentially many solutions (Jozsa, 1991; Deutsch and Jozsa, 1992; Yao, 1993; Bennett *et al.*, 1997). Thus, a brute-force approach to some of the hardest computational questions, known as NP-complete problems, will not succeed with the aid of quantum parallelism. Any progress for such problems will require finding a deeper structure within them. Thus, it is possible that the direction the field of quantum computation will take will be along the line of simulating (or manipulating) small quantum systems (Feynman, 1982, 1986; DiVincenzo, 1995b; Lloyd, 1996). Notwithstanding the above comments, another class of algorithms for quantum computers gives more modest gains, though still sizable in comparison with the best classical algorithms. This class is based on Grover's (1996a, 1996b, 1997; Boyer *et al.*, 1996) database-searching algorithm which searches a "virtual" database for a specific entry. Unlike a classical database, a virtual database is a function that must be computed each time it is used. For searching a unique item from such a virtual database of N items, only $\pi\sqrt{N}/4$ iterations calling the virtual database are required for a close to 100% efficiency compared with only a 50% probability of success requiring $N/2$ iterations for a conventional computer. Certainly if quantum computers ever get to rival the complexity of conventional computers, the Grover algorithm will play a central role in their surpassing their rival's performance for the traditionally hard problems of computer science.

How difficult will it be to build a quantum computer? Currently, several implementations are being considered by theoreticians and experimentalists worldwide (Barenco *et al.*, 1995b; Sleator and Weinfurter, 1995; Turchette *et al.*, 1995; Monroe *et al.*, 1995; Cirac and Zoller, 1995; Pellizzari *et al.*, 1995; Lloyd, 1993; Gershenfeld and Chuang, 1997; Loss and DiVincenzo, 1997). The most promising scheme to date appears to involve linear ion traps (Monroe *et al.*, 1995; Cirac and Zoller, 1995; Pellizzari *et al.*, 1995). There are already several theoretical studies investigating the limitations to these systems, and for numerous reasons it seems that ion-trap quantum computers will be limited to computations involving no more than around 10–20 ions (Plenio and Knight, 1996a, 1996b; Hughes *et al.*, 1996; Steane, 1997c). It seems likely, then, that the first generation of quantum computers will not be performing traditional computations but will be used for the manipulation of small amounts of quantum information: a quantum information processor employed possibly for quantum cryptography, quantum teleportation, quantum storage, and quantum communication of quantum information. Indeed, these nontraditional tasks will probably lead to new types of technology, even with the relatively modest quantum computers we will be capable of building within a few years.

Over the next couple of decades we will approach computing at the atomic scale. Heat dissipation will become an ever increasing problem. The lessons from reversible classical computation and quantum computation may help us overcome this engineering hurdle and may even open doors to new faster algorithms.

GLOSSARY

Algorithmic Complexity: See **Computational Complexity**.

Computational Complexity: A measure of the complexity of a question as measured by the number of computational steps that must be performed to find the answer. The scaling relation of the number of steps required to the size of the input information described in the question is typically quoted as the associated complexity of that question (or class of questions).

Environment: Any uncontrolled external degrees of freedom.

Fault-Tolerant Computation: Computation that is robust even when a modest amount of noise is present in the logic gates performing operations and the wires connecting them.

Modular Exponentiation: The operation of taking the remainder after division by N of some number m to a power e, is called the modular exponential; it is written $m^e (\bmod N)$.

Public-Key Cryptography: A method of encoding secret information to a specific recipient who has made his/her encoding key publically known. The security of this scheme relies on the computational complexity of any attempt to invert the known encoding procedure.

Quantum Bit: See **Qubit**.

Quantum Error Correction: A scheme to "reverse" the affects of dissipation, decoherence, or dephasing due to inadvertent coupling to an environment.

Quantum Fourier Transform: A quantum mechanical analog of the discrete Fourier transform acting on a superposition of quantum states.

Qubit: Quantum bit of information; the amount of information that can be stored by a two-level quantum system.

Reversible Computer: A hypothetical computer that can actually "run" backwards, yielding its input from its output.

RSA: An accronym based on the names, Rivest, Shamir, and Adleman, of the inventors of the prototypically public-key cryptographic system.

Toffoli Gate: A specific three-bit gate that is universal for classical reversible computations.

Turing Machine: Prototypical classical universal computer using a read/write head and one or more paper tapes.

APPENDIX

Here we describe Euclid's algorithm for finding the greatest common divisor (gcd) between a pair of numbers $n_0 \geq n_1$ (Hardy and Wright 1979). The algorithm proceeds by calculating the sequence of divisions with remainder for these numbers:

$$\begin{aligned} n_0 &= d_1 \times n_1 + n_2 \\ n_1 &= d_2 \times n_2 + n_3 \\ &\vdots \\ n_{m-2} &= d_{m-1} \times n_{m-1} + n_m \\ n_{m-1} &= d_m \times n_m + 0, \end{aligned} \tag{A1}$$

where the d_m are the quotients and $n_{m-1} \geq n_m$ at each stage. The last nonzero remainder n_m yields the answer, *i.e.*, $\gcd(n_0, n_1) = n_m$. For example, the sequence

$$91 = 3 \times 28 + 7 \tag{A2a}$$

$$28 = 4 \times 7 + 0, \tag{A2b}$$

shows that $\gcd(28, 91) = 7$ in just two steps. The worst-case number of steps required to complete Euclid's algorithm is $O(\log \log n_1)$.

INTRODUCTION

Most compound semiconductors contain at least one element that consists of more than one stable isotope. Silicon, the most commonly used semiconductor, for example, is composed of the three isotopes $^{28}_{14}$Si, $^{29}_{14}$Si and $^{30}_{14}$Si with abundances of 92.23, 4.67 and 3.10%, respectively. The important compound semiconductor GaAs consists of monoisotopic $^{75}_{33}$As and two Ga isotopes $^{69}_{31}$Ga and $^{71}_{31}$Ga, with abundances of approximately 60 and 40%, respectively. The isotopic abundances are a direct consequence of the nucleosynthesis that led to the formation of the elements making up the matter in our region of the universe.

Most physical properties of semiconductor crystals depend to some degree on their isotopic composition (Berezin, 1989). While these dependences may be rather weak for many properties, they nevertheless teach us a lot about the origin of some basic physical processes occurring in a crystal and enhance our theoretical understanding. When determined with very high precision, they may establish new, rugged standards of length and mass and new, highly accurate values of Avogadro's number.

Not all isotope effects are subtle, though. For example, the room-temperature thermal conductivity of isotopically controlled diamond has been shown to change by tens of percent depending on the isotopic composition. By far the largest effects due to isotopic composition can occur after the capture of a thermal neutron by the nucleus of a specific isotope. Either the new nucleus is stable and the element remains unchanged, or it decays, transmuting into a new element. This so-called neutron-transmutation doping (NTD) is used to introduce phosphorus donors into high-purity floating-zone (FZ) silicon (Schnöller, 1974). The phosphorus atoms are created in the beta decay of $^{31}_{14}$Si, an unstable Si isotope, formed when a $^{30}_{14}$Si isotope captures a thermal neutron. The extreme homogeneity and the excellent control of the phosphorus concentration that can be achieved with NTD led to the rapid development and acceptance of NTD as a doping technique in the 1970s for Si single crystals used in the fabrication of high-power, high-voltage rectifiers and thyristors. The NTD process has in recent years been extensively applied to ultrapure Ge used in the fabrication of very low-temperature thermistors operating in the few-kelvin to millikelvin

range (Haller *et al.*, 1994). These thermal sensors work in the hopping conduction regime and require extremely homogeneous doping. They are used as single sensors or in two-dimensional arrays in terrestrial and space-borne infrared, millimeter-wave, and radio telescopes (Kreysa *et al.*, 1996; Holland *et al.*, 1996).

The natural isotopic composition of some compound semiconductor crystals in which the various isotopes are randomly distributed can be used to determine the sublattice on which certain impurities reside. Carbon impurities in gallium arsenide show localized vibrational modes (LVM) with several frequencies indicating that they occupy the As sublattice and that the two stable Ga isotopes, $^{69}_{31}$Ga and $^{71}_{31}$Ga, form nearest neighbors in several distinct combinations. If carbon were residing on the Ga sublattice, it would be surrounded by monoisotopic As neighbors forming identical surroundings. Such a configuration would produce one sharp line in the LVM spectrum. A second example, which is discussed in further detail, involves oxygen impurities in both Si and Ge single crystals. Occupying a bond-centered interstitial position, oxygen has two nearest neighbors. The atomic masses of these neighbor atoms slightly affect the various oxygen vibrational-mode frequencies, again creating the opportunity of a precise determination of the oxygen position.

The natural isotopic composition of a crystalline solid leads to a subtle state of disorder, which affects several intrinsic physical properties. For example, the thermal conductivity, which has been determined as a function of temperature for many semiconductor crystals, is rather sensitive to isotopic composition. Reduction or elimination of the isotope disorder through isotopic enrichment was used by Geballe and Hull (1958) to demonstrate experimentally the increase in the low-temperature thermal conductivity in Ge that was predicted by Pomeranchuk (1942) as early as 1942. In recent years the interest in the thermal conductivity of isotopically enriched diamond (treated in this article as a wide–band-gap semiconductor) has led to some extreme speculations. Careful experimentation and a good theoretical understanding have produced record values of thermal conductivity, which are currently only limited by the size of the diamonds and by the available experimental techniques. It is surprising that the 1% $^{13}_{6}$C in natural diamond leads to a reduction of the room-temperature thermal conductivity of 30% (Banholzer and Anthony, 1992; Anthony *et al.*, 1990) as compared with an isotopically pure diamond. At lower temperatures these effects become very much larger, as is shown in Sec. 2. Less dramatic effects are observed for the phonon dispersion relationship, the lattice constant, and the Raman frequencies and intensities, to name a few properties.

One of the main reasons why we may experience a strong increase in the scientific and technical interest in the control of the isotopic composition of semiconductors is closely related to the recent geopolitical changes. Russia and the Ukraine have a well developed isotope-enrichment industry and possess sizable quantities of certain highly enriched isotopes. Many of them are elements forming semiconductors. The availability of highly enriched isotopes at affordable costs will be required to change the attitude of semiconductor researchers and technologists towards isotopically controlled semiconductors. The availability of many different isotopes in tens-of-grams quantities, together with advanced thin-film crystal growth techniques such as molecular-beam epitaxy (MBE), is opening completely new opportunities in semiconductor research. Isotope superlattices of $^{70}_{32}$Ge and $^{74}_{32}$Ge, grown recently with the MBE technique, exhibit fascinating phonon spectra (Spitzer *et al.*, 1994). $^{69}_{31}$GaAs/$^{71}_{31}$GaAs multilayer thin-film structures have been grown for the study of Ga self-diffusion (Wang *et al.*, 1996; Tan *et al.*, 1992) in GaAs. Using the NTD technique, isotope superlattices can be selectively doped after they have been grown. The doping level may be increased in finished devices by reimmersion of the crystal in a thermal-neutron bath.

It is the aim of this article to familiarize the reader with the recent developments in semiconductor isotope engineering in the hope that this will stimulate many creative ideas for studies and structures generating new scientific results and in due time new semiconductor devices.

1. MATERIALS ASPECTS

The periodic table of elements shows that approximately 80% of all the elements consist of more than one stable isotope. The remaining elements are monoisotopic. Focusing on those elements that are of importance for semiconductors either by being a constituent of the semiconductor lattice or by acting as a neutral, shallow- or deep-level impurity, we find that nature offers an interesting and useful mixture of mono- and polyisotopic elements. As a general rule we find that the number of different stable isotopes for a given element increases with atomic number. There are important exceptions including Al, P, As, and Au, all of which are monoisotopic. Table 1 shows a selection of elements that are of importance for this article.

The information contained in the first two columns, the isotopes and their natural abundances, illustrates the very large number of isotopic compositions that can be formed, at least in principle, when we consider binary compound or ternary and quaternary alloy semiconductors. Because excessively small abundances and/or difficulties in forming molecules suitable for separation will lead to very large isotope separation costs, it will not be feasible to obtain large enough quantities to grow bulk single crystals or thin films of all these isotopes. However, certain experiments with isotopically engineered compounds have already been performed. For example, the phonon dispersion of natural-cadmium–based II–VI compounds including CdS, CdSe, and CdTe cannot be deduced with inelastic neutron scattering because of the extremely large thermal-capture cross section of ${}^{113}_{48}\mathrm{Cd}$, which occurs with an abundance of 12.22%. [This large cross section is the reason why Cd metal rods are used to control (to absorb!) the neutron flux in a nuclear reactor.] In order to circumvent this problem, Rowe *et al.* (1974) have used ^{114}CdTe single crystals to study lattice dynamics. Measurement of the phonon-dispersion relationships with inelastic neutron scattering of CdS and CdSe await the growth of crystals with negligible ^{113}Cd content.

A key question regarding broad-scale semiconductor isotope engineering must address the availability and costs of a given isotope. From extensive discussions with many experts it appears to this author that every stable isotope can in principle be separated and enriched with one or more techniques. However, it seems to be very difficult to establish realistic cost estimates, since these depend in complicated ways on the required quantity of the desirable isotope, on the existing reserves, on electricity, and on manpower costs. For small quantities of highly enriched isotopes (>90%) we find that isotopes present at tens of percent in naturally occurring elements may cost several US dollars per milligram (several million dollars per kilogram). As soon as several kilograms are produced, the costs decrease by factors of between 10 and 100. From this we conclude that isotope engineering will become feasible once a substantial demand for certain isotopes arises.

2. PHONONS AND RELATED PROPERTIES

2.1 Lattice Dynamics in Bulk Crystals

2.1.1 Phonons and Thermal Conductivity The strong coupling between neighboring atoms in a crystal together with the symmetry of the crystal lattice leads to a number of extended vibrational modes, *i.e.*, phonons, which can propagate through the solid. The simplest dependence of the phonon frequency ω on mass M can be described within the virtual-crystal approximation (VCA) (Vegard, 1921; Nordheim, 1931) by a "spring and ball" model and is given by

$$\omega \propto M^{-1/2}. \quad (1)$$

Figure 1 shows the phonon dispersion relationship for single-crystal Ge (Nilsson and Nelin, 1971). The two optical-phonon branches become degenerate at $\mathbf{k} = 0$, the center of the Brillouin zone. The energies of the phonons of the acoustical branches go to zero at this point. At the zone boundary $\mathbf{k} = (2\pi/a)(1/2, 1/2, 1/2)$ we find four different phonons, TO, LO, LA, and TA in order of descending energy. Inelastic neutron scattering allows the measurement of the energies of phonons spanning the full Brillouin zone. Optical techniques allow much simpler and highly accurate measurements at $\mathbf{k} = 0$ and $\mathbf{k} = (2\pi/a)(1/2, 1/2, 1/2)$. Raman spectroscopy, a photon-scattering process involving vanishingly small changes in $\mathbf{k}$, is ideally suited for the study of optical phonons at $\mathbf{k} = 0$. Pho-

[a] From De Laeter *et al.* (1991).
[b] From Lederer and Shirley (1978).

toluminescence (PL) studies based on the radiative decay of free excitons allow the accurate determination of zone-boundary phonons in Ge because of the particular band structure of this semiconductor (Fig. 2). The recombination of an electron at the conduction-band minimum [$\mathbf{k} = (2\pi/a)(1/2, 1/2, 1/2)$, L point] with a hole at the valence-band maximum ($\mathbf{k} = 0$, Γ point) requires the emission or absorption of a phonon to satisfy the conservation of wave vector momentum. Raman spectroscopy and PL have been used for the study of phonons in isotopically enriched and deliberately mixed germanium crystals.

Figure 3 shows superimposed Raman lines of natural and of isotopically enriched Ge single crystals recorded near liquid-nitrogen temperatures (90 K) (Fuchs *et al.*, 1992). The lines

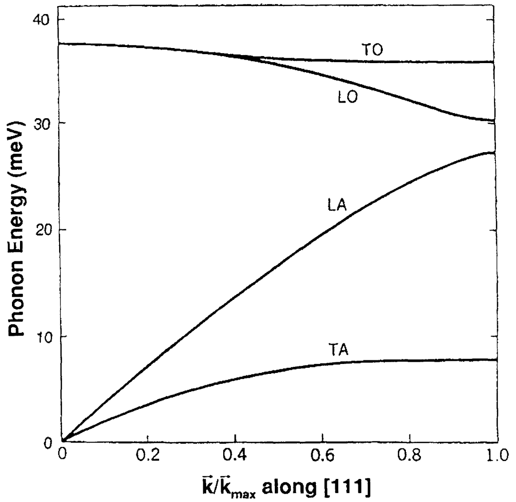

FIG. 1. Phonon dispersion relations in the [111] direction in germanium at 80 K. The two TA-phonon branches are horizontal at the zone-boundary position, ($\mathbf{k} = \pi/a$, L point). The LO and TO branches are degenerate at the center of the Brillouin zone ($\mathbf{k} = 0$, Γ point); this also is a consequence of the crystal symmetry of Ge. The results were obtained with neutron inelastic scattering. (After Nilsson and Nelin, 1971.)

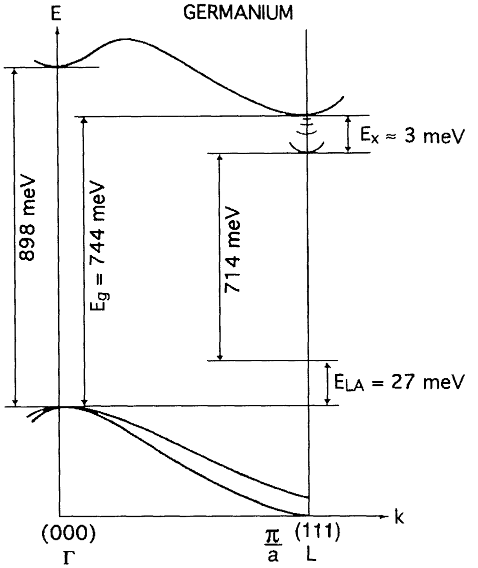

FIG. 2. Energy bands $E(\mathbf{k})$ for electrons and holes in Ge versus wave vector $\mathbf{k}$ in the $\langle 111 \rangle$ direction. The two lower lines are valence-band edges, the upper is the conduction-band edge. An electron–hole pair binds into an exciton with an energy $E_x = 3\,\text{meV}$ below the band edge; it decays by luminescence at 714 meV. The exciton decay is assisted by an LA phonon for the case shown. Other types of phonons (TA, LO, TO) can also assist exciton decay, leading to several replicas in the PL spectrum.

in these spectra are fully resolved instrumentally and their width is caused by homogeneous broadening. The centroid of the Raman line shifts following Eq. (1). What is surprising at first sight is the very weak dependence of the phonon linewidth of $\approx 1\,\text{cm}^{-1}$ on isotopic composition. The close to constant linewidth has been explained with phonon delocalization (Fuchs *et al.*, 1991a, 1991b; Etchegoin *et al.*, 1993; Cardona *et al.*, 1992, 1993), which can be discussed within the framework of Anderson localization (Anderson, 1955). If we express the relative mass fluctuations $\Delta M/\overline{M}$ in the form of a frequency bandwidth $(\Delta M/\overline{M})\omega_0 = 12\,\text{cm}^{-1}$, with ω_0 being the angular optical-phonon frequency at $\mathbf{k} = 0$, and compare it with the bandwidth of the optical phonons in the first Brillouin zone, $\Delta\omega_0 \approx 100\,\text{cm}^{-1}$, we immediately see that the mass-fluctuation bandwidth is much smaller than the intrinsic optical-phonon bandwidth. Under these circumstances phonons do not become localized on individual atoms but remain spread out over a large number of unit cells, leading to a close to perfect linear averaging of the various isotope masses.

The Raman linewidth has been shown to be due to the phonon lifetime for the anharmonic decay into two phonons. In good approximation one writes

$$\Delta\omega_0 \cdot \tau \simeq 1. \tag{2}$$

Time-resolved measurements have yielded lifetimes of 6 ps, in very good agreement with the observed $\Delta\omega_0 = 1\,\text{cm}^{-1}$ (equivalent to $3 \times 10^{10}\,\text{Hz}$) (Fuchs *et al.*, 1991a). This natural linewidth (or lifetime) is dominated by anharmonic interactions leading to the decay of an optical phonon at $\mathbf{k} = 0$ into two phonons. At the low temperature where these Raman experiments were conducted, the rate for anharmonic decay (τ^{-1}) is proportional to the amplitudes u of the two phonons created in the process:

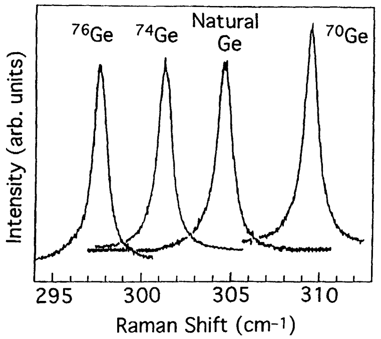

FIG. 3. Raman spectra of the optical zone-center phonons of several Ge isotopes and natural Ge at 90 K (courtesy of Fuchs *et al.*, 1992).

$$\tau^{-1} = \Delta\omega_0$$

$$\propto \langle u_1^2\rangle\langle u_2^2\rangle = \hbar^2/4M^2\omega_1\omega_2. \qquad (3)$$

Using Eq. (1), $\omega \propto M^{-1/2}$, we find

$$\Delta\omega_0 \propto M^{-1}. \qquad (4)$$

The widths of the Raman lines obtained from the four isotopically enriched Ge crystals indeed follow such a simple dependence (Fig. 4). The Raman linewidths for the crystals of natural composition and of maximum isotope disorder are slightly larger. Cardona *et al.* (1993) have shown that this extra broadening requires an anharmonic effect on the density of phonon states for three-dimensional crystals. They further showed that on going to two dimensions, isotope disorder broadening can be explained in the harmonic approximation.

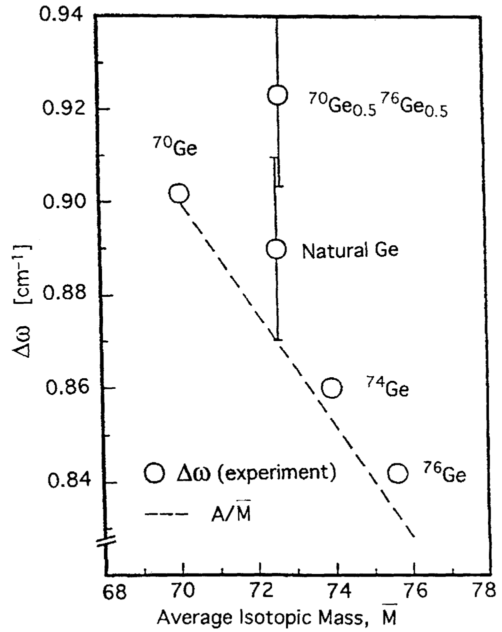

FIG. 4. Full width at half maximum of the Raman lines shown in Fig. 3 and of a ^{70}Ge$_{0.5}$/^{76}Ge$_{0.5}$ sample. The dashed line represents the M^{-1} dependence for isotopically pure samples. (Courtesy of Fuchs *et al.*, 1992.)

Photoluminescence studies of several isotopically enriched Ge crystals at low temperatures were reported by Davies *et al.* (1992, 1993, 1994) and by Etchegoin *et al.* (1992). Figure 5 shows representative luminescence spectra of highly enriched ^{70}Ge and ^{74}Ge crystals. The LA- and the TO-phonon assisted free-exciton (FE) lines are clearly shifted in energy. Excitons bound to deliberately introduced substitutional Cu acceptors generate both phonon-assisted (TA, LA, TO) and no-phonon (NP) lines. In addition one observes a sharp no-phonon line due to P donors. Whereas the phonon-assisted lines suffer energy shifts due to phonon and band-gap energy changes, the NP lines are displaced solely because of band-gap energy changes. This information allows the quantitative determination of isotope-related phonon and band-gap energy changes. After correction for the band-gap shifts, the phonon energies accurately follow the frequency dependence given in Eq. (1).

Stimulated in part by speculations regarding very large increases of the thermal conductivity in isotopically pure diamonds, a series of diamond crystal growth and characterization studies with extensive theoretical interpretation has been conducted. Using the well established multiple-scattering formalism of the coherent-potential approximation (CPA), Hass *et al.* (1991, 1992) were able to explain quantitatively the large effects of isotopic disorder on the frequencies of optical phonons at $\mathbf{k} = 0$ and for the Raman linewidths for a range of isotopic compositions. Figure 6 shows the Raman frequencies and linewidths as functions of the normalized ^{13}C concentration. Isotopic disorder causes the upwards bowing of the Raman frequency dependence as well as the large asymmetric increase in linewidth with

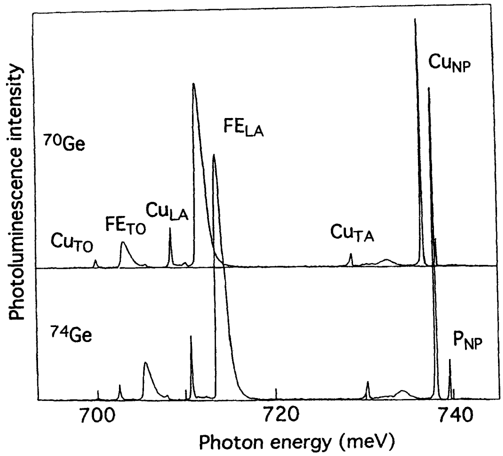

FIG. 5. Luminescence from the decay of free excitons and excitons bound to Cu acceptors and P donors in ^{70}Ge and ^{74}Ge at 4.2 K. The subscripts indicate the *L*-point phonons assisting in the exciton decay. The impurity-bound excitons can decay without emission of a phonon (NP). (Courtesy of Davies *et al.*, 1992.)

isotopic composition. Both dependences are well described with CPA theory, especially when the intrinsic linewidth of the isotopically purest samples is subtracted from all the data points.

It is interesting to note that the success in describing optical-phonon frequencies and Raman linewidths of isotopically mixed diamonds does not help in the understanding of the very strong dependence of the thermal conductivity (which depends on acoustic phonons) on small levels of isotopic disorder.

The thermal conductivity of dielectrics is given by

$$K = \tfrac{1}{3}CvL, \tag{5}$$

with C = specific heat, v = phonon velocity, and L = phonon mean free path (Ziman, 1963). Neither the velocity of low-frequency phonons nor the specific heat, which has been determined by Morelli *et al.* (1991), are predicted to change much at a 1% isotope impurity level. The large thermal-conductivity increases that are observed for diamonds with increasing isotopic purity must be due to changes in the *phonon scattering rates*. This suggestion goes again back to Pomeranchuk (1942).

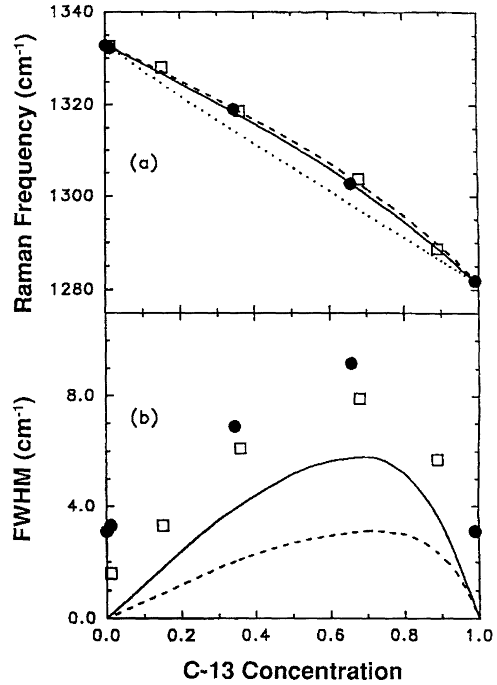

FIG. 6. Isotopic composition dependence of the diamond (a) Raman frequency and (b) linewidth (FWHM). CPA results for pure and adjusted "TPZ" models and VCA results in (a) shown as dashed, solid, and dotted lines, respectively. Open squares courtesy of Chrenko (1988); filled dots courtesy of Hass *et al.* (1992).

Wei *et al.* (1993) have measured a record thermal conductivity of 410 W cm^{-1} K^{-1} at 104 K for a 99.9% ^{12}C-enriched diamond (Fig. 7). They fitted their data with the Callaway model (Callaway, 1959), using four independent scattering processes. The functional form of the individual scattering rates were chosen as follows:

$$\tau^{-1}_{\text{normal}} = AvT^3\lambda^{-1}, \tag{6}$$

$$\tau^{-1}_{\text{Umklapp}} = BvT\lambda^{-1}\exp(-C/T), \tag{7}$$

$$\tau^{-1}_{\text{boundary}} = v/D, \tag{8}$$

$$\tau^{-1}_{\text{isotope}} = 4\pi^3 v\lambda^{-4}V_0 x(1-x)(12+x)^{-2}, \tag{9}$$

with v and λ corresponding to the average phonon velocity and wavelength, respectively;

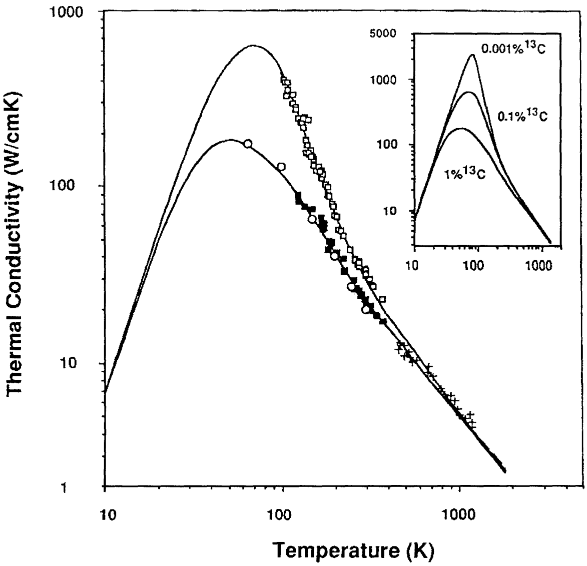

FIG. 7. Thermal conductivity of natural-abundance (1.1% ^{13}C) diamond (lower squares), isotopically enriched (0.1% ^{13}C) diamond (upper squares), together with the low-temperature data of Slack (1973) (circles) and the high-temperature data of Olson *et al.* (1993) (crosses). The solid curves are the result of fitting the Callaway theory (Callaway, 1959) to the data, using the same set of fitting parameters. Inset: The calculated thermal conductivity corresponding to 1%, 0.1%, and 0.001% ^{13}C concentrations according to the Callaway theory. (Adapted from Wei *et al.*, 1993.)

x is the isotope fraction of ^{13}C, V_0 is the atomic volume, and T is the absolute temperature. The constants A, B, C, and D were determined from the fits: $A = 7.2 \times 10^{-11}\,\text{cm}\,\text{K}^{-3}$, $B = 1.5 \times 10^{-12}\,\text{cm}\,\text{K}^{-1}$, $C = 670\,\text{K}$, and $D = 0.33\,\text{cm}$. Once the constants A through D have been determined it is possible to predict the dependence of thermal conductivity on temperature and isotopic composition. This has led to their prediction of a thermal conductivity as great as $2000\,\text{W}\,\text{cm}^{-1}\,\text{K}^{-1}$ near 80 K, exceeding Geballe's prediction (Geballe, 1990) that the thermal conductivity of pure diamond may surpass $1000\,\text{W}\,\text{cm}^{-1}\,\text{K}^{-1}$ around liquid nitrogen temperature (77 K). Similar results have very recently been reported by Olson *et al.* (1993). It should be pointed out that measurements of such extreme thermal conductivities for millimeter-size samples are extremely difficult. The samples act like close to perfect thermal short circuits.

Thermal conductivity studies have also been performed on very highly enriched, ultrapure ^{70}Ge crystals (Ozhogin *et al.*, 1996). In these 99.99% enriched single crystals the thermal conductivity exceeds the maximum values recorded by Geballe and Hull (1958) by a factor of $\gtrsim 3$. Further detailed measurements have been conducted, and an in-depth analysis has been reported recently (Asen-Palmer *et al.*, 1997).

Increased thermal conductivity in isotopically enriched semiconductors could become interesting for Si integrated circuits, for which the thermal budget is always pushed to the limit. At this point in time it is difficult to estimate if the cost increases related to increased isotopic purity can be justified by the gains in thermal conductivity.

2.1.2 Lattice Constants and Bulk Modulus

The lattice constants a_0 of large, chemically pure and crystallographically highly perfect crystals can be measured with very high precision. Because of this "naturally" occurring precision there exists an interest in using the lattice constant of a suitable crystal as a length standard (Becker, 1995). However, as a consequence of the zero-point motion the atomic volumes change with isotopic composition. The resulting effect on a_0 has been carefully studied for an enriched ^{74}Ge crystal (Buschert *et al.*, 1988) and for a series of diamonds with varying ^{12}C/^{13}C composition (Holloway *et al.*, 1991).

The theoretical treatment of the dependence of the lattice constant on isotopic composition is straightforward. Starting with the equation of state

$$P + \left[\frac{\partial F}{\partial V}\right]_T = 0, \tag{10}$$

we evaluate the Helmholtz free energy F in regard to volume (V), temperature (T) and atomic mass (M):

$$F = U_0(V) + \sum_i \left\{ \frac{1}{2}\hbar\omega_i + kT \ln\left[1 - \exp\left(\frac{-\hbar\omega_i}{kT}\right)\right]\right\}. \tag{11}$$

Here $U_0(V)$ is the binding energy of the a crystal with infinite-mass atoms, ω_i are the frequencies of the phonon modes, and k is Boltzmann's constant. The atomic mass is reflected by the inverse square-root dependence of ω on M.

For a small range of isotope masses ΔM, the equation of state yields

$$\frac{\Delta V}{V} = -\Delta M \frac{\partial^2 F/\partial V \partial M}{V \partial^2 F/\partial V^2} = -C\Delta M \frac{\partial^2 F}{\partial V \partial M}, \tag{12}$$

with C the isothermal compressibility. The above expression can now be further modified by inserting the expression for F [Eq. (11)], giving the following equation for the relative changes in the lattice constant a_0 with isotopic mass at low temperatures ($\exp[-\hbar\omega/kT] \ll 1$):

$$\frac{\Delta a}{a} = -\frac{C}{a^3}\frac{\Delta M}{M}\left(\gamma_0 \hbar\omega_0 + \frac{3}{4}\gamma_a k\theta\right), \tag{13}$$

where $\gamma_0 = 1.12$ and $\gamma_a = 0.40$ are the Grüneisen parameters for optical and acoustical phonon modes in Ge, $\theta = 374\,\mathrm{K}$ is the Debye temperature, and the optical phonon energy $\hbar\omega_0 = 37.3\,\mathrm{meV}$. Buschert *et al.* (1988) evaluated the above equation for a 95.8% enriched ^{74}Ge crystal [the same crystal that was measured by Geballe and Hull (1958)] in comparison with a natural Ge crystal. Theory, Eq. (13), predicts a 12-ppm and a 6-ppm reduction in a_0 for $T = 0\,\mathrm{K}$ and $T = 300\,\mathrm{K}$, respectively. Buschert *et al.* (1988) found experimentally reductions by 14.9 ppm and 6.3 ppm at $T = 77\,\mathrm{K}$ and at $T = 300\,\mathrm{K}$, respectively. Though this agreement between theory and experiment is considered adequate, better experimental results may be obtained today with more highly enriched crystals of at least four isotopes of Ge.

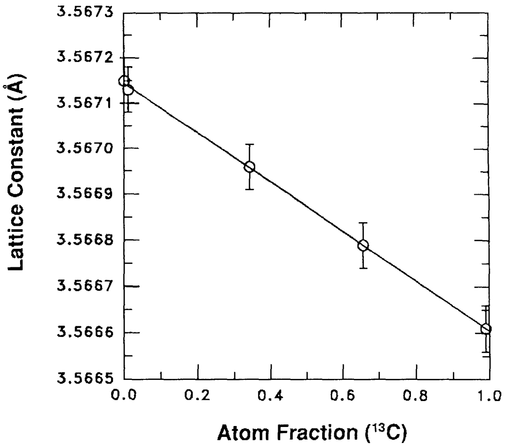

FIG. 8. Isotopic dependence of the lattice constant of diamond at 25 °C. The line is a least-squares fit to the data. (Courtesy of Holloway *et al.*, 1991.)

Similar lattice-parameter determinations have been conducted for several isotopically mixed diamonds. Figure 8 shows the experimental data obtained by Holloway *et al.* (1991). The data can be fitted by

$$a_0(T = 25\,^\circ\mathrm{C}, x) = [3.56714 - 0.00054x]\ \text{Å} \tag{14}$$

Theoretical estimates of the dependence of a_0 on isotopic composition by Collins *et al.* (1988, 1990) based on the London theory of the variation of crystal volume with isotopic substitution (Berezin and Ibrahim, 1988) are larger by a factor 1.4–3.2 than the experimental findings and have been attributed to the oversimplified assumptions made in the theory. It is unlikely that the crystalline quality of the diamonds is the cause for the discrepancy, since all the crystals exhibited x-ray rocking curves with full width at half maximum between 10 and 20 arc sec, indicating a very high degree of perfection.

The decrease in lattice constant of diamonds with increasing ^{13}C content has led to the speculation that ^{13}C diamonds may be harder than their natural counterparts (Banholzer and Anthony, 1992). In a recent study of the Brillouin and Raman scattering in natural and isotopically controlled diamond, Vogelgesang *et al.* (1996) explored the effects of zero-point motion and the anharmonicity of the lattice vibrations. On the basis of a valence-force model explicitly incorporating the isotopic composition, they predicted the isotopic mass dependence of the elastic moduli deduced from Brillouin spectra, of the zone center optical mode frequency, and of the lattice constant. On the basis of the anharmonicity parameter, deduced from a comparison of the theory with the experimentally reported dependence of the lattice constant discussed above, they predicted that the bulk modulus of ^{13}C diamond should exceed that for ^{12}C diamond by one part in 10^3, just below the sensitivity of their high-precision Brillouin-scattering experiment. The predicted increase in the bulk modulus of ^{13}C diamond, if confirmed, would imply that it is the hardest terrestrial material [Ramdas *et al.*, (1993)]. Such diamonds would also represent solids with the highest atomic density.

2.1.3 Band Gaps The width and the character (direct or indirect) of the lowest-energy band gap is of paramount importance for a large number of semiconductor properties and in turn for all semiconductor devices. Because of this great significance there exists a strong interest in all effects that influence the band structure.

The isotopic composition affects the band gaps through the electron–phonon coupling and through the change of volume with isotopic mass. Several groups have conducted low-temperature studies of the direct and indirect band gaps of natural and isotopically controlled Ge single crystals. Agekyan *et al.* (1989) used photoluminescence, infrared absorption, and Raman spectroscopy with a Ge crystal of natural composition and a crystal with 85% ^{76}Ge and 15% ^{74}Ge. They found an indirect–band-gap change of $\Delta E_G = 0.09$ meV and a direct–band-gap change of $\Delta E_G = 1.25$ meV with an error of ±0.05 meV. Etchegoin *et al.* (1992) and Davies *et al.* (1992, 1994) reported PL studies of natural and several highly enriched, high-quality single crystals of Ge. Measurement of the energies of impurity-bound excitons shown in Fig. 5 permits the direct determination of band-gap shifts with the crystal isotope mass because the radiative recombination does not require phonon participation. Figure 9 shows the no-phonon energies of excitons E_{NP} bound to P and Cu in several isotopically controlled crystals. As may be expected from the very large Bohr orbits of the excitons, their binding energy only depends on the average isotope mass and not on the isotopic disorder. The rate of band-gap energy change, which is equal to the exciton binding-energy change, with isotope mass as determined by Davies *et al.* (1992, 1994) is

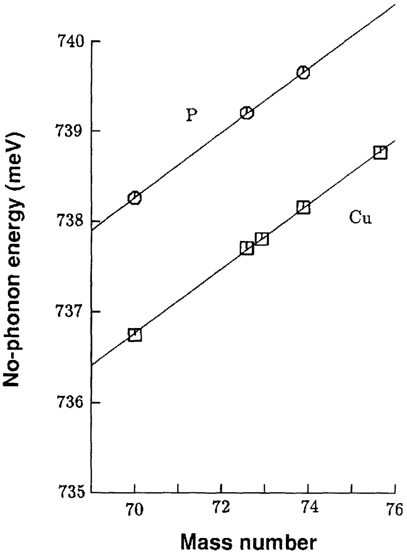

FIG. 9. Energies of the no-phonon lines of excitons bound to Cu acceptors (squares) and P donors (circles) (courtesy of Davies *et al.*, 1992; Davies, 1994).

$$\frac{dE_{IG}}{dA} = \frac{dE_{NP}}{dA} = 0.35 \pm 0.02\,\mathrm{meV\,u^{-1}}. \tag{15}$$

Etchegoin *et al.* (1992) obtained a very similar value.

The contribution to the band-gap shift originating in the volume change can be estimated using the results of Buschert *et al.* (1988) for lattice-constant change with isotope mass and the published dependence of E_{IG} with volume (Schmid *et al.*, 1990). One finds

$$\left.\frac{dE_{IG}}{dA}\right|_{vol} = 0.132\,\mathrm{meV\,u^{-1}}. \tag{16}$$

This is the smaller contribution to the experimentally determined energy-gap change with isotope mass. It is in reasonable agreement with the earlier estimates of Agekyan *et al.* (1989).

The main contribution to $\mathrm{d}E/\mathrm{d}A$ can be directly related to the change of the energy gap with temperature. This change is described by structure factors that contain electron–phonon interaction terms (Debye–Waller factors) and self-energy terms. For practical calculations these terms are expanded in a power series of the atomic displacements. The leading terms are proportional to the mean square displacements $\langle u^2\rangle$ of each atom. Describing the lattice atoms in terms of harmonic oscillators, we find

$$\langle u^2\rangle = \hbar\left(\tfrac{1}{2}+n\right)/M\omega. \tag{17}$$

With increasing temperature both n and $\langle u^2\rangle$ increase, leading to the observed reduction of the energy gap. At low temperature, $n = 0$ and we only deal with the zero-point oscillation. Combining the dependence of ω on M with the above equation we find

$$\langle u^2\rangle \propto 1/\sqrt{M}. \tag{18}$$

Zollner *et al.* (1992) have performed a numerical calculation of the electronic bands using an empirical pseudopotential method including the necessary lattice dynamics. They find for Ge $(\mathrm{d}E_{\mathrm{IG}}/\mathrm{d}A)_{\text{e-p}} = 0.41\,\mathrm{meV}$. The total calculated shift of the indirect band-gap energy with isotope mass adds up to $(\mathrm{d}E_{\mathrm{IG}}/\mathrm{d}A)_{\mathrm{total}} = 0.48\,\mathrm{meV}$. This result compares favorably with the experimental values stated above by Davies *et al.* (1992, 1994), and by Etchegoin *et al.* (1992) who reported $(\mathrm{d}E_{\mathrm{IG}}/\mathrm{d}A)_{\mathrm{total}} = 0.37 \pm 0.01\,\mathrm{meV\,u^{-1}}$.

Measurements of the direct band gap at the Γ point ($\mathbf{k} = 0$) in the Brillouin zone have also been performed. Though the direct band gap is technologically less important than the minimum indirect band gap, determining the dependence of this gap on isotope mass is of the same fundamental significance as the indirect-band-gap studies. Davies *et al.* (1993) used low-temperature optical-absorption measurements on very thin samples of Ge single crystals with natural composition and of three different, highly enriched isotopes. They found

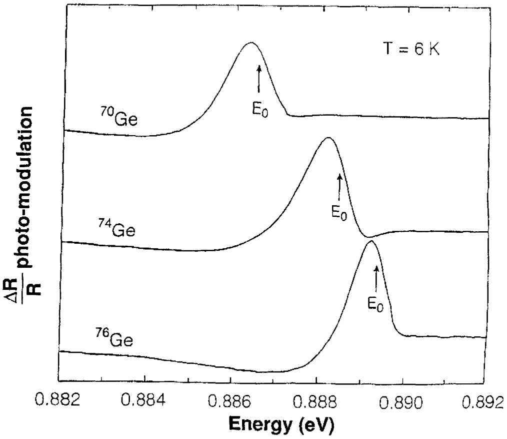

FIG. 10. Photomodulated reflectivity showing the direct band gap of single crystals of ^{70}Ge, ^{74}Ge, and ^{76}Ge at $T = 6\,\mathrm{K}$ (courtesy of Parks *et al.*, 1994).

$$\frac{\mathrm{d}E}{\mathrm{d}A} = 0.49 \pm 0.03\,\mathrm{meV\,u^{-1}} \tag{19}$$

for the temperature extrapolated to zero. Parks *et al.* (1994) have used piezo- and photomodulated reflectivity spectra of four monoisotopic and one natural Ge crystals. These techniques do not require the extreme sample thinning that is necessary for optical-absorption measurements, and the derivative nature of the spectra emphasizes the small changes. Figure 10 shows the photomodulated reflectivity of three monoisotopic Ge crystals at $T = 6\,\mathrm{K}$. The position of the direct energy gap M is indicated by an arrow marked E_0. The excellent signal-to-noise ratio and the superb spectral resolution allow a very accurate determination of the dependence of E_{DG} on isotopic mass. At very low temperatures an inverse square-root dependence accurately describes band-gap dependence:

$$E_{\mathrm{DG}} = E_{\mathrm{DG}}^{\infty} + C/\sqrt{M}. \tag{20}$$

A fit through five data points yields $E_{\mathrm{DG}}^{\infty} = 959\,\mathrm{meV}$ and $C = -606\,\mathrm{meV\,u^{1/2}}$. Written as a linear dependence for the small range of isotopic masses, Parks *et al.* (1994) find

$dE_{DG}/dA = 0.49\,\mathrm{meV\,u^{-1}}$, in perfect agreement with the results of Davies *et al.* (1993). Parks *et al.* (1994) also determined the isotope mass dependence of the sum of the direct gap and the split-off valence band (Δ_0) and found $d(E_{DG} + \Delta_0)/dA = 0.74\,\mathrm{meV\,u^{-1}}$.

The experimental results can be compared with Zollner *et al.*'s calculations (1992), which are found to be of the correct order of magnitude. The theoretical estimates for the contribution of the linear isotope shift of the minimum indirect gaps, which are caused by electron–phonon interaction, are too large by a factor of ≈1.7, and for the smallest direct gap they are too large by a factor ≈3.2.

We conclude this discussion of the bandgap shifts with isotope mass by observing that the effects are exceedingly small and most likely will not have any consequences for Ge nor any other semiconductors for technological applications. However, this exercise is an excellent demonstration of the advanced state of our quantitative theoretical understanding of the subtle effects of temperature, pressure, and isotope mass on the electronic band structure.

2.2 Isotope Superlattices

The discussion of phonons, their dispersion, and the dependence of their properties on the isotopic composition of the host crystal has so far been restricted to bulk crystals, crystals sufficiently large so as not to affect phonon properties. What do we expect when the dimensions of the crystal are significantly reduced? This is the focus of the discussion of the fascinating features shown by short-period isotope superlattices consisting of layers each made up of a few atomic planes of ^{A}Ge and ^{B}Ge. These are ideal structures for phonon studies because the electronic band structure is not significantly affected by the isotope superlattice, *i.e.*, the material looks bulklike for electrons throughout the crystal layers. In superlattices with very significant periodic band-structure discontinuities and large changes in host atom masses (*e.g.*, AlGaAs/GaAs), it is impossible to perform phonon studies using Raman spectroscopy.

The first problem to be addressed relates to the normal phonon modes of a short-period isotope superlattice. The vibrational modes and the phonon dispersion relation for a $^{70}\mathrm{Ge}_4/^{76}\mathrm{Ge}_4$ [001] superlattice at $\mathbf{k} = 0$ were calculated using the planar force-constant model (Fuchs *et al.*, 1993). These theoretical results were tested with Raman studies of a series of MBE-grown, short-period isotope superlattices of ^{70}Ge and ^{74}Ge (Spitzer *et al.*, 1994). The experimental and theoretical results are summarized in Fig. 11. The shortest periods studied consisted of two atomic layers each and produce a single Raman line corresponding to the zone-center optical phonon in a Ge crystal with isotope mass $A = 72$, the linear average of the two masses. The experts who grew this superlattice are quite certain that this result is not due to intermixing of more than one atomic layer during growth because they used very low growth temperatures ($T = 350\,°\mathrm{C}$) and low growth rates ($4\,\mathrm{Å\,min^{-1}}$). The $n = 4$ superlattice shows the Raman line predicted at $\approx 290\,\mathrm{cm^{-1}}$, though at a slightly lower intensity. In the $n = 12$ superlattice we observe at least three strong Raman lines. For $n = 32$ the Raman spectra begin to approach the structure we would expect to observe for two isotopically pure bulk crystals, one made up of ^{70}Ge, the other of ^{74}Ge.

These first Raman spectroscopy studies of isotope superlattices demonstrate Brillouin-zone folding in a very pure form. The relative intensities of the Raman lines reflect the densities of states at $\mathbf{k} = 0$. It is quite impressive how well the experimental data are reproduced by the planar bond-charge and bond-polarizability models. For layers thicker than approximately 30 atomic planes we observe close to perfect localization in the individual layers, *i.e.*, bulklike behavior.

3. LOCAL VIBRATIONAL-MODE SPECTROSCOPY

Local vibrational-mode (LVM) spectroscopy is a well established research tool for the study of impurities and impurity complexes in semiconductors (Barker and Sievers, 1975; Newman, 1973; Spitzer, 1971; Haller, 1995). A very large body of information on static and dynamic structural information has been ac-

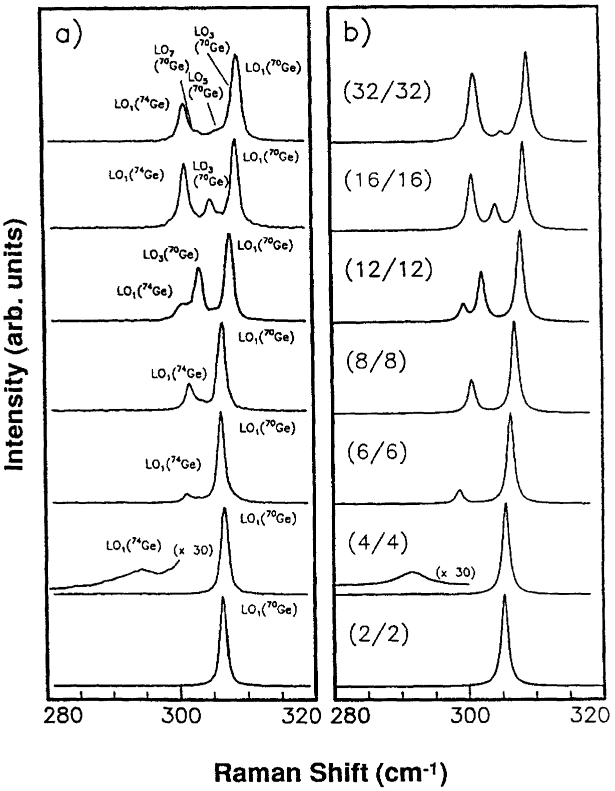

FIG. 11. (a) Measured at $T = 10\,\text{K}$ and (b) calculated Raman spectra for a series of isotope superlattices $^{70}\text{Ge}_n/^{74}\text{Ge}_n$ grown along [001] with $n = 2, 4, 6, 8, 12, 16$ and 32. A number of modes confined to the ^{70}Ge and ^{74}Ge layers are evident. (Courtesy of Spitzer *et al.*, 1994.)

cumulated using LVM spectroscopy. In general LVM studies are performed on impurities that have a mass lower than the average mass of the host-lattice atoms. Depending on the details of the lattice location of the impurity, particularly on symmetry and on how many bonds are formed with host-lattice atoms, one observes a number of normal vibrational modes with well defined frequencies above the vibrational spectrum of the host lattice. In order to obtain a crude understanding of an LVM spectrum, it usually suffices to model the impurity and the nearest bound neighbors as a quasimolecule imbedded in the host crystal. The number of normal modes of this molecule, their frequencies, and even their intensity ratios can be extracted with limited accuracy from such a simple approach. The model can be improved substantially by taking into account next-nearest neighbor atoms in the form of an additional mass correction, the "host interaction mass" and by extending the linear force dependence on impurity displacement with higher terms (anharmonicity).

Because of the simple dependence of vibrational frequencies on the inverse square root of the vibrating mass,

$$\nu_1/\nu_2 = \sqrt{M_2/M_1}, \tag{21}$$

isotope substitutions have already been used since the earliest studies to obtain unambiguous proof for the association of an LVM feature with a certain impurity. The largest isotope shift caused by such a substitution of stable isotopes is close to 40% and is obtained with hydrogen and deuterium. Extensive use of this particular isotope substitution has been made in recent years by a large number of investigators studying the very many properties exhibited by hydrogen in crystalline semiconductors (Haller, 1978; Stavola *et al.*, 1988; Watkins *et al.*, 1990; Denteneer *et al.*, 1989; McMurray *et al.*, 1987; Hoffman *et al.*, 1992; McCluskey *et al.*, 1995, 1996; Götz *et al.*, 1996).

Hydrogen-related studies are not the only ones that have profited from LVM spectroscopy and isotopic substitution. A large number of impurities in many semiconductors have been investigated. Whenever available, isotopes have been used to help identify LVM lines. Newman (1993) has written a comprehensive review of LVM studies of defects in III–V compounds.

What then can isotope engineering contribute to this already highly successful characterization technique? One group of studies that can profit concerns LVM spectroscopy of impurities and impurity complexes in semiconductors that are naturally composed of several stable isotopes with some of these present at significant atomic fractions. LVM spectra of impurities in such crystals are usually composed of many closely spaced or overlapping lines because the impurity and its host lattice neighbors form quasimolecules with a number of different reduced masses (Sciacca *et al.*, 1996). Isotope enrichment of the host material can lead to drastic simplification of the LVM spectra in such cases.

In order to give an illustration of the effect of isotope enrichment on spectral complexity we want to review briefly the LVM structure of O in natural and isotopically controlled Ge. To model the LVM of this bond-centered impurity one takes into account the two nearest neighbors, while the rest of the lattice appears as a small correction, called interaction mass. The ^{x}Ge–O–^{y}Ge molecule has three fundamental modes. The "wag" mode (ν_3) has the highest frequency and was observed in oxygen-rich Ge quite some time ago (Kaiser *et al.*, 1956). High-resolution studies show 11 lines, each one split into several components whose intensities depend on temperature. The 11 lines result from the different mass combinations of ^{x}Ge and ^{y}Ge. Combinations with identical linear mass averages (*e.g.*, ^{72}Ge/^{74}Ge and ^{73}Ge/^{73}Ge) lead to almost the same oxygen vibrational frequencies.

The complexity of such spectra can be reduced very significantly through the use of isotopically pure (or at least highly enriched) crystals. Figure 12 shows two spectra that were reported by Mayur *et al.* (1994). They used one natural and four highly enriched Ge crystals doped with oxygen. The reduction from 11 to one LVM line is significant because it allows a quantitative study of the linewidth and of the coupling between ν_3 and the other modes as a function of temperature. The splitting is a result of the nonlinear superposition of the ν_2 and the ν_3 modes. The low-frequency ν_2 modes can already be thermally populated near to the temperature of liquid helium.

The vibrational modes of carbon impurities on As sites in GaAs represent a similar physical system. C_{As} vibrations are modeled with an X_4Y molecule with two different masses for X. Experimentally one has resolved five very closely spaced lines (Theis and Bajaj, 1982; Theis *et al.*, 1983) of the nine lines predicted by theory (Leigh and Newman, 1982). Even though the experimental findings are in good agreement with theory, it would be instructive to see what happens when only one Ga isotope is present in an isotopically pure GaAs crystal. One extremely sharp line of a triply degenerate mode should be observed.

4. DIFFUSION

One of the most fundamental processes characterizing all matter is the random motion of its atomic constituents. In semiconductors much has been learned in recent years about the motion of host and impurity atoms as well as native defects such as vacancies and interstitials. A number of comprehensive review papers on this subject have been written (Gösele, 1989, 1994; Frank *et al.*, 1984; Tan *et al.*, 1991; Hu, 1992; Chen *et al.*, 1994; Shaw, 1988; Palfrey, 1989). When a concentration gradient $\mathrm{d}N/\mathrm{d}x$ is introduced, random motion leads to a net flux of matter J, which is proportional to the concentration gradient:

$$J = -D\frac{\mathrm{d}N}{\mathrm{d}x}. \tag{22}$$

The diffusion coefficient D, in many (though not in all) cases, can be described by a thermally activated constant

$$D = D_0 \exp(-E/kT). \tag{23}$$

Impurity diffusion in semiconductors plays a

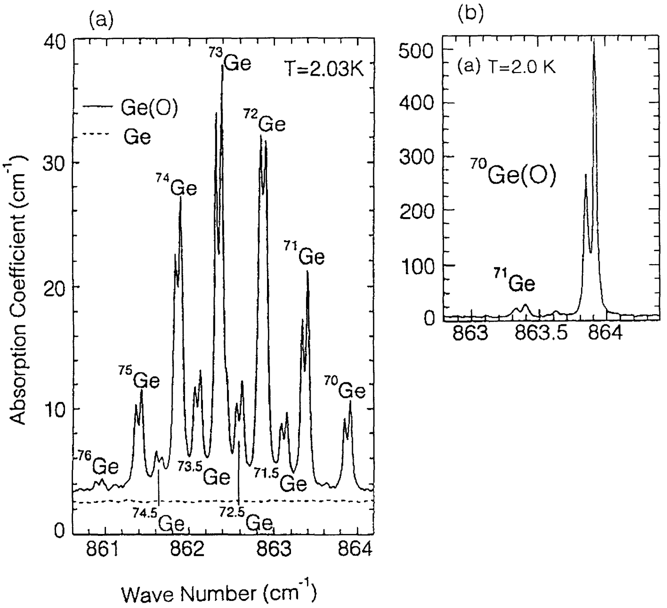

FIG. 12. (a) Spectrum of the Ge_2O quasimolecules in natural Ge at 2.05 K. Eleven lines split by $\nu_2 + \nu_3$ coupling excitations correspond to the distinct isotopic mass combinations of the two Ge atoms in the quasimolecule. An oxygen-free sample produced the dashed line. (b) The spectrum of an oxygen-doped, highly enriched sample of ^{70}Ge. The lines labeled ^{71}Ge are caused by traces of ^{72}Ge in ^{70}Ge. (Courtesy of Mayur *et al.*, 1994.)

key role in the fabrication of electronic devices. By way of example, diffusion can be utilized as a desirable process enabling the introduction of dopant impurities into areas defined by a mask on a semiconductor wafer. Diffusion can act also as a detrimental process, broadening narrow impurity implantation profiles or admitting rapidly diffusing, undesirable impurities. There exists a very extensive literature on diffusion studies for most semiconductors. The field is extremely active, especially for the semiconductors which have become important recently for high-temperature electronics (*e.g.*, SiC) and light-emitting devices working in the green and blue range of the visible spectrum (*e.g.*, ZnSe, GaN).

An impressive body of experimental and theoretical work on Si has accumulated over the past 30 years. A major advance was made in the late 1960s and early 1970s when electron-microscopy observations of A-type swirl defects in dislocation-free Si confirmed the theoretical prediction that Si interstitials are present in addition to vacancies at high temperatures. It took many years before it became generally accepted that both interstitials and vacancies were the native defects assisting self- and impurity diffusion in Si. A series of metal diffusion experiments, which started with Au and were later extended to Pt and most recently to Zn (Bracht *et al.*, 1995), eventually convinced the most critical experts of the coexistence of interstitials and vacancies in Si at high temperatures. Au is especially suitable to explore the role of Si interstitials because it diffuses via the so-called "kick-out" mechanism. Interstitials arriving at Au on substitutional sites (Au_s) exchange their place and form a highly mobile Au interstitial species (Au_i). The process reverses at a new location returning a Au_s. Au_s concentration profiles after diffusion from a surface source into a Si wafer exhibit a shape that is very characteristic for the kick-out process and allow the determination of the equilibrium concentrations of interstitials (C_I^{eq}) and vacancies (C_V^{eq}) as well as the individual equilibrium diffusion coefficients (D_I^{eq}, D_V^{eq}) at the diffusion temperature.

Despite progress in recent years, significant errors remain, and the large disparities between the values reported by numerous authors (Gösele, 1989; 1994; Frank *et al.*, 1984; Tan and Gösele, 1985; Willoughby, 1994; Zimmermann and Ryssel, 1992) illustrate the limited state of our knowledge of self-diffusion in Si. Diffusion in compound semiconductors and their alloys as well as impurity diffusion adds considerable further complexities to the problem leading to even greater uncertainties.

Isotope control is expected to be able to contribute with new experimental approaches to the study of diffusion and hopefully can help in improving our understanding of the many interacting factors. Tan *et al.* (1992) were the first to make use of a GaAs isotope superlattice to study Ga self-diffusion. Their basic idea was to grow a superlattice consisting of approximately 1000-Å thick, undoped layers of ^{69}GaAs and ^{71}GaAs. Only ^{69}Ga/^{71}Ga interdiffusion can be studied because As is monoisotopic. Because the isotopically pure layers were grown on a Si-doped substrate, the Ga self-diffusivity may have been affected and may not reflect the intrinsic Ga self-diffusivity in GaAs. Wang *et al.* (1996) have designed and executed a new experiment on Ga self-diffusion in GaAs using undoped, semi-insulating substrates with undoped 2000 Å isotopically enriched ^{69}GaAs and ^{71}GaAs layers. Instead of capping layers, which can introduce strain and impurities, individual samples were annealed in ampoules with very tight As ambient control. This allowed the determination of the Ga diffusion constant over six orders of magnitude. All the data points lie on one straight line in the Arrhenius plot shown in Fig. 13. A best fit leads to

$$D = (43 \pm 25)\exp[(-4.24 \pm 0.06\,\mathrm{eV})/k_{\mathrm{B}}T], \tag{24}$$

using for the pre-exponential factor the expression

$$\mathrm{D}_0 = ga^2\nu_0\exp(S^{\mathrm{SD}}/k_{\mathrm{B}}) \tag{25}$$

where g is a geometric factor, a is the lattice constant, ν_0 is the highest vibrational mode frequency, S^{SD} is the self-diffusion entropy, and k_{B} is Boltzmann's constant.

Assuming $g \simeq 1$, Wang *et al.* (1996) found a Ga self-diffusion entropy value $S^{\mathrm{SD}} = 8k_{\mathrm{B}}$. Recent molecular-dynamics calculations confirm this value as well as the activation energy to within a few percent (Bockstedte and Scheffler, 1996). This exceptionally good agreement may be a sign that diffusion experiments and theory begin to measure and describe the proper diffusion physics, at least for these well defined conditions.

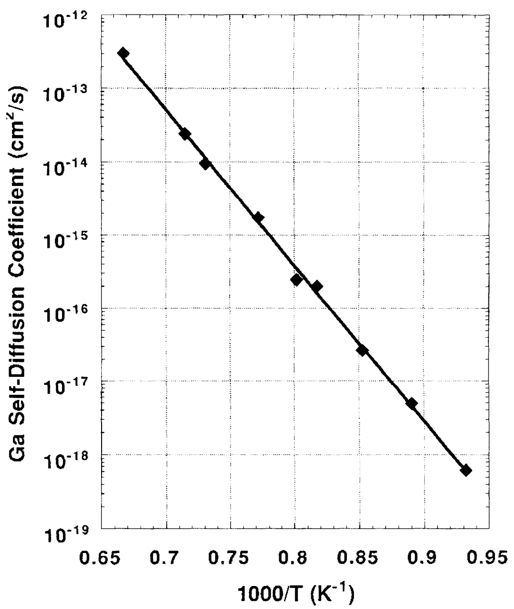

FIG. 13. Arrhenius plot of the Ga self-diffusion coefficient in GaAs determined with ^{69}Ga/^{71}Ga isotope interdiffusion (adapted from Wang *et al.*, 1996).

Very recently the same type of experiment has been performed for GaP (Wang *et al.*, 1977). The activation energy for Ga self-diffusion in this semiconductor is very similar to that in GaAs but the entropy is only $4k_{\mathrm{B}}$. These results await a detailed theoretical evaluation.

In order to test the new approach to self-diffusion studies based on isotopically controlled multilayer structures with a well understood system, the Ge self-diffusion coefficient has been determined with bilayers of ^{70}Ge and ^{74}Ge (each 1000 or 2000 Å thick) which were grown by MBE on a natural Ge substrate (Fuchs *et al.*, 1995). Disregarding the small differences in diffusivity caused by different isotope masses, (Campbell, 1975), we expect the Ge isotopes to diffuse symmetrically into each other following complementary error functions. Figure 14 shows SIMS results for the as-grown sample and for the sample diffused at 586 °C for 55.55 h. Because the isotopes are only enriched into the high 90 percentile range, we obtain SIMS data from some of the residual minor Ge isotopes. This redundancy in data is very useful in the deconvolution of the SIMS instrument function and in

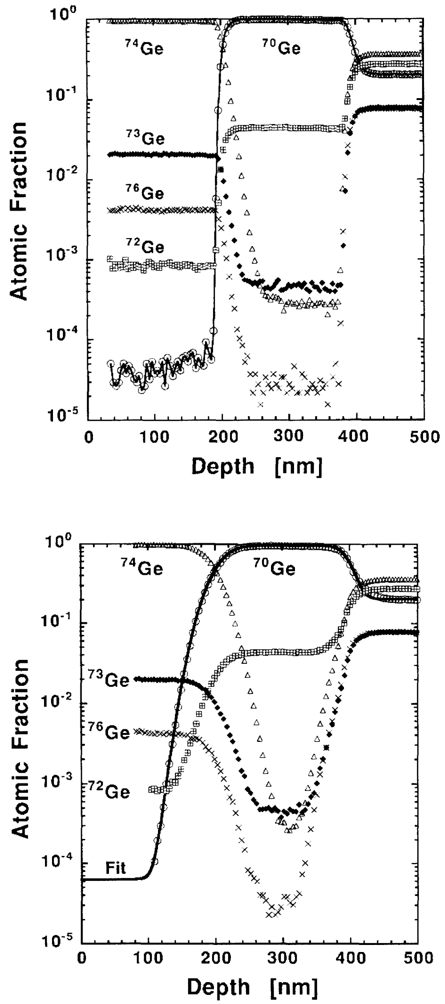

FIG. 14. Experimental concentration–depth profiles obtained with SIMS of the atomic fractions of ^{70}Ge, ^{72}Ge, ^{73}Ge, ^{74}Ge and ^{76}Ge of a ^{74}Ge/^{70}Ge bilayer (top) on a natural Ge substrate of the as-grown sample and (bottom) after annealing at 586°C for 55.55 h. The solid line is a fit to the ^{70}Ge profile. (Courtesy of Fuchs *et al.*, 1995.)

improving the accuracy of the data. The results for the Ge self-diffusivity are in excellent agreement with the earlier results (Vogel *et al.*, 1983; Werner *et al.*, 1983).

Summarizing the opportunities offered by internal isotope interfaces and multilayer structures for diffusion, we can make the following observations. First, the combination of isotope multilayers and SIMS makes studies with radioactive tracers obsolete. This happens at a convenient time when numerous regulations for laboratory work are making the use of any radioactive substance at least tedious but sometimes even impossible. Second, we can study diffusion at buried interfaces, away from surfaces, which always influence the intrinsic point-defect concentrations, the drivers for most diffusion processes. Third, the redundancy in data obtained from the major and the minor isotopes helps in obtaining improved data. Fourth, we foresee self- and impurity diffusion studies with doped isotope multilayers and SIMS. The case of superlattices selectively doped with NTD appears especially attractive (see Sec. 5). Heavily doped layers can be created between undoped ones with NTD, allowing the simultaneous observation of self- and impurity-diffusion. A Si superlattice consisting of alternating layers of undoped ^{28}Si and ^{30}Si represents such a case. Self-diffusion studies could be performed with the as-grown layers. NTD can be used to dope the ^{30}Si layers n-type with different P concentrations. Diffusion followed by SIMS analysis will generate one consistent and complete set of data, especially when the P concentration is chosen sufficiently high so as to exceed the SIMS sensitivity limit. Si self-diffusion studies using isotope heterostructures have been conducted recently by Bracht *et al.* (1998).

5. NEUTRON TRANSMUTATION DOPING (NTD) AND ELECTRONIC TRANSPORT STUDIES

5.1 Bulk Crystals

Compared with the relatively subtle effects generated by small isotope mass differences on a number of physical properties, some of which we have discussed, the consequences of thermal-neutron absorption by the various isotopes of a given element can be quite spectacular. Table 1 is a selective list of isotopes that are relevant to semiconductor science and technology. Every nucleus has a finite cross section for thermal neutron capture because neutrons carry no electrical charge and can reach the vicinity of a nucleus, where they experience the strong force that binds nuclei together.

Table 2. NTD Ge thermistor data (Fig. 15).

NTD No.	n Dose (cm^{-2})	N_{Ga} (cm^{-3})	N_{As} (cm^{-3})	N_{Se} (cm^{-3})	$N_{\mathrm{Ga}} - \sum N_{\mathrm{D}}$ (cm^{-3})
4	3.38×10^{17}	9.94×10^{15}	2.83×10^{15}	1.86×10^{14}	6.74×10^{15}
5	7.50×10^{17}	2.21×10^{16}	6.29×10^{15}	4.13×10^{14}	1.50×10^{16}
13	1.24×10^{18}	3.65×10^{16}	1.04×10^{16}	6.83×10^{14}	2.47×10^{16}
15	1.54×10^{18}	4.53×10^{16}	1.29×10^{16}	8.49×10^{14}	3.07×10^{16}
16	2.07×10^{18}	6.09×10^{16}	1.73×10^{16}	1.14×10^{15}	4.13×10^{16}
18	2.61×10^{18}	7.67×10^{16}	2.19×10^{16}	1.44×10^{15}	5.20×10^{16}
26	2.82×10^{18}	8.29×10^{16}	2.36×10^{16}	1.55×10^{15}	5.62×10^{16}
28	3.07×10^{18}	9.03×10^{16}	2.57×10^{16}	1.69×10^{15}	6.11×10^{16}
12	3.33×10^{18}	9.79×10^{16}	2.79×10^{16}	1.83×10^{15}	6.64×10^{16}
25	4.20×10^{18}	1.23×10^{17}	3.52×10^{16}	2.31×10^{15}	8.37×10^{16}

Neutron transmutation is especially intriguing for semiconductors because it can lead to doping (Lark-Horowitz, 1951; Larrabee, 1984; Fritzsche and Cuevas, 1960; Haller *et al.*, 1984). For example, P donors are formed in Si through the following NTD reaction:

$$^{30}_{14}\mathrm{Si} + \mathrm{n} \rightarrow ^{31}_{14}\mathrm{Si} \xrightarrow{T_{1/2}=2.62\,\mathrm{h}} ^{31}_{15}\mathrm{P} + \beta^{-} + \bar{\nu}_e \qquad (26)$$

The β^{-} is an electron of nuclear origin, and it shares the total energy of the reaction with an electronic antineutrino. These two particles are leptons and in nuclear reactions the sum of the leptons is conserved.

The P concentration is proportional to the concentration of $^{30}_{14}\mathrm{Si}$ (3.1% of the natural Si), the integrated thermal neutron flux n, and the thermal neutron capture cross section σ_{n}:

$$[\mathrm{P}] = \sigma_{\mathrm{n}}[^{30}_{14}\mathrm{Si}]\, n \qquad (27)$$

The major advantage of NTD is the extreme doping uniformity achieved. This is due to three factors. First, the $^{30}_{14}\mathrm{Si}$ isotopes are ideally randomly distributed in Si crystals; second, the thermal-neutron cross-sections are so small that several centimeters of Si will absorb an insignificant fraction of the thermal neutrons; and third, the thermal-neutron field is very much larger than any Si crystal produced today, which, in turn, guarantees a homogeneous flux. Disadvantages include radiation damage caused by residual fast neutrons and, in the specific case of natural Si, the small fraction of $^{30}_{14}\mathrm{Si}$. The latter disadvantage could be minimized with $^{30}_{14}\mathrm{Si}$ enrichment. A pure $^{30}_{14}\mathrm{Si}$ crystal would have an over 30 times faster transmutation rate than a natural Si crystal! The fast-neutron exposure and the concentration of deep levels would be reduced accordingly. Again cost-benefit issues will have to be resolved before any large-scale $^{30}_{14}\mathrm{Si}$ enrichment will become economically feasible.

The first NTD of Si used in the fabrication of high-voltage, high-power devices was reported in 1974 by Schnöller (1974). Since that time NTD has matured into a well controlled technology (Larrabee, 1984), and most high-power rectifiers and thyristors are fabricated from floating-zone Si doped with the NTD process.

Natural Ge contains five stable isotopes, three of which transmute into dopants after thermal-neutron capture (see Table 1). Fritzsche and Cuevas (1960) have used NTD of Ge for their electronic transport studies. In 1982 Haller *et al.* (1984) began doping ultrapure Ge with NTD to obtain crystals with a wide range of dopant concentrations for use in low-temperature sensors. The acceptor and donor concentrations are sufficiently high (Table 2) to lead to thermally assisted hopping conduction (Shklovskii and Efros, 1984) in the kelvin and millikelvin temperature range (Fig. 15). This material is now widely used for the fabrication of extremely sensitive low-temperature thermal detectors, also called thermistors (Haller, 1994; Haller *et al.* 1994). These thermistors are used as far-infrared photon detectors in a wide variety of laboratory instruments and in focal planes of terrestrial and balloon- and space-borne telescopes for far-infrared and millimeter- and radio-wave observations of sources in the universe. Currently there is a well focused worldwide effort under way to develop large thermistor arrays oper-

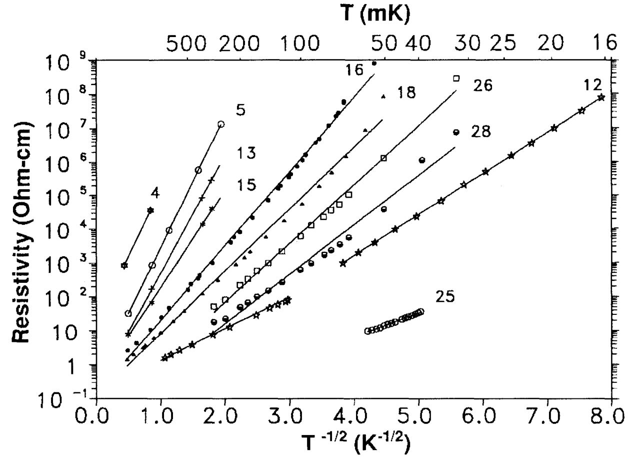

FIG. 15. Resistivity as a function of $T^{-1/2}$ for a number of NTD natural Ge samples. Hopping conduction is dominant and the simple dependence $\rho = \rho_0 \exp(T_0/T)^{-1/2}$ holds over nine orders of magnitude. Table 2 contains neutron fluences and dopant concentrations for the various samples. (Haller *et al.*, 1994.)

ating at subkelvin temperatures (Kreysa *et al.*, 1996; Holland *et al.*, 1996). This interest is a direct consequence of the spectacular successes already achieved with small NTD Ge bolometer arrays.

5.2 Selectively Doped Isotopic Superlattices

Homogeneous and heterogeneous superlattices and quantum wells can be formed with subatomic layer control by a number of epitaxial growth techniques. They have led to a variety of new devices and physical phenomena. The expression "band-gap engineering" has been introduced to describe the deliberate manipulation of the elemental composition of thin films and superlattices, which in turn creates changes in the band structure.

In view of the rich spectrum of the multilayer structures and the techniques to synthesize them, it is surprising that isotope superlattices consisting of layers with differing isotopic composition have only recently been considered. The idea of forming isotope superlattices by an epitaxial crystal growth technique and doping the various layers *selectively* with NTD was first proposed by Haller (1990).

Isotope superlattices offer a host of new possibilities and improved processing control. The main advantage of isotope superlattices is the possibility to separate the multilayer-layer growth and the doping into two completely independent processes. The following advantages arise from this separation:

1. The growth of multilayered structures of chemically pure isotopes automatically excludes impurity auto doping;
2. layer interdiffusion is limited to host isotope autodiffusion, the slowest diffusion process in all semiconductors; and
3. using NTD, one can selectively dope the various layers after the growth process.

The dopant concentration and species can be controlled by the proper selection of the isotope and its atomic concentration. The radiation damage caused by the fast neutrons accompanying the NTD process can be removed by thermal annealing at temperatures that are modest compared with the epitaxial growth temperatures.

The potential of superlattices selectively doped by NTD can be best illustrated with the formation of a Ge *nipi* structure. The necessary donors are created by neutron transmutation of ^{74}Ge into ^{75}As while the acceptors are obtained from ^{70}Ge by electron capture and ^{71}Ga formation. ^{72}Ge and ^{73}Ge can be used for the intrinsic layer or to reduce the atomic concentration of ^{70}Ge and ^{74}Ge. This may be necessary if one wants to adjust the relative doping concentrations in the *n* and *p* layers. Isotopic composition and doping of a hypothetical Ge *nipi* structure may look like this:

$$[^{74}\mathrm{Ge}_x : \mathrm{As}/^{72\text{ or }73}\mathrm{Ge}_{1-x}] : [^{72\text{ or }73}\mathrm{Ge}] :$$

$$[^{70}\mathrm{Ge}_y : \mathrm{Ga}/^{72\text{ or }73}\mathrm{Ge}_{1-y}] : [^{72\text{ or }73}\mathrm{Ge}] : \cdots .$$

The dopant concentrations after NTD are

$$[\mathrm{As}] = n_{\mathrm{thermal}}\sigma_{^{74}\mathrm{Ge}}x[^{74}\mathrm{Ge}]t, \tag{28}$$

$$[\mathrm{Ga}] = n_{\mathrm{thermal}}\sigma_{^{70}\mathrm{Ge}}y[^{70}\mathrm{Ge}]t. \tag{29}$$

Choosing the ratio of x and y to be the inverse of the ratio of the thermal neutron cross sections $\sigma_{^{74}\mathrm{Ge}}$ and $\sigma_{^{70}\mathrm{Ge}}$, respectively, leads to identical concentrations of As and Ga for any neutron exposure time t.

Isotope superlattices of the other semiconductors offer similar opportunities. Elemental heterogeneous superlattices (Si/Ge) as well as homogeneous and heterogeneous superlattices and quantum wells of III–V and II–VI semiconductors can be grown and doped with NTD. As Table 1 shows, most transmutation products form donors. This strong asymmetry in favor of n-type doping can be balanced to some degree by chemical doping during growth, with the known shortcomings.

A unique aspect of isotope multilayer structures selectively doped via NTD is the option of repeated doping of the same structure. This makes possible doping-dependent studies with the identical structure or device redoped with NTD as many times as necessary.

The idea of isotope multilayer structures predated our access to highly enriched isotopes of semiconductor elements. Now, where larger quantities of enriched isotopes have become available, we expect that such structures will soon be synthesized for doping purposes.

5.3 Electronic Transport and Metal–Insulator Transition

The electrical conductivity σ in a semiconductor is described by

$$\sigma = e(n\mu_n + p\mu_p) \tag{30}$$

with e = charge of the electron (-1.6×10^{-19} A s); n, p = concentration of electrons and holes, and μ_n, μ_p = mobilities of the electrons and holes, respectively. The motion of free charge carriers, *i.e.*, electrons in the conduction band and holes in the valence band, is affected by a number of scattering processes, each dominating over certain temperature ranges.

The total mobility can be related to the effective mass m^* of the free carrier and to an average relaxation time $\langle\tau\rangle$,

$$\mu = e\langle\tau\rangle/m^*. \tag{31}$$

The average relaxation time is obtained using the Maxwell–Boltzmann integration:

$$\langle\tau\rangle = \frac{4}{3\sqrt{\pi}}\int_0^\infty \frac{x^{3/2}\exp(-x)}{\tau_{\mathrm{ac}}^{-1} + \tau_{\mathrm{ion}}^{-1} + \tau_{\mathrm{neutral}}^{-1}}\,\mathrm{d}x, \tag{32}$$

with x being the ratio of the kinetic energy of the carrier and the thermal energy kT. The acoustic relaxation time τ_{ac}, or its inverse the scattering rate, are caused by phonons modulating the bandgap described by the deformation potential. This process dominates at high temperatures:

$$\tau_{\mathrm{ac}} \propto T^{-3/2}. \tag{33}$$

At lower temperatures Coulomb scattering from ionized impurities becomes important:

$$\tau_{\mathrm{ion}} \propto T^{3/2}. \tag{34}$$

In doped, low-compensation crystals the impurities de-ionize at very low temperature, and ionized-impurity scattering diminishes while a third process, neutral-impurity scattering, begins to dominate. This scattering process is rather weak and does not depend strongly on temperature. Several theoretical studies have been performed on neutral-impurity scattering (Erginsoy, 1950). They are all based on the scattering of an electron from a neutral hydrogen atom. The results of the various studies could not be tested satisfactorily up to now, because of a lack of suitable crystals.

The availability of highly enriched isotopes of Ge, which can be purified to residual dopant levels $<10^{12}\,\mathrm{cm}^{-3}$, has provided the first opportunity to measure neutral-impurity scattering over a wide temperature range (Itoh *et al.*, 1993). Itoh *et al.* (1994) reported on transport studies with a series of specially grown high-purity crystals of ^{70}Ge and ^{74}Ge. These crystals were doped with NTD followed by appropriate thermal annealing leading to well defined and ideally homogeneous Ga acceptor and As donor concentrations, respectively.

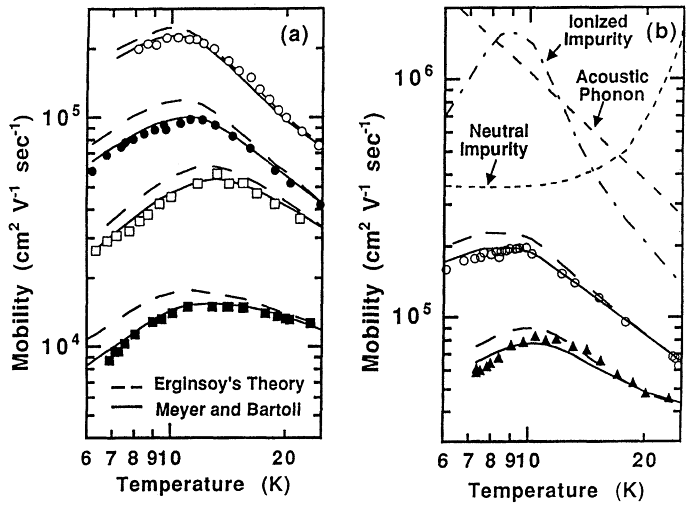

FIG. 16. Mobility measured for (a) four differently doped ^{74}Ge/As samples and (b) two ^{70}Ge/Ga samples. The theoretically determined mobilities are shown as broken lines (Erginsoy, 1950) and continuous lines (Meyer and Bartoli, 1981). The contributions of the different scattering mechanisms to the total mobility of the high-mobility sample ^{70}Ge/Ga are also shown in (b). (Courtesy of Itoh *et al.*, 1994.)

Doping levels between 10^{14} and $10^{16}\,\mathrm{cm}^{-3}$ with less than 1% compensation were chosen. Extensive Hall-effect and resistivity measurements from room temperature down to 4.2 K yielded very accurate free-carrier concentrations and mobilities as functions of temperature and doping level. Below 10 K the dopant impurities rapidly de-ionize and the neutral-impurity concentration rises to more than 100 times the residual ionized-impurity concentration. It is this large excess of homogeneously distributed neutral scattering centers that is necessary for an accurate study of τ_{neutral} and that can be achieved through the combination of the control of isotopic composition and NTD. Figure 16 shows data points for four *n*-type ^{74}Ge crystals [16(a)] and two *p*-type ^{70}Ge crystals [16(b)]. The continuous lines are not fits to the data but represent the theoretical prediction of the model proposed by Meyer and Bartoli (1981). No adjustable parameters had to be used to obtain this excellent agreement between theory and experiment. The older and less sophisticated theory of Erginsoy (1950) clearly leads to a less satisfactory agreement. The approach taken for these transport studies in Ge could easily be adapted to other semiconductors. Si and GaAs would be good candidates because high-quality crystals with low residual dopant concentrations can be grown. Both materials become *n*-type through the NTD process, which limits the studies to electron transport.

A long-standing problem in solid state physics is the metal–insulator transition (MIT). A very large body of experimental and theoretical studies exists but is far too extensive to be reviewed here. In principle, semiconductors are ideally suited for the study of this important transition of a solid from the insulating to the conducting state. All that has to be done is to increase the doping concentration in a semiconductor in a systematic fashion from values below to values above the MIT and to measure the transport properties. Close to the MIT the conductivity becomes very sensitive to the homogeneity of the dopant distribution. In melt-doped, diffused, and ion-implanted crystals the doping homogeneity seems to be the major cause for large discrepancies between the results reported by various groups. In the absence of consistent data, the theoretical contributions cannot be tested thoroughly.

The combination of isotope enrichment, ultrapurification, and NTD has led to *p*-type ^{70}Ge crystals that are homogeneously doped with a truly random dopant distribution and a donor compensation of the order 1% (Itoh *et al.*, 1996). A series of crystals with Ga acceptor concentrations ranging from 3×10^{16} to $2.6 \times 10^{17}\,\mathrm{cm}^{-3}$ have been studied in detail on the insulator and the metal sides of the transition. Figure 17 shows that the experimentally determined parameter T_0 as a function of the Ga concentration on the insulator side and the

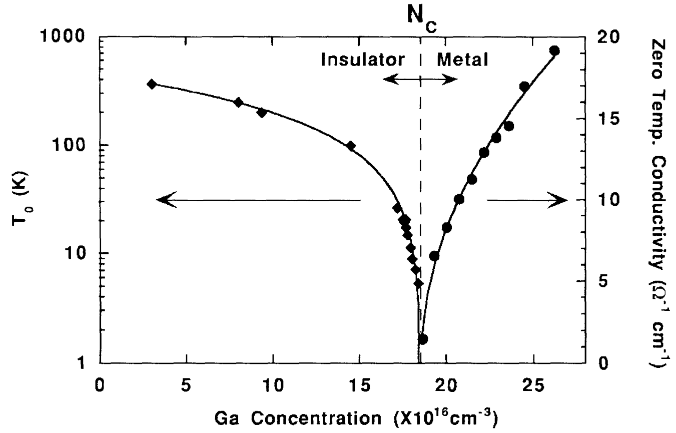

FIG. 17. Conductivity parameters for NTD ^{70}Ge below and above the metal–insulator transition. The left-hand side shows the experimentally determined values of T_0 [Eq. (35)] of 14 insulating samples as a function of Ga concentration (◆). The right-hand side shows the zero-temperature conductivity $\sigma(0)$ obtained from ten metallic samples as a function of Ga concentration (●). The critical concentrations obtained on the insulator and on the metallic side agree to within a few percent. (Courtesy of Itoh *et al.*, 1996.)

zero-temperature conductivity on the metal side converge precisely at the critical concentration of $1.856 \times 10^{17}\,\text{cm}^{-3}$. The resistivity ρ on the insulator side follows the expression developed by Shklovskii and Efros (1984):

$$\rho = \rho_0 \exp(T_0/T)^{\nu} \qquad (36)$$

with ρ_0 the prefactor, T_0 a constant depending on the dopant concentration, and ν the critical exponent.

Temperature-dependant resistivity measurements show that $\nu \cong 0.5$ for all doping concentrations below the MIT. The value of ν remains 0.5 for donor compensation up to $\gtrsim 40\%$. Most of the published MIT theories find values for ν different from 0.5. Stimulated by the MIT studies with isotopically engineered Ge, Phillips (1997) has formulated new theoretical treatments that produce the experimentally determined value of ν. Work is in progress to repeat the same type of experiment with ^{74}Ge, which turns *n*-type with As donors after NTD.

6. FUTURE DEVELOPMENTS AND CONCLUSIONS

Considering what has been achieved with isotopically controlled semiconductors, we are confident that a very large number of interesting experiments can be performed if there is enough commitment to creating the necessary materials. There can be little doubt that we will see experiments with isotopically controlled Si bulk crystals and perhaps ^{28}Si/^{30}Si thin films and superlattices. The studies performed with Ge should definitely be repeated with Si in order to verify and consolidate the understanding gained with Ge. Once they are grown, Si isotope superlattices can be doped *n*-type in the ^{30}Si layers.

Isotopically controlled III–V and II–VI compound semiconductors and their alloys are most promising in connection with NTD. Zn-containing II–VI semiconductors can be doped either with Cu or Ga or not at all, depending on the particular choice of the Zn isotope (Wheeler *et al.*, 1997). The Group VI partners S, Se, or Te offer an abundance of doping possibilities including donors and acceptors. Post-growth doping of II–VI semiconductors with the standard techniques (diffusion and ion implantation) has found rather limited success, and NTD in combination with isotope control should be explored as a possible solution to the doping problem. In exchange one will have to deal with nuclear-decay recoil and fast-neutron radiation damage.

NTD will play a role in diffusion studies. Self-diffusion in several semiconductors has been studied with isotope multilayer structures and superlattices. Such isotope superstructures can be doped over a broad range of impurity concentrations. With such an approach one can obtain large sets of data for self- and dopant diffusion with built-in redundancy and a minimal chance of errors introduced by hidden materials parameters (*e.g.* electrically inactive impurities, dislocations, precipitates). If undoped superlattices are grown, extremely sharp interfaces, unaffected by impurity-promoted interdiffusion, can be obtained.

A family of semiconductors that can profit from isotope control are the Cd-containing II–VI compounds. Rowe (*et al.*, 1974) led the way with CdTe crystals, in which ^{113}Cd, the isotope with one of the largest thermal-neutron capture cross sections, was essentially eliminated. The other members of this family, *i.e.*, CdS, CdSe, and alloys, can also be studied with neutron diffraction after ^{113}Cd has been removed.

Moving to atomic-level dimensions we can foresee exciting experiments with scanning tunneling microscopy (STM) (see TUNNELING MICROSCOPY AND SPECTROSCOPY). Recent reports indicate that donors have been observed with STM in GaAs (Zheng *et al.*, 1994). Let us imagine that a semiconductor is exposed to a certain neutron fluence and that the half-life of the transmutation process lies in the range of hours to days. The crystal surface can be observed with an STM after neutron exposure. If the concentration of the STM-observed impurities should increase exponentially with the same half-life as that of the transmuting isotope, we would have strong proof for STM observations of dopant impurities or other impurities, as well. With very high-speed STM it may become possible to observe relaxation around a defect or dopant formed by neutron transmutation or another nuclear reaction in real time!

Local vibrational-mode studies could become even more powerful than they already are, if isotopically controlled host crystals were available. The enormous simplification gained from isotopically pure host crystals has been clearly demonstrated with LVM studies of O in Ge. LVM studies of Ca and Ti in CdTe and Mg in ZnTe have shown spectrally resolved isotope effects of both the Te host-crystal isotopes and the impurity isotopes (Sciacca *et al.*, 1996). "Isotopically doubly controlled" experiments in which both the impurity and the host crystal are isotope controlled (pure as well as deliberately mixed isotopes) present ideal solid state systems for LVM studies.

Nuclear reactions with specific isotopes of semiconductor-forming elements offer a range of opportunities that have so far not been explored. There exists information on a very large number of nuclear reactions between energetic ions and practically all the stable isotopes of the periodic table. We foresee experiments focusing on radiation damage, on ion implantation, and on nuclear transmutation. Isotope control will simplify many of these studies.

Isotope control and engineering of semiconductors and other solids offers numerous possibilities for solid state studies and novel devices. The post-Cold War era has brought great opportunities for making highly enriched isotopes more readily available to the science and technology community. Inventiveness and creativity are required to take full advantage of the vast array of natural, stable isotopes, which so far have played only a minor role in a few special cases.

ACKNOWLEDGMENTS

First and foremost, I wish to thank Valerii Ozhogin of the Kurchatov Institute in Moscow, who had the courage to make the first macroscopic quantities of highly enriched Ge available for many exciting experiments. I am indebted to many colleagues at Berkeley and all over the world with whom we have been collaborating on various experiments with isotopically controlled semiconductors. Their names are presented in alphabetical order: Gerhard Abstreiter, Jeffrey W. Beeman, Fernando Briones, Manuel Cardona (and the members of his group), Gordon Davies, Karl Eberl, Jon Erickson, John Farmer, Heinz D. Fuchs, William L. Hansen, Kohei M. Itoh, Anant K. Ramdas (and the members of his group), Wladek Walukiewicz, and Lei Wang.

The author acknowledges the Max-Planck-Research Prize, which he shared with Manuel Cardona, offered by the Max-Planck Society, Germany, in support of our research on isotopically controlled semiconductors. The work at Berkeley was also supported in part by the Lawrence Berkeley National Laboratory Directed Research and Development Program and in part by the Office of Energy Research, Office of Basic Energy Sciences, Materials Sciences Division of the U.S. Department of Energy, under contract DE-AC03-76SF00098.

INTRODUCTION

The Group III metals (B, Al, Ga, In) when combined with nitrogen form a special family of materials that are extremely hard, refractory, and resistant to chemical attack. Their physical characteristics include strong chemical bonds, large electronic band gaps, and low electron affinities. Because of these properties the Group III materials have found a niche is several important technological applications. Boron nitride is second only to diamond in terms of hardness and thermal conductivity, and it is used for coating surfaces of tools used for abrasive purposes and in other adverse environments. The alloys resulting from the combination of AlN, GaN, and InN can be grown with an electronic band gap appropriate for visible- and ultraviolet-light emitters and detectors, as well as with robust mechanical and thermal properties that make them useful for high-temperature and high-power electronic applications.

This article provides a concise review of the

development of the nitrides, their properties, and their applications. Extensive journal reviews and books have recently been produced, and some are listed at the end for the interested reader.

Brief history. The Group III nitrides are not really new materials, and their recent success results from much effort over the last three decades. A brief account of the development of the nitrides follows; more details and references on the evolution of the nitrides are found in Ponce and Bour (1997). AlN was first reported in 1907, placing it among the first compound semiconductors ever synthesized. The wurtzite lattice structure of GaN was determined in 1937. In the last four decades, much of the research in the field has been stimulated by the desire to achieve short-wavelength light emission such as for green and blue solid-state lamps. Growth of GaN crystalline films by hydride vapor-phase epitaxy was first reported by Maruska and Tietjen (1969). Pankove *et al.* (1971) produced the first blue GaN LEDs using metal–insulator–semiconductor structures. Also in the same year Manasevit grew GaN by metalorganic chemical vapor deposition for the first time, a technique that is widely used today; and Dingle reported stimulated light emission at 2 K from GaN needles. The search for high-quality materials encountered three important problems that appeared insurmountable for many years: the first thin films were rough and fractured, *n*-type conductivity was difficult to control, and *p*-type conductivity appeared virtually impossible to achieve. Akasaki and Amano conquered these obstacles: smooth morphologies were achieved by Amano *et al.* (1986) using low-temperature AlN nucleation layers. Once specular films had been achieved, it was shown that the use of silane (SiH_4) could produce effective and controllable *n*-type doping. It took a few more years to achieve *p*-type conductivity. Magnesium was expected to be a good acceptor (*p*-type dopant), but the first films with high concentrations of Mg failed to exhibit *p*-type characteristics. Amano *et al.* (1989) showed that low-energy electron-beam irradiation (LEEBI) converted the highly resistive Mg-doped GaN into conductive films with high hole concentrations ($10^{16}\,cm^{-3}$). Under these conditions they were able to produce the first *p–n* junction LED. Nakamura (1991) introduced low-temperature GaN nucleation layers, with further improvement of the electronic properties, and then demonstrated (Nakamura *et al.*, 1992) that thermal annealing caused activation of Mg in GaN in a similar manner as the LEEBI technique. At that point few could predict the rapid development and commercialization of GaN-based optoelectronic devices in the following years.

Current relevance. The nitride semiconductors have positioned themselves for high impact in important emerging technologies. Blue and green LEDs based on GaN are now commercially available and, in combination with red AlInGaP LEDs, they can provide solid-state illumination with substantially better power efficiencies than incandescent tungsten-filament light bulbs. Blue laser diodes operating continuously at room temperature with long lifetimes ($>10\,kh$) have been demonstrated and are now commercially available. Much excitement and activity currently exists for the further commercialization of these new materials, and substantial technological innovations are foreseen. One area is in the production of the three primary colors for large-panel displays, outdoor signs, and ultimately full solid-state indoor lighting. Another area results from the ability to focus shorter wavelengths into smaller spots without increment in size and cost of the optical system. This will allow high-density optical information storage and readout, full-color photographic laser printing, and high-resolution xerographic laser printing. The development of green and blue laser diodes will make possible the implementation of small and inexpensive full-color projection television.

1. CRYSTAL CHEMISTRY

1.1 General

This section deals with the chemical aspects of the Group III nitrides, their crystal structures, and the electronic and thermal properties. For in-depth data and references consult Madelung (1982). A detailed treatment of the properties of the Group III nitrides by Edgar (1994) is also recommended.

1.2 Chemical Bonding

Tetrahedral coordination is a characteristic of the atomic bonding configuration in many

Table 1. Electronic properties of the elements found in the nitride semiconductors. Values are for atoms in tetrahedrally coordinated environments. Values taken from Kittel (1976) and Philips (1973).

	Ground-state electron configuration	Electronegativity	Atomic radius (Å)
B	[He] $2s^2$ $2p^1$	2.0	0.88
Al	[Ne] $3s^2$ $3p^1$	1.18	1.26
Ga	[Ar] $3d^{10}$ $4s^2$ $4p^1$	1.13	1.26
In	[Kr] $4d^{10}$ $5s^2$ $5p^1$	0.99	1.44
N	[He] $2s^2$ $2p^3$	3.0	0.70

semiconductor materials such as silicon, germanium, the III–V and II–VI compounds, and SiC. Table 1 shows the ground-state configurations of the elements in the nitride semiconductors. The s and p orbitals in the outer electron shells combine to produce hybrid sp^3 orbitals where the probability of finding an electron in a p state is three times as much as finding it in an s state. The directions of greatest electronic charge density in sp^3 orbitals is such that bonding will occur with fourfold coordination, forming a regular tetrahedron about a particular lattice site. The atomic radii can be used to obtain a good approximation of the bond lengths (actual values for the binary compounds are given in Table 2). The chemical properties of the binary nitrides, such as the cohesive energy per bond, increase with the value of the electronegativity of the Group III element (see Tables 1 and 2). The melting characteristics also follow a similar trend (Table 3).

1.3 Crystal Structures

The tetrahedral coordination produces a characteristic atomic array that can be viewed as consisting of hexagonal closed-packed layers consisting of two sublayers; one sublayer is occupied by nitrogen, while the other contains the Group III elements. The cubic zincblende structure [space group $F\bar{4}3m$, T_d^2 (No. 216)] occurs when the hexagonal layers are stacked in a periodic ABCABC sequence along the ⟨111⟩ directions. The hexagonal wurtzite structure (space group $P6_3mc$, C_{6v}^4 [No. 186]) follows an ABABAB arrangement along the [0001] direction. The unit cells and the layer sequences of the two lattices are shown in Fig. 1. The lattice parameters and other properties of the wurtzite structure are given in Table 4. The ideal wurtzite structure consists of regular tetrahedra with a c/a ratio of 1.633. Other lattice structures are also possible; in particular, the rocksalt (NaCl) structure is typically observed in the nitrides under high-pressure conditions.

1.3.1 Boron Nitride Boron nitride exists in the high-density tetrahedrally coordinated forms (zincblende and wurtzite structures), as well as in a low-density hexagonal layered structure. These structures and their properties are often compared with those of carbon. The zincblende form has a similar structure and properties to those of diamond. The low-density, hexagonal form of BN has similar lattice properties to those of graphite. The differences between BN and C originate mostly in the nature of their chemical bonds, mixed co-

Table 2. Chemical properties of the nitride semiconductors. This table shows the experimental cohesive energy per bond (Harrison, 1980), bond lengths of the Group III nitrides (with wurzite structure), the standard molar enthalpy (heat) of formation $\Delta_f H^0$, the Gibbs free energy of formation $\Delta_f G^0$, the standard entropy ΔS^0, and the molar heat capacity C_p at 298.15 K.

	Cohesive energy per bond (eV)	Bond length (Å)	$\Delta_f H^0$ (kJ mol^{-1})	$\Delta_f G^0$ (kJ mol^{-1})	ΔS^0 (J mol^{-1} K^{-1})	C_p (J mol^{-1} K^{-1})

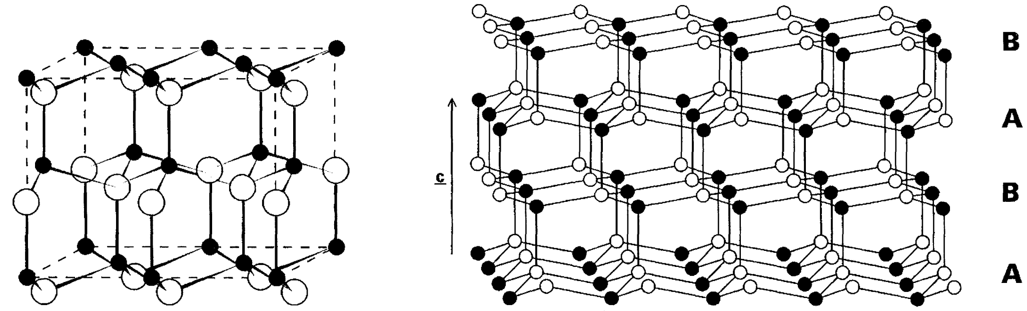
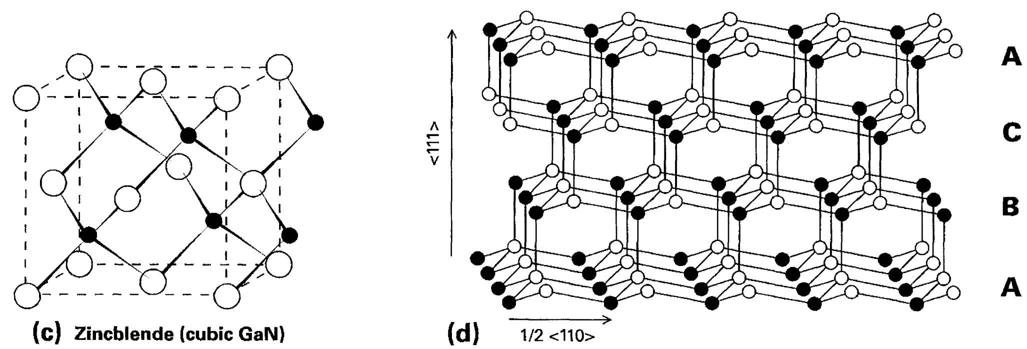
valent–ionic in BN versus strongly covalent in diamond. BN has a slightly higher energy band gap and lattice constant, but lower mechanical strength, thermal conductivity, and Debye temperature than diamond. The rocksalt form of BN is stable under ambient conditions. The zincblende form is the most stable under normal conditions, and the wurzite form is metastable under all conditions. Lattice constants and densities for various forms of BN are given in Table 5.

1.3.2 Aluminum Nitride AlN crystallizes in the wurtzite structure under normal conditions, with a c/a ratio reportedly ranging form 1.600 to 1.602; the deviation from the ideal value is attributed to ionicity. A metastable zincblende form has been reported with a lattice parameter of 4.38 Å. A phase transition to rocksalt has been observed at 14 GPa.

1.3.3 Gallium Nitride GaN usually crystallizes in the wurtzite form with a c/a ratio of



(a) Wurtzite (hexagonal GaN) **(b)**



(c) Zincblende (cubic GaN) **(d)**

1.6252. A zincblende form is also observed in thin-film form with a lattice parameter of 4.55 Å. Several high-pressure forms have been reported (see Edgar, 1994).

1.3.4 Indium Nitride Small InN crystallites have been produced in the wurtzite and zinblende structures. It has been noted that nitrogen vacancies are common and may be responsible for a large uncertainty in the lattice constant *c*. A transition to rocksalt at about 245 GPa has been experimentally and theoretically reported.

1.4 Band Gap

The nitride semiconductors have a direct band gap. This is the energy difference between the conduction band and the valence band, and it determines the frequency (color) of absorbed and emitted light. A *direct* band-gap transition involves only the emission of a photon, while an *indirect* band-gap transition requires the combination of a photon and a phonon (lattice vibration). As a result, direct band-gap materials are much better light detectors and emitters. Figure 2 illustrates the values of band gap and lattice constant for binary compound semiconductors commonly used in optoelectronic applications. The electronic bandgap in the Group III nitrides extends from 2.0 to 6.4 eV, including most of the visible and ultraviolet portions of the electromagnetic spectrum. The ternary alloy $In_xGa_{1-x}N$ ranges over most of the visible spectrum. This range of band gaps is a very useful property of the nitride semiconductors.

1.5 Mechanical Properties

The elastic constants and moduli are shown in Table 6. These values are generally significantly greater that those of other semiconductors.

Table 5. Lattice constants and densities of boron nitride (adapted from Edgar, 1994).

	Structure	a (Å)	c (Å)	Density (g cm^{-3})
h-BN	Hexagonal	2.5040	6.6612	2.28
r-BN	Rhombohedral	2.507	10.00	2.276

w-BN	Wurtzite	2.556	4.175	3.47

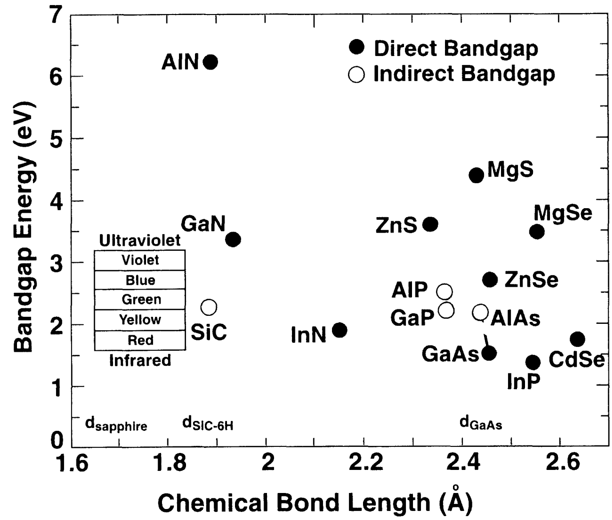

FIG. 2. Band gap *versus* chemical bond lengths of semiconductor compounds that emit in the visible range of the electromagnetic spectrum. The chemical bond length is used instead of the lattice parameter in order to allow comparison between interatomic separations in the zincblende (cubic) structure of the phosphides, arsenides, and II–VI compounds with the wurtzite (hexagonal) structure of the nitrides (Ponce and Bour, 1997).

1.6 Thermal Stability and Etching

The strength of the chemical bond makes these materials thermally stable and mechanically hard. Tables 2 and 7 show the thermal properties of the semiconductor nitrides. With increasing atomic number of the anions, the electronegativity decreases, their ionic nature increases, and the covalent bonding becomes weaker. It is also natural to expect less stability towards oxidation. Even though the heats of formation (such as in $2GaN + 2O_2 \rightarrow Ga_2O_3 + N_2O$) predict strong tendency toward oxidation, no such reactions are observed in practice. This may be due to kinetic barriers introduced by the lattice structure. These materials are also very difficult to etch. No wet etching method is known for GaN. Chemically assisted ion-beam etching (CAIBE) has been successfully used for device fabrication using Cl_2/BCl_3 reactive gas.

2. GROWTH TECHNIQUES

2.1 General

Nitride formation is commonly observed by heating the metal in ammonia at temperatures usually between 500 and 550 °C. The first synthesis of GaN was reported in 1932 by reaction of metallic Ga in an NH_3 stream following the reaction $2Ga + 2NH_3 \rightarrow 2GaN + 3H_2$. Using the same technique, AlN was syn-

Table 6. Mechanical properties of the Group III nitrides. The values for the wurtzite and zincblende structures are shown in the top and bottom (in parenthesis) positions, respectively. The elastic constants (c_{ij}), Poison's ratio (v), Young's Modulus (E) and shear modulus (μ) values are adapted from Edgar (1994).

Properties	c_{11} (GPa)	c_{12} (GPa)	c_{13} (GPa)	c_{33} (GPa)	c_{44} (GPa)	v	E (GPa)	B (GPa)	μ (GPa)

thesized from Al and InN from $InF_6(NH_4)_3$. Single-crystal nitride semiconductors can be grown in bulk and thin-film forms. Growth of semiconductor-grade material requires the use of special techniques for the control of chemical purity and crystalline quality. An in-depth review of growth techniques and references is given by Strite and Morkoc (1992).

2.2 Bulk Growth

The growth of large single crystals of the nitride semiconductors has been inhibited by the high vapor pressures and extremely high temperatures at the melting point (see Table 3). These characteristics make virtually impossible the growth from stoichiometric melts by conventional methods such as the Bridgman and Czochralski techniques. Further information can be found in Chap. 9 of Pearton (1997).

2.2.1 Aluminum Nitride Bulk single crystals of AlN were first produced by Slack and McNelly (1976) using sublimation techniques in closed tungsten crucibles. Crystals with dimensions of a few millimeters were produced. The technique shows promise for growth of centimeter-size crystals.

2.2.2 Gallium Nitride GaN single crystals have been grown from gallium melt saturated with molecular nitrogen at ≈1600 °C under nitrogen vapor pressures of about 15 kbar. This approach has produced GaN platelets with dimensions of several millimeters and thickness of ≈0.1 mm, and with a typical high *n*-type conductivity due to high levels of impurities (oxygen being the most abundant).

2.2.3 Indium Nitride Attempts to grow bulk crystals of InN have resulted in small crystallites (5–50 μm). Pressures beyond 20 kbar are believed necessary.

2.3 Substrates for Heteroepitaxy

In the absence of bulk nitride single crystals, other materials have been extensively evaluated as substrates for thin-film growth. Two important considerations for the selection of substrates are the lattice characteristics and the thermal/chemical stability of the substrate surface. ZnO and SiC have similar lattice characteristics and thermal expansion rates to those of the nitrides. Both have tetrahedral atomic coordination and exhibit polarity along the *c* axis. Wurzitic ZnO crystals are available, but they are unstable in the highly corrosive environment and high temperatures needed for growth of the nitrides. The Si face of SiC is quite stable at typical growth temperatures. Sapphire (α-Al_2O_3) has hexagonal symmetry and highly chemically stable surface properties. Lattice-mismatch value are given in Table 8.

Table 8. Lattice mismatch (%) and resulting misfit dislocation separation (in Å) corresponding to complete misfit relaxation for basal plane interfaces.

Crystalline properties	Substrate	GaN	AlN	InN	α-Al_2O_3	6H-SiC
Lattice mismatch (%) with	Sapphire	14.8	12.5	25.4	—	11.5
	SiC	3.3	1.0	14.0	−11.5	—
	GaN	—	−2.4	10.6	−14.8	−3.3
Dislocation distance (Å) on	Sapphire	17.2	20.3	10.6	—	21.9
	SiC	80.9	276.7	20.4	21.9	—
	GaN	—	114.4	27.3	17.2	80.9

2.3.1 Silicon Carbide as a Substrate The lattice of SiC bears many similarities to the wurtzite lattice of the nitrides. It is tetrahedrally coordinated and exhibits a polar structure along the *c* axis. The arrangement of the basal planes in SiC occurs in a variety of ways, resulting in a lattice structures with cubic (C), hexagonal (H), and rhombohedral (R) symmetries. The lattice arrangement in SiC is usually described by its symmetry (C, H, or R), and by the number of planes in a period along the direction normal to the basal planes. Thus, the notation 2H refers to the wurtzite structure and 3C refers to the zincblende structure. The 6H form is the most common form that is available commercially. The lattice properties of SiC are listed in Table 4. Note that the lattice constant and the thermal expansion rates along the basal plane between AlN and SiC are very similar. High-quality epitaxy can be routinely achieved using SiC substrates; blue LEDs are commercially available, and blue laser diodes have been demonstrated.

2.3.2 Sapphire as a Substrate α-Al_2O_3 is currently the most commonly used substrate for the epitaxial growth of nitride semiconductor thin films. It has a hexagonal lattice structure with constants given in Table 4. The (0001) basal planes consist of hexagonal close-packed planes of oxygen, alternated with hexagonal arrays of aluminum planes. The Al planes have one third of the sites vacant. The 2/3 occupation of aluminum sites accounts for the Al/O stoichiometry in its chemical formula. The (0001) planes are favored for substrates, although the $\{\bar{2}110\}$ planes have also been recently used for the fabrication of state-of-the-art devices.

2.4 Growth with Molecular Beams

Molecular-beam epitaxy (*q.v.*) (MBE) is performed in ultrahigh-vacuum (UHV) conditions at relatively low temperatures. Gallium beams can be produced from gallium melt effusion cells, and from gaseous trimethylgallium (TMG) and GaCl. Growth under UHV conditions is difficult because of the requirement of large nitrogen equilibrium overpressures. The two most common sources of nitrogen, N_2 and NH_3, have strong bonds and are highly thermally stable. Growth at reasonable rates requires the breaking of the molecular structure to produce more reactive radicals. This can be accomplished at very high temperatures, where growth is difficult to handle. New nitrogen sources and methods to break the molecular structure into more reactive atomic or ionic species at low temperatures ($\approx$600 °C) are of high current interest. A technique that has achieved limited success is gas-source molecular-beam epitaxy (RMBE) using NH_3 or the more reactive hydrazine (N_2H_4) as nitrogen sources. Plasma excitation (such as by electron-cyclotron resonance, ECR) has been used frequently to increase the reactivity of the nitrogen source. However, ECR-plasma sources produce highly energetic particles that result in somewhat poor growth efficiencies and in the formation of subsurface defects due to atomic impact during growth.

2.5 Growth by Vapor-phase Transport

Since 1971, vapor-phase transport [see CVD (CHEMICAL VAPOR DEPOSITION)] has been the most commonly used technique for the growth of Group III nitrides. The hydride vapor-phase epitaxy (HVPE) technique uses NH_3 and GaCl (formed by HCl flowing over a Ga melt) as sources, with purified N_2 as the carrier gas. Growth is typically performed at about 1100 °C. HVPE is characterized by high growth rates and is suitable for the production of thick films (tenths of a millimeter in thickness). Metalorganic chemical vapor deposition (MOCVD) uses NH_3 and metalorganic Group III sources (such as the trimethyl and triethyl forms of Ga, Al and In). The reaction is of the form $(CH_3)_3Ga + NH_3 \rightarrow GaN + 3CH_4$. To date, the best optoelectronic properties have been achieved from materials grown by MOCVD. Low-temperature buffer layers (deposited at about 550 °C) are used to overcome three-dimensional nucleation in the early stages of growth. Epitaxial thin films of AlN, GaN, InN, and their alloys have been grown by this technique at temperatures in the range of 700–1100 °C.

2.6 Doping

As with other semiconductor systems, the electronic properties of the nitrides are very sensitive to doping impurities. Unintentional background impurities resulting from all the growth techniques have a typical *n*-type behavior. The lowest background concentrations currently achieved are around $1 \times 10^{16}\,\mathrm{cm}^{-3}$.

2.6.1 *n*-Type Silicon and germanium are the most commonly used *n*-type dopants. Silane (SiH_4) and germane (GeH_4) are commonly used as doping sources in MOCVD. The Si donor state is located at about 12–22 meV from the conduction band. Electron carrier concentrations up to $10^{19}\,\mathrm{cm}^{-3}$ are obtained by use of silicon as the dopant. Room-temperature electron mobilities as high as $900\,\mathrm{cm}^2\,\mathrm{V}^{-1}\,\mathrm{s}^{-1}$ have been reported.

2.6.2 *p*-Type Zn and Mg are the most common *p*-type dopants for GaN, AlN, and InN. *Bis*-cyclopentadienyl magnesium is commonly used in MOCVD. As-grown GaN doped with Mg is usually highly resistive, but a thermal anneal at about 800 °C activates the *p*-type doping. It is believed that Mg–H complexes are responsible for this behavior. The Mg acceptor state is located at 165–182 meV above the valence band. Room-temperature hole concentrations in the mid-$10^{17}\,\mathrm{cm}^{-3}$ range (corresponding to magnesium concentrations of $\approx 10^{20}\,\mathrm{cm}^{-3}$) are commonly achieved using the thermal activation technique. Room-temperature hole mobility values as high as $20\,\mathrm{cm}^2\,\mathrm{V}^{-1}\,\mathrm{s}^{-1}$ have been observed.

3. MATERIALS PROPERTIES

3.1 Lattice Defects

Lattice defects are closely associated with the properties of semiconductors. Point defects in the nitrides are responsible for the light-emission properties. Dislocations are abundant in current state-of-the-art epitaxy and may strongly affect the distribution of point defects and therefore the optical and electrical properties. The properties of lattice defects in the nitride semiconductors are subject of much current interest.

3.1.1 Point Defects Point defects can be classified as native defects (vacancies, self-interstititals and antisites) and impurities (unintentional impurities and dopants).

3.1.1.1 Native Defects. Theoretical formation energies of various native defects in GaN have been reported by Neugebauer and Van de Walle (1994). The nitrogen vacancy (V_N) is suspected to be abundant in these materials, and manifests itself as a shallow donor, about 0.8 eV above the conduction band edge. The Ga vacancy (V_Ga) is expected to be a shallow triple acceptor. The Ga interstitial (I_Ga) is energetically favorable. The N interstitial (I_N) is expected to form a split-interstitial configuration by joining a host N atom and sharing the same lattice site. Antisite defects can be largely interpreted in terms of the covalent radii of the cation and anion species. A nitrogen on a gallium site (N_Ga) defect should involve N–N bonds similar to those found in the N_2 molecule; and since the covalent radius of N is much smaller than Ga, such defects are under tensile stress with a formation energy of about 6 eV. Similarly, gallium on a nitrogen site ($\mathrm{Ga_N}$) is under compressive stress with a formation energy ranging from 7 to 11 eV, depending on the Fermi level.

3.1.1.2 Impurities. The most common growth-related impurities are hydrogen, oxygen, carbon, and silicon. High concentrations of hydrogen ($\approx 10^{21}\,\mathrm{cm}^{-3}$) are easily incorporated into GaN (during growth as well as during processing). Hydrogen is commonly present in most crystal-growth techniques. Hydrogen can easily form stable complexes resulting from interaction with dangling bonds, and it is expected to easily passivate shallow acceptors and sometimes shallow donors. Hydrogen passivation or compensation of Mg in GaN has been historically an important effect that was overcome by thermal annealing (see Sec. 2.6.2). Carbon is present in the organometallic precursors, and silicon and oxygen originate from the quartz parts in growth equipment. As substitutional impurities, C, Si, and O are single donors. Doping species are discussed in Sec. 2.6.

Table 9. Magnitude of the Burgers vectors for dislocations observed in the nitrides (in Å).

Burgers vectors	GaN	AlN	InN
$a=\frac{1}{3}\langle 11\bar{2}0\rangle$	3.186	3.111	3.545
$c=[0001]$	5.178	4.979	5.703
$c+a=\frac{1}{3}\langle 11\bar{2}3\rangle$	6.080	5.871	6.715

3.1.2 Dislocations Dislocations form following the wurtzite $\{0001\}\langle 11\bar{2}0\rangle$ and the zincblende $\{111\}\langle 110\rangle$ slip systems. Dislocations of the screw, edge and mixed types have been observed in nitrides with the wurtzite structure. Table 9 shows the Burgers vectors and expected relative energies of these dislocations. The large values of the Burgers vectors and the elastic constants (Table 6) imply large strain energies. It has been observed that sometimes screw dislocations with $\mathbf{b}=[0001]$ exhibit hollow cores (nanopipes); this behavior may be due in part to the large dislocation energies.

3.1.3 Inversion Domains Inversion domains are a result of the polar nature of the Group III nitrides and have been observed in GaN thin films.

3.1.4 Stacking Faults Faults in the stacking sequence of the lattice occur during growth by nucleation of a rotated layer, or subsequently by motion of a dislocation along a slip plane. Intrinsic stacking faults involve the absence of a plane in the lattice (ABCAB$\underline{\text{CB}}$CABC in zincblende, and ABAB$\underline{\text{AC}}$ACAC in wurtzite). Extrinsic stacking faults involve the presence of an extra plane (as in ABCABC$\underline{\text{B}}$ABCABC in zincblende and ABABAB$\underline{\text{C}}$ABABAB in wurtzite). In the nitride semiconductors, stacking faults are observed in the early stages of growth, and are commonly observed in low-temperature nucleation layers. Stacking faults are rarely observed in regions more than 1 μm away from the substrate.

3.2 GaN on Silicon Carbide

High-quality nitride films and devices have been reported based on GaN epitaxy on SiC using AlN and GaN buffer layers. As described in Sec. 2.3.1, SiC exhibits many similarities to the nitride semiconductors and serves well as a substrate. Because of the close lattice match and very similar thermal expansion characteristics with AlN, very high crystalline quality growth is possible. The $[0001]_{\mathrm{Si}}$ substrate surface, which has silicon on the top position of the basal plane, gives best results. Figure 3 shows the atomic arrangement at the interface between AlN and SiC. The projection of the 6H structure exhibits the characteristic sixfold zigzag in the stacking sequence of the basal planes, compared with the vertical stacking sequence of the wurtzite (2H) structure. The atomic bonding at the interface is coherent with both lattices, producing a bonding sequence C–Si—C–Si—N–Al—N–Al or C–Si—C–Al—N–Al, and charge balance is possible leading to stable interfacial structures and defect-free epitaxy (Ponce *et al.*, 1996). A current limitation is in the preparation of the substrate, where surface steps cause lateral offsets (due to the zigzag of the 6H structure) in the position of the atomic sites on the basal

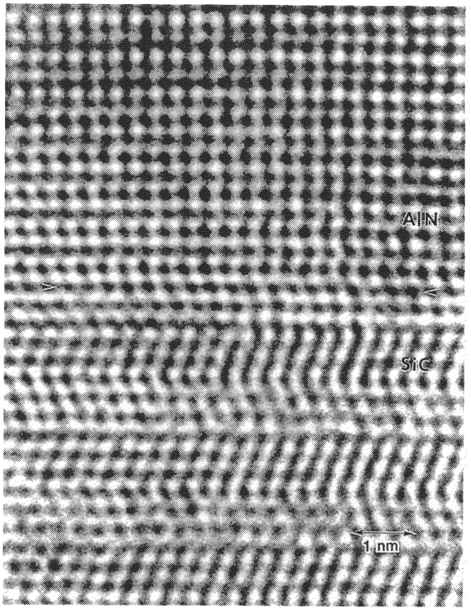

FIG. 3. Transmission electron microscopy lattice image of the AlN/SiC interface. Note the transition between the 6H-SiC and the 2H-AlN as shown by the arrangement of the lattice spots (sixfold zig-zag in the SiC, *versus* vertical columns in the AlN) (Ponce *et al.*, 1996).

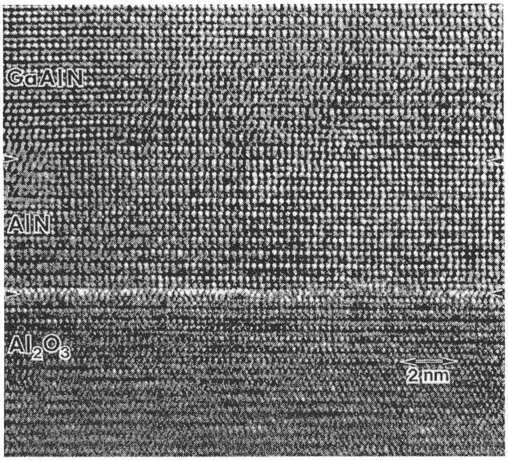

FIG. 4. AlN/sapphire interface (Ponce *et al.*, 1994).

planes, which are difficult to remedy with the 2H wurtzite structure, causing the appearance of complex faults in the epilayer.

3.3 Epilayers on Sapphire

Nitride semiconducting thin films grown on sapphire have been shown to have superior device quality despite the large differences in lattice structure and thermal-expansion characteristics that exist between GaN and α-Al_2O_3.

3.3.1 Microstructure The difference in lattice structures between sapphire and the nitrides is resolved at their interface. Figure 4 shows an image of the AlN/sapphire interface. The interface is planar and abrupt, consisting of a single atomic layer. The lattice mismatch of 12.5% (see Table 8) is accommodated by the atomic arrangement at the interface plane. The buffer layer plays a key role in determining the properties of the film. With an initial amorphous structure, it undergoes solid-phase crystallization as the temperature is increased. The resulting crystallites act as templates for growth, producing a columnar array of crystals with the *c* axis closely aligned along the growth direction. The distribution of the columnar orientation is on the order of 5 arcmin for the tilt of the *c* axis, and 8 arcmin for the twist (rotation of the *c* axis) component shown in Fig. 5. Dislocations exist to maintain the coherency in these very-low-angle tilt boundaries. Figure 6 shows a cross-section transmission electron microscope image of a high-efficiency light-emitting diode (Ponce and Bour, 1997). Dislocations are observed propagating in the growth direction with a density of $\approx 10^{10}\,\mathrm{cm}^{-2}$. Initially, it was surprising that materials with such high dislocation density could be adequate for high–light-emission efficient LEDs. Data from other systems, shown in Fig. 7, indicate that dislocation densities above $10^3\,\mathrm{cm}^{-2}$ have a significantly adverse

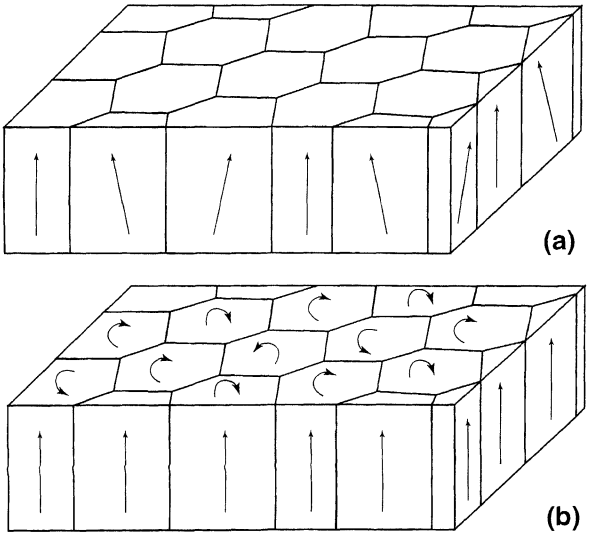

FIG. 5. Columnar structure model for the III–V nitrides. The epilayer consists of a columnar array with a distribution in orientations distinguished by two components: (a) tilt of the *c* axis (typically about 5 arcmin) and (b) rotation about the *c* axis (typically about 8 arcmin).

Table 10. Electrical and optical properties of the nitride semiconductors (Madelung, 1996).

	BN	AlN	GaN	InN

spond to significant lower mobility values than the best achievable.

3.3.3 Optical Light emission and absorption depend on many factors. One is the band-edge emission of the material, determined by the composition as shown in Fig. 2. Other factors are the nature and concentration of the doping impurities that introduce states in the band gap. Silicon introduces shallow donor states and causes in GaN only a slight reduction in the light energy. Magnesium introduces deep acceptor states and causes in GaN a shift of the emission and absorption peaks towards longer wavelengths. Higher–band-gap AlGaN alloys are used for ultraviolet applications, while InGaN alloys are used for applications involving blue and green. The optical properties of these materials are reviewed in Chap. 5 of Pearton (1997).

4. APPLICATIONS

4.1 General

The nitride semiconductors have found a niche in several important technologies such as short-wavelength light emitters and detectors, high-power and high-temperature electronics, and cold-cathode electron sources. These applications are based on their unique properties that include large chemical-bond energies, large electronic band gap, and low electron affinities.

4.2 Light-Emitting Diodes

Much of the GaN research has been driven by the search for short-wavelength light-emitting diodes. An important milestone was reached by the introduction in 1994, by Nichia Chemical in Japan, of blue LEDs with emissivities above one candela. In order to understand the significant impact of such event it is important to view the progress of visible LEDs depicted in Fig. 8. All commercially available LEDs operating in the infrared to visible range (≈450–1500 nm) are fabricated using III–V compound semiconductors grown by chemical vapor-deposition techniques. The first LEDs were produced by General Electric in 1962, and consisted of $GaAs_{1-x}P_x$ epitaxial layers. The efficiency of LEDs has increased since then by about an order of magnitude per decade. Nitrogen was introduced as a dopant in the mid-1970s in order to enhance the emission efficiency of GaAsP, allowing the production of brighter red, yellow, and green LEDs. The use of heterojunctions and double heterostructures in the 1980s allowed greater confinement of free carriers and increased the efficiency of AlGaAs red LEDs beyond that of filtered incandescent lamps. The use of AlGaInP in the 1990s placed the efficiency of red and orange LEDs above the level of unfiltered incandescent lamps. Bright materials operating in the green to blue range were eagerly sought during this period. ZnSe-based materials were emphasized, but the ease of generation of lattice defects in these II–VI compounds impeded their commercialization. Severe difficulties were encountered in the initial efforts with the nitrides that were overcome in due course by

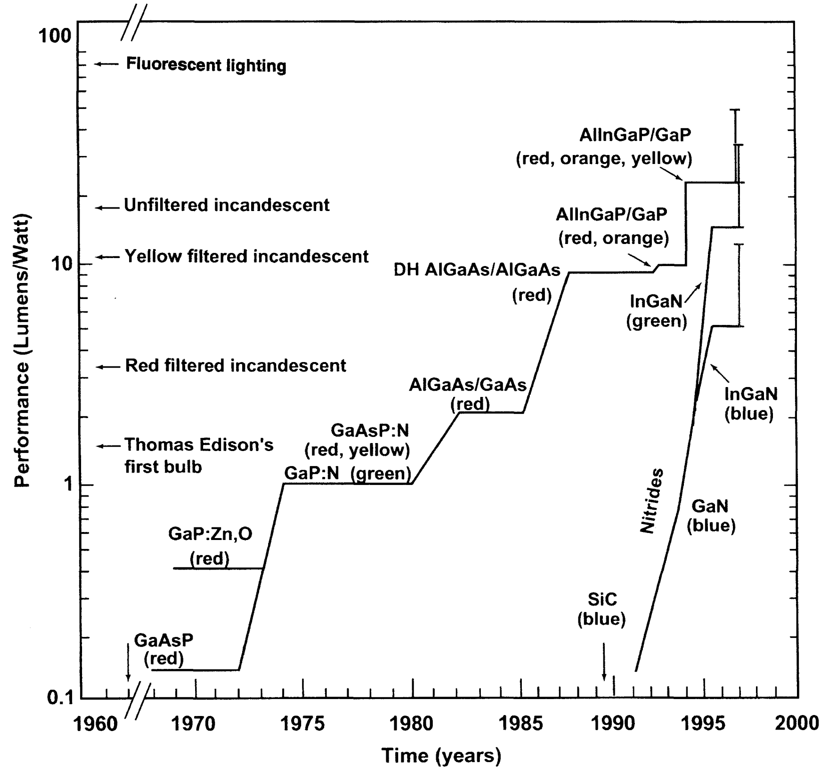

FIG. 8. Performance of light-emitting diodes through the years. The original branch was based on the arsenides and phophides, and started in 1962. Since then the light output (measured in lumens per watt) of devices has increased by about one order of magnitude per 10 years. In the 1990s, such performance surpassed that of the incandescent lamps used for interior lighting. The development of the nitrides advanced rapidly during the mid-1990s to reach similar levels of performance as the phosphides. (Ponce and Bour, 1997.)

key contributions described in Sec. 2.5. Great excitement resulted from the announcement by Nakamura (1994) of high-efficiency blue LEDs based on Group III nitride thin-film technology. Green LEDs were announced shortly after. With the introduction of quantum wells in the active region of the devices, Nakamura was able to gain another order of magnitude in power output. As a result, LEDs covering the full visible spectrum were commercially available by 1996, with efficiencies exceeding those from incandescent tungsten-filament lamps ($>10\,\mathrm{lm\,W^{-1}}$), long lifetimes (estimated at $>50\,000$ h for the nitride-based LEDs), and quick response times, and at competitive prices (Ponce and Bour, 1997). LEDs are currently being introduced into a number of applications; these are described as follows.

4.2.1 Traffic Lights Traffic lights utilize high amounts of energy since they must be turned on continuously. Tungsten-filament incandescent lamps lose a significant amount of power in the filtering process ($\approx 85\%$ for red, $\approx 30\%$ for green and amber). This makes monochromatic LEDs highly attractive. For example, a red (filtered) incandescent lamp using 170 W can be replaced with an LED array using only 19 W. In addition LEDs have longer lifetimes than incandescent lamps (several years versus several months, respectively), reducing replacement costs. Therefore, the use of LEDs causes significant economic savings

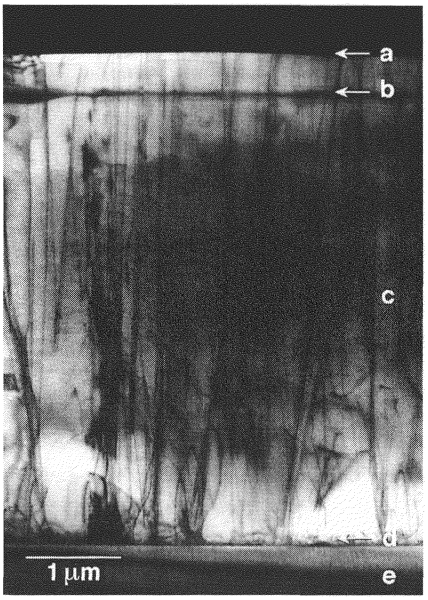

FIG. 6. High-efficiency blue LED viewed by cross-section transmission electron microscopy. A high dislocation density of $\approx 10^{10}\,\text{cm}^{-2}$ is observed. *a*, top surface of device; *b*, InGaN active region of device; *c*, GaN film; *d*, low-temperature buffer layer; and *e*, sapphire substrate. (Ponce and Bour, 1997.)

effect on device performance. The nitride semiconductors exhibit six orders of magnitude higher dislocation densities than other systems used for light emitters. Another interesting feature of GaN epitaxy on sapphire is the relatively low thermal stresses, which are inconsistent with the high growth temperature and the large difference in thermal expansion between the nitrides and sapphire. Dislocations should play a role in the relaxation of such thermal stresses and hence the relation between high dislocation densities and device performance.

3.3.2 Electrical Some electrical and optical properties of the nitrides are summarized in Table 10. As discussed in Sec. 2.6, high carrier densities are possible with use of Si and Mg as *n*-type and *p*-type dopants, respectively. Electron concentrations of $10^{19}\,\text{cm}^{-3}$ and hole concentrations in the mid 10^{17}-cm^{-3} range, at room temperature, are commonly achieved in laboratories today. Carrier mobility values are very sensitive to doping concentrations. Under low background impurity concentrations and low doping concentrations mobility values as high as $900\,\text{cm}^2\,\text{V}^{-1}\,\text{s}^{-1}$ and $20\,\text{cm}^2\,\text{V}^{-1}\,\text{s}^{-1}$ have been observed for *n*-type and *p*-type materials, respectively. Low-resistive device materials are achieved by optimizing the product of the carrier concentration and the mobility. Actual values used in devices typically corre-

and is bound to have a substantially desirable environmental impact.

4.2.2 Signals Bright outdoor signs, such as for advertising in streets and signaling in highways, require high light emissivity and longevity.

4.2.3 Interior Automobile Lighting Longevity makes LEDs highly desirable for interior automotive lighting and for monochromatic panel indicators.

4.2.4 Full-Color Large-panel Displays Large full-color, outdoor electroluminescent displays are currently available using AlInGaP LEDs for red and InGaP LEDs for green and blue.

4.2.5 Interior Lighting As manufacturing costs drop with increased mass production, considerations of energy savings and longetivity will apply to all types of lighting. This includes the home and the office, where permanent light fixtures could be installed to last the lifetime of the building.

4.3 Diode Lasers

Nakamura (1996) achieved pulsed blue laser operation based on the InGaN multiple-quantum-well structure shown in Fig. 9. Using a similar layered structure, Nakamura achieved continuous-wave operation for more than an extrapolated 10 000 h at room temperature (Ponce *et al.*, 1998). In early 1999 commerical blue-violet laser diodes operating at 400 nm were introduced by Nichia Chemical. Several important applications are envisioned for short-wavelength laser diodes based on nitride semiconductors; among them are the following.

4.3.1 High-Density Data Storage There exists a large market for data storage in the compact disk (CD) industry, which currently operates with 780-nm (near-infrared) diode lasers. The size of the bits of information in the CDs is associated with the optical diffraction limit of the optical lenses used during recording and reading of data. In this limit, the spot size is proportional to the wavelength of light. The use of violet–blue lasers operating at about 410 nm should produce a fourfold increment in the recording density. This is sufficient to produce a feature-length movie on a digital video disk (DVD) using current compression technology.

4.3.2 High-Resolution Printing Short-wavelength laser diodes should enable high-resolution printers, where the same reasoning as in CD technology applies. The smaller spot size associated with shorter wavelengths provides higher resolutions while maintaining an adequate depth of field and optical aperture size, *i.e.*, without a significant increase in the cost of the optical system. Higher power attainable from the nitride semiconductors should allow higher printing speeds. Higher on/off speeds (rise/fall times of ≈1 ns) should enable improved image quality. Such high-resolution raster-output systems would have application for printing directly on photographic film as well as for xerography (using photoconductive plates and charged toner). In the latter, the use of shorter wavelengths should minimize decomposition of commonly used organic photoconductor materials.

4.3.3 Projection Displays These include projection high-definition television where the current liquid-crystal modulation system is replaced by three diode lasers with $\lambda = 655$ (red), 530 (green), and 455 nm (blue). Current technology involves costly optical systems for collimating, splitting, polarizing, and recombining the primary color beams. The optical design is greatly simplified and the costs significantly reduced by the coherent, monochromatic, and polarized nature of the light from the diode lasers. In addition, a broader color gamut can be achieved compared with that of phosphor or of filtered light. Some big challenges lie ahead, however. The most important is perhaps achieving green laser action, which would require the use of InGaN (see following section on challenges).

4.3.4 Underwater Communications Nitride lasers operating in the blue–green range of the visible spectrum are desirable because water has a passband between 450 and 550 nm (blue–green region where transmission of light is maximized), and can be used for optical communications between submarine vehicles.

4.4 Solid-State Electronics

The nitrides are very attractive for solid-state electronics, in particular for high-temperature applications (such as inside nuclear reactors or automobile engines) and high-power electronics (as in power transmission and distribution systems, and microwave transmitters). This is due to the high carrier mobilities and wider band gap of devices based on nitride semiconductors. In addition to the intrinsic high carrier mobilities reported in Sec. 2.6, band-gap engineering has produced room-temperature electron mobilities in excess of $1700\,\mathrm{cm}^2\,\mathrm{V}^{-2}\,\mathrm{s}^{-1}$ using modulation-doped AlGaN/GaN structures. AlN has excellent electronic insulating properties and is used as a gate dielectric in field-effect transistors (FETs). Together with InGaN, high-transconductance FETs have been reported capable of handling large currents. For further information, see Chap. 16 in Pearton, 1997.

4.4.1 High-Temperature Electronics The wide band gap of the nitrides allows for semiconductor behavior at significantly higher temperatures. For instance, an intrinsic carrier concentration of $10^{15}\,\mathrm{cm}^{-3}$ is reached at ≈300 °C in silicon, at ≈500 °C in GaAs and at ≈1300 °C in GaN. Thus, cooling may not be necessary when the nitrides are used, bringing down the costs of fabrication of high-power devices (see e.g. Khan, 1995).

4.4.2 High-Power Electronics Higher breakdown fields are also a result of the wide band gap. For instance, breakdown fields for silicon and GaN are $(\approx 0.2 \text{ and } 3.0) \times 10^6\,\mathrm{V\,cm}^{-1}$, respectively. Applications for GaN power electronics include switching on power grids, automotive (specially the all-electric vehicle), military avionics, and industrial motor drives (see, *e.g.*, Wu, 1996).

4.4.3 Solar-Blind Electronics The ozone layers absorbs all the solar energy in the ultraviolet between 210 and 290 nm. Electronic devices operating in this range of frequencies enjoy the absence of optical ambient noise and are highly desirable for defense applications.

4.5 Cold Cathodes

Aluminum-containing nitrides, such as $Al_xGa_{1-x}N$, are known to have negative electron affinities. This characteristic makes them useful for electron emitters in a number of applications such as vacuum electronics, flat-panel displays, and electron sources for microscopy. The surface properties of the nitrides make them rugged to electron-induced decomposition, and provide the ability to operate in poor vacuum conditions, with longer operating lifetimes and with higher energy efficiency.

4.6 Challenges and Future Developments

It is surprising to see a high optoelectronic performance of the nitrides in spite of their high dislocation densities. Following conventional wisdom, it is believed that reducing the defect densities should produce increasingly superior materials. Currently blue–violet laser diodes are available. True blue laser diodes will require mastering the growth of $In_xGa_{1-x}N$ thin films with $x > 0.10$. Successful development of green laser diodes will require the growth of high indium concentrations of $In_xGa_{1-x}N$. If pure InN films become available ($\lambda \approx 605\,\mathrm{nm}$), a GaN/InN/GaN double heterostructure should provide orange–red diode lasers as well. On the shorter wavelength range, the development of ultraviolet diode lasers from $Al_xGa_{1-x}N$-based heterostructures should further increase optical data storage capacity by approximately another four times ($\lambda \approx 200\,\mathrm{nm}$ for AlN). The use of $B_xAl_{1-x}N$ should establish the maximum limit for data storage density within the nitride semiconductors.

5. SUMMARY

The nitride semiconductors have become important technological materials during the decade of the 1990s. This is based on their unique properties that include light emission in the visible and ultraviolet range, semiconductor properties at elevated temperatures, and low electron affinity. With the ability to produce high-quality semiconducting thin films, a number of applications are becoming commercially feasible. The advent of bright LEDs operating in the green and blue brings to an end the long search for bright solid-state sources covering the full range of the visible spectrum. The nitride-based LEDs have superior energy efficiency when compared with other means of light production, and their long device lifetimes make them economically desirable. Blue and ultraviolet laser diodes promise high-density storage, high-resolution printing, and compact, high-quality projection TV.

GLOSSARY

Band Gap: The minimum energy difference between the conduction band and the valence band. A direct band-gap transition involves only the emission of a photon, while an indirect band-gap transition requires the combination of a photon and a phonon (lattice vibration).

Bridgman Growth Technique: Method for crystal growth from the liquid phase, resembling the static freeze method. The ampoule containing the melt is moved within the furnace, while the freezing-point temperature remains fixed.

Chemical-Assisted Ion-beam Etching (CAIBE): Method to remove materials with use of highly reactive ion beams.

Cohesive Energy: Energy required to separate a solid into isolated atoms.

Cold Cathode: A surface that emits electrons purely by the effect of a voltage gradient, without thermal assistance. This is in contrast to thermionic emission, where the cathode is heated until electrons boil off the surface.

Czochralski Growth Technique: A common method to grow crystals from the melt. A seed is used to trigger growth at the top surface of the melt. With the use of appropriate thermal gradient and by pulling the seed away from the melt, a large boule can be produced. This technique is popular in the growth of silicon crystals for microelectronics.

Direct Band gap: See **Band Gap**.

Double Heterostructure: A sandwich of materials with two heterostructure interfaces. The use of double heteostructure improves carrier and optical confinement.

Electroluminescence: Light emission by direct conversion from electrical energy. An example is a *p–n* junction where electron–hole recombination generates light. See also **Light–Emitting Diode**.

Heterojunction: The junction of two dissimilar semiconductors that differ in their chemical composition and their doping levels.

High-Density Data Storage: Storage of information in the form of bits, using photographically defined structures and a laser probe.

High-Power Electronics: Electronic circuitry that operates at elevated current densities, such as found in electric utilities.

High-Temperature Electronics: Electronic circuitry designed for operation at high temperatures.

Incandescent Lamp: A light source that operates by heating of a filament by means of electronic current.

Indirect Band Gap: See **Band Gap**.

Light-Emitting Diode: A *p–n* junction that emits light when forward biased. The energy of light is typically close to the value of the band gap.

Metalorganic Chemical Vapor Deposition: A technique for growth of thin films by vapor transport, using organic compounds that react at the surface of the growth front.

Nitride Semiconductors: The semiconducting form of the Group III nitrides, including the binary compounds BN, AlN, GaN, and InN, as well as their alloys.

Nucleation Layer: Also referred as initiation layer and buffer layer. Thin film that is deposited at the very beginning of growth, at typically lower temperatures, in order to overcome surface tension and equilibrium nucleation kinetics. After the substrate is covered with the nucleation layer, temperature is raised for growth of the main film.

Sapphire: A crystalline variety of the mineral corundum (α-Al_2O_3), exhibiting a rhombohedral unit cell, with a three-fold axis along the diagonal. Sapphire is hard (9 on the Mohs scale), and highly stable at high temperatures and under corrosive environments. It is a substrate of choice for the growth of nitride semiconductors.

Wurtzite Lattice: Hexagonal crystalline form of zinc sulfide. A common lattice structure observed in most of the Group III nitrides, and in many II–VI compounds such as CdS.

Zincblende Lattice: Cubic form of zinc sulfide. A common lattice structure found in the binary III–V compounds such as GaAs and GaP and in binary II–VI compounds such as CdTe and ZnSe. It is also referred as the sphalerite structure.

INTRODUCTION

The topic of symmetry is a vast one. Books have been written about each one of the topics in the table of contents, and so our treatment perforce covers only some of the highlights.

Simple notions of symmetry are present in many considerations, but the central role of symmetry was not realized until the 20th century. In fact Wigner repeatedly argued that progress in physics was largely based on the ability to separate a physical problem into analyses of the laws of nature independently of the initial conditions. The latter are arbitrary and complicated while the former are general. Symmetries aid in formulating the regularities in physical laws without reference to the specific dynamics. To quote Gross (1995) in his tribute to Wigner, "Wigner argued that invariance principles provide a structure and coherence to the laws of nature just as the laws of nature provide a structure and coherence to a set of events".

In this article we attempt to provide a birds-eye view of the application of symmetry considerations to problems in atomic and molecular physics, condensed matter physics, particle physics, and field theory. The article is weighted to the last because conservation laws appear naturally as a consequence of continuous symmetries of the Lagrangian and are seen most clearly in this context. The brief description of symmetry in other phenomena is intended as an attempt at completeness.

The central mathematical tool in a discussion of symmetry is group theory. This was also realized by Wigner (1959) soon after the development of quantum mechanics. Much of the advance of physics has been based on the employment of techniques it provides —point groups, Lie groups, or more exotic creations.

1. SYMMETRIES OF RIGID BODIES

The symmetry transformations of a finite system such as an atom or a molecule consist of the set of transformations that leave the body unchanged. All such transformations are combinations of rotations and reflections. Rotations are through definite angles about specified axes and reflections are through a plane.

The usefulness of such an analysis is considerable. Not only does the symmetry restrict the form of the allowed interactions, but it also provides a simple method for finding selection rules of transition-matrix elements.

One must specify the order in which one performs operations since, in general, two operations do not commute: that is, performing a given rotation and then a reflection generally gives a different result from that of performing these operations in the reverse order.

A body is said to have an axis of symmetry of *n*th order if it is left unaltered by a rotation

digital Encyclopedia of Applied Physics

of $2\pi/n$ about a given axis. We denote this operation symbolically by R_n. Repeating this operation n times gives us back the identity transformation, which we denote by E, and so we write

$$R_n{}^n = E. \tag{1}$$

Symmetry transformations of finite bodies must leave at leave at least one point invariant. Symmetry groups having this property are known as *point groups*. Landau and Lifshitz (1981) give the description of these groups. They are classified as $C_n, S_{2n}, C_{nh}, C_{nv}, D_n, D_{nh}$, D_{nd}, the tetrahedron group, the octahedron group and the icosahedron group. The simplest example, C_n, has already been described. C_{nh} and C_{nv} are obtained by adding to the axes in C_n planes of symmetry that respectively are perpendicular to or pass through a symmetry axis. D_n has two symmetry axes, one of nth order and a second one perpendicular to the original axis. D_{nh} and D_{nd} are defined by adding planes of symmetry in addition to the axes of symmetry. S_{2n} is a group with $2n$ elements defined by symmetry transformations about axes defined by combinations of rotations and reflections. Two continuous groups are also possible symmetry groups, namely the full rotation group and the group of rotations about a fixed axis. It is clear that a spherically symmetric body's appearance is unchanged by an arbitrary rotation and a cylindrically symmetric one's by a rotation about the axis of symmetry.

The analysis of the matrix elements of operators between atomic or molecular states is enormously simplified through the classification of the states by their transformation properties under the rotation group—*e.g.*, for atoms the S, P, D, etc. states. To pick a more sophisticated example consider the ammonia molecule, NH_3, which one may picture in terms of the plane defined by the location of the three hydrogen atoms with the nitrogen atom free to oscillate through the plane. The group of transformations that leave the molecule in its equilibrium state invariant is C_{3v}. The analysis proceeds by studying the group properties of C_{3v} on the space of the coordinates of the four atoms. For an excellent pedagogical review of this case see Lax's book (Lax, 1974).

2. SYMMETRIES OF CRYSTALS

The symmetries of atoms and molecules are described by rotations and reflections. At least one point in the body must be left unchanged by the combination of transformations; *e.g.*, a single body cannot be transformed into itself by successive rotations about two nonintersecting axes.

For infinite crystals, there is another type of symmetry transformation, namely translations. This is a vast subject, of which we can do no more than present a few highlights. For good introductions to the subject see the text by Ashcroft and Mermin (1976).

As we already said, symmetry operations are combinations of rotations, reflections, and translations. Rotations about a given axis combined with a translation perpendicular to the axis do not give a new symmetry; they are simply equivalent to the original rotation, but now about an axis parallel to the first one. Similarly reflections through a plane combined with displacements perpendicular to the plane do not give new symmetries.

On the other hand, if we combine a rotation about an axis with a displacement along the same axis we do obtain a new type of symmetry. The axis is known as a screw axis. In an n-fold screw, the system repeats itself after a rotation by $2\pi/n$ and a displacement by some distance d.

Similarly reflection through a plane combined with a displacement parallel to the plane leads to a so-called glide reflection plane symmetry, in which the lattice has symmetry through the simultaneous operations of reflection and translation.

The structure of a crystalline lattice is described most easily making use of the concept of the Bravais lattice, which specifies the the periodic ordering of the units of the lattice. These units may be atoms, molecules or other entities. All we are interested in now is their location. The Bravais lattice is defined as the set of all position vectors $\boldsymbol{R}$ such that

$$\boldsymbol{R} = n_1\boldsymbol{a}_1 + n_2\boldsymbol{a}_2 + n_3\boldsymbol{a}_3 \tag{2}$$

where $\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3$ are three vectors not all lying in the same plane and n_1, n_2, n_3 are allowed to range through all the values of the integers. The vectors $\boldsymbol{a}_i$ are called primitive vectors and are said to span the lattice. In general there are many inequivalent choices of primitive vectors for any given Bravais lattice.

The primitive unit cell is defined as that volume of space which, when translated by the allowed vectors of the Bravais lattice, fills all of space without leaving any voids. For a cubic lattice, *e.g.*, it is simply a cube. Once again there is no unique choice of the primitive cell.

The symmetries of a crystal are usually classified by the simpler set of symmetries of the underlying Bravais lattice. The set of operations that take the Bravais lattice into itself is known as the symmetry group or space group of the Bravais lattice. The space group can be shown to consist of

1. translations through Bravais lattice vectors,
2. operations, *i.e.*, rotations and reflections, that leave a particular point of the lattice fixed, and
3. combinations of the first two.

The subset of the symmetry group that leaves a particular point in the Bravais lattice fixed is known as the point group of the Bravais lattice. There are only seven distinct point groups and hence seven crystal systems. Relaxing the restriction to point groups, one finds 14 distinct symmetry groups and hence 14 independent Bravais lattices. The symmetry group of a crystal structure is still larger, depending on both the symmetry of the object and the symmetry of the underlying Bravais lattice. For crystals of arbitrary shape based on arbitrary Bravais lattices, there are 230 possible space groups. For a discussion of these we refer the reader to the text by Ashcroft and Mermin (1976).

A fundamental concept to which one is led in the analysis of periodic structures is that of the reciprocal lattice. In particular, it is the key tool for systematizing discussions of diffraction scattering. Consider a plane wave $e^{i\boldsymbol{k}\cdot\boldsymbol{r}}$. In general the plane wave will not have the symmetries of the Bravais lattice; *i.e.*, translation through a vector $\boldsymbol{R}$ will not leave the plane wave unchanged; but there is a set of vectors $\boldsymbol{K}$ for which the wave is unchanged by translations through $\boldsymbol{R}$. They satisfy

$$e^{i\boldsymbol{K}\cdot\boldsymbol{R}} = 1. \tag{3}$$

The vectors $\boldsymbol{K}$ form what is called the reciprocal lattice. It is straightforward to show that the reciprocal lattice is itself a Bravais lattice. The primitive cell of the reciprocal lattice is known as the first Brillouin zone. The great usefulness of the reciprocal lattice lies in the fact that, because of the above equation, when rays or neutrons are scattered from a crystal, the scattering is coherent if the momentum transfer is $h\boldsymbol{K}$, with $\boldsymbol{K}$ a reciprocal lattice vector and h equal to Planck's constant. The pattern of bright spots due to the coherent scattering allows us to reconstruct the crystal structure.

An interesting development in crystal symmetry of the past decade is the discovery of *quasicrystals*, an intermediate between crystal structures and glassy structures. The former, as we have already seen, have

1. long-range translational order and
2. long-range order under rotations and reflections.

A glassy structure, by contrast, has none of the above. Quasicrystals have long-range translational and rotational order. However, the translational order is of a subtler kind: it is quasiperiodic rather than periodic. Quasicrystals also may have rotational symmetries that are not allowed for ordinary crystals. Their group-theoretical analysis leads to some interesting new properties (Steinhardt and Ostlund, 1987).

3. SYMMETRIES AND THE LORENTZ GROUP

We now turn to the main subject of this review, namely symmetries and conservation laws. In quantum mechanics an operator A that has no explicit time dependence is said to be conserved if its commutator with the Hamiltonian of the system, H, vanishes:

$$[H, A] = 0. \tag{4}$$

A state is represented by a normalized vector Ψ in Hilbert space, where Hilbert space is a complex vector space (Weinberg, 1995). Observables are represented by Hermitian operators A, linear mappings $\Psi \to A\Psi$ of the Hilbert space into itself. The probability of a measurement yielding the result that a state Ψ is in one of a set of states represented by mutually orthogonal vectors Ψ_n is given by

$$P = (\Psi, \Psi_n)^2. \tag{5}$$

A symmetry operation is one that does not change the results of possible experiments; *i.e.*, if Ψ and Ψ' are two states related to one another by a symmetry transformation, then

$$(\Psi, \Psi_n)^2 = (\Psi', \Psi'_n)^2. \tag{6}$$

What we are saying is that if an observer O makes a measurement and obtains a result, an observer O' related to O by a symmetry transformation will obtain the same result.

In Wigner's (1959) pioneering work in the 1930s, he showed that to satisfy the above equation Ψ had to be related to Ψ' by either a unitary or an antiunitary transformation U. Both take the form

$$U^\dagger = U^{-1} \tag{7}$$

Unitary transformations can be discrete or continuous. We treat discrete symmetry transformations in Sec. 5 and here concentrate on continuous ones. The transformation $U = 1$ is of course just the identity. Continuous transformations that differ infinitesimally from the identity are represented by

$$U = 1 + i\varepsilon t \tag{8}$$

where ε is an infinitesimal real parameter and t is an operator. The fact that U is unitary means that t is Hermitian and therefore a physical observable.

Symmetry transformations forming a group are of particular interest. A group has multiplication and an inverse defined for each element. A set of symmetry operations forming a group corresponds to a set of unitary transformations $U(T)$ acting on the vectors Ψ of the Hilbert space.

Of particular interest in physics are the connected Lie groups. They are continuous groups; any element of the group can be connected to the identity by a path that lies within the group space. This allows us to describe the group elements by infinitesimal transformations, because any finite transformation can be built up by an infinite sequence of infinitesimal transformations. We therefore write

$$U(T(\theta)) = 1 + i\theta_a t_a + \cdots \tag{9}$$

The t_a are the generators of infinitesimal transformations, repeated indices are assumed to be summed over, and we take $a = 1, 2, \ldots, n$. The condition of group multiplication requires the t_a to satisfy a set of consistency conditions, which can be expressed as commutation relations:

$$[t_a, t_b] = iC_{abc}t_c \tag{10}$$

with C_{abc} a set of numbers, the so-called structure constants of the group. This set of commutation relations form what is called a Lie algebra and characterize the group. If all the commutators vanish, or eqivalently all the structure constants are zero, we have what is called an Abelian Lie group. In this case the finite transformations can be trivially built up out of infinitesimal ones and we obtain

$$U(T(\theta)) = \exp(i\theta_a t_a). \tag{11}$$

In general, Lie groups are non-Abelian.

The most important symmetry operations are the rotations, the translations, and the Lorentz boosts. To these we append the discrete reflection transformations. These operations form the so called Poincaré group or inhomogeneous Lorentz group (the homogeneous Lorentz group is the latter minus translations). The coordinate transformation corresponding to such an operation is

$$x'_\nu = \Lambda^\mu_\nu x_\mu + a_\nu. \tag{12}$$

In the above a_ν is the four-vector corresponding to translations and Λ^μ_ν the tensor corresponding to rotations and boosts. The equivalence of inertial frames dictates that the latter must satisfy

$$\eta_{\mu\tau}\Lambda^\mu_\sigma\Lambda^\tau_\rho = \eta_{\sigma\rho} \tag{13}$$

where $\eta_{\mu\nu}$ is the diagonal matrix

$$\eta_{11} = \eta_{22} = \eta_{33} = 1, \quad \eta_{00} = -1. \tag{14}$$

For the identity transformation, we simply have Λ^ν_μ equal to the Kronecker delta. For infinitesimal transformations we have

$$\Lambda^\mu_\nu = \delta^\mu_\nu + \omega^\mu_\nu$$

and

$$U(\omega,\varepsilon) = 1 + \frac{1}{2}i\omega_{\mu\nu}J^{\mu\nu} - i\varepsilon_\mu P^\mu. \tag{16}$$

The four components of P_μ, the generator of infinitesimal translations, are respectively P_0, the Hamiltonian or energy of the system, and P_i, the three-vector momentum (the latin indices take on values $1,2,3$ as opposed to greek indices which take values $0,1,2,3$). $J_{\mu\nu}$ is an antisymmetric tensor with six independent components: J_{23}, J_{31}, J_{12} are the generators of infinitesimal rotations, labelled as $J_i = \varepsilon_{ijk}J_{jk}$. The J_{i0} are the generators of Lorentz boosts, K_i.

The commutators, which specify the algebra of the group, are

$$[J_i, J_j] = -[K_i, K_j] = i\varepsilon_{ijk}J_j, \tag{17}$$

$$[J_i, K_j] = i\varepsilon_{ijk}K_k, \tag{18}$$

$$[J_i, P_j] = i\varepsilon_{ijk}P_k, \tag{19}$$

$$[K_i, P_j] = iH\delta_{ij}, \tag{20}$$

$$[K_i, H] = iP_i, \tag{21}$$

$$[J_i, H] = [P_i, H] = [H, H] = 0. \tag{22}$$

The above imply that $\boldsymbol{J}$, $\boldsymbol{K}$, $\boldsymbol{P}$, whose Cartesian components are J_i, K_i, P_i, are all vectors under ordinary spatial rotations and that J_i, P_i, H are all conserved quantities, *i.e.*, constants in time. To rephrase these results in a more intuitive manner, note that if H is invariant under a continuous symmetry U, we have $UHU^{-1} = H$. This implies that the generator of infinitesimal transformations commutes with the Hamiltonian. The last of the array of equations above simply restates then that the Hamiltonian is invariant under rotations and space-time translations.

4. CONSERVATION LAWS AND NOETHER'S THEOREM

Classical mechanics can be formulated by the principle of least action. This states that for all paths that go from a fixed q_1 at time t_1 to a fixed q_2 at time t_2, the physical trajectory corresponds to a stationary value of the action

$$I = \int_{t_1}^{t_2} \mathrm{d}t\, L(q(t), \dot{q}(t)), \tag{23}$$

where $L(q,\dot{q})$ is the Lagrangian of the system. The stationarity of the action implies in turn Lagrange's equations

$$\frac{\partial L}{\partial q} - \frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{q}} = 0. \tag{24}$$

For the simplest cases L is the difference between the kinetic and the potential energy of the system and is unchanged by the addition of a total time derivative.

An alternative formulation of mechanics makes use of the Hamiltonian, which is simply related to the Lagrangian by

$$H = p\dot{q} - L, \tag{25}$$

with p the momentum conjugate to q, defined as

$$p = \frac{\partial L}{\partial \dot{q}}. \tag{26}$$

Hamilton's equations can be shown to follow from the principle of least action (Itzykson and Zuber, 1980). For a system described by N independent coordinates and hence $2N$ independent variables, we extend the principle straightforwardly and obtain N independent Lagrange's equations.

Let us now consider continuous infinitesimal changes of coordinates $q_i \rightarrow q_i + \varepsilon\Delta q_i$ where ε is an infinitesimal parameter and Δq_i is a deformation of q_i. Such transformations are symmetry operations if they leave the equations of motion unchanged. This is ensured if L is invariant or, more generally, only changes by a total time derivative (in both cases the action is unchanged):

$$\begin{aligned}\Delta L &= \frac{\partial L}{\partial q_i}\Delta q_i + \frac{\partial L}{\partial \dot{q}_i}\Delta \dot{q}_i + \frac{\mathrm{d}C}{\mathrm{d}t}\\ &= \frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial L}{\partial \dot{q}_i}\Delta q_i + C\right] + \Delta q_i\left[\frac{\partial L}{\partial q_i} - \frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{q}_i}\right].\end{aligned} \tag{27}$$

Repeated indices (in this case $i = 1, 2, \ldots, N$) are assumed to be summed over. The second term in the above equation vanishes because of

Lagrange's equations. We see that a continuous symmetry of L, which implies $\Delta L = 0$, leads to the existence of a conserved quantity, namely a quantity whose time derivative is zero,

$$Q = \frac{\partial L}{\partial q_i} \Delta q_i + C = p_i \Delta q_i + C. \qquad (28)$$

This is Noether's theorem.

For systems with an infinite number of degrees of freedom, we introduce the concept of a field $\phi(x)$ where x is a continuous variable denoting time and spatial locations. Again this is readily generalizable to N independent fields. We introduce a Lagrangian density $\mathscr{L}$ and the action is now

$$I = \int \mathrm{d}^4 x \mathscr{L}(x). \qquad (29)$$

The Lagrange equations for the fields take the form

$$\frac{\partial \mathscr{L}}{\partial \phi(x)} - \partial_\mu \frac{\partial \mathscr{L}}{\partial [\partial_\mu (\phi(x))]} = 0 \qquad (30)$$

The least-action principle once again leads to conservation laws. Consider, for instance, the effect of translation of the coordinates by $x \to x + a$. The change in the Lagrange density is

$$\mathscr{L}[x + a] = \mathscr{L}[\phi(x + a), \partial_\mu \phi(x + a)]. \qquad (31)$$

For an infinitesimal displacement, the variation of the action is given by

$$\delta I = \int \mathrm{d}^4 x \left[\partial_\nu \mathscr{L} - \partial_\mu \left[\frac{\partial \mathscr{L}}{\partial (\partial_\mu \phi)} \partial_\nu \phi(x) \right] \right] \delta a^\nu = 0 \qquad (32)$$

From the vanishing of δI for arbitrary δa^μ we deduce the existence of a tensor $T^{\mu\nu}$ satisfying the conservation law

$$\partial_\mu T^{\mu\nu} = 0 \qquad (33)$$

where the tensor, known as the energy-momentum tensor, is defined as

$$T^{\mu\nu} = \frac{\partial \mathscr{L}}{\partial (\partial_\mu \phi)} \partial_\nu \phi - \eta_{\mu\nu} \mathscr{L} \qquad (34)$$

The $\eta_{\mu\nu}\mathscr{L}$ term in the above equation is the analogue of the $\mathrm{d}C/\mathrm{d}t$ term defined earlier. From the form of the Lagrangian density, it usually follows that the energy-momentum tensor is explicitly symmetric in μ and ν. If this is not the case, one defines a modified energy-momentum tensor, which has the desired symmetry. Since $T^{\mu\nu}$ is conserved, we can also define four conserved charges

$$P^\nu = \int \mathrm{d}^3 x T^{0\nu}, \qquad (35)$$

which are time independent if the fields vanish sufficiently fast at spatial infinity so that

$$\int \mathrm{d}^3 x \partial_i T^{i\nu} = 0. \qquad (36)$$

As before latin indices $i = 1, 2, 3$ refer only to spatial components. This implies that

$$\partial_0 P^\nu = \int \mathrm{d}^3 x \partial_0 T^{0\nu} = \int \mathrm{d}^3 x \partial_\mu T^{\mu\nu} = 0. \qquad (37)$$

The conserved quantities P^ν we have just defined are of course the four components of a four-vector and are simply the energy and momentum of the system as described in the previous section. They are also the generators of infinitesimal time and space translations.

So far we have discussed space-time symmetries. As we shall see shortly, Noether's theorem is also useful for internal symmetries.

5. DISCRETE SYMMETRIES: *T*, *C* AND *P*

Discrete symmetries play an important role in field theory. Space reflection corresponds to the improper Lorentz transformations, which reverse the signs of coordinates leaving time unchanged—*i.e.*, under space reflection

$$\mathbf{x}' = -\mathbf{x}, \quad t' = t; \qquad (38)$$

and, under time reflection, $t' = -t$ while spatial coordinates are unchanged. Under a parity transformation scalars and axial vectors are invariant while vectors change sign. A pseudoscalar, which may be thought of as the invariant product of a vector and an axial vector, is of course an invariant under rotations, but changes sign under parity transformations.

Charge conjugation C relates particles with equal masses and spins, but opposite charges, *i.e.*, it relates particles to antiparticles. As an example, it changes electrons into positrons, protons into antiprotons, and π^+ into π^-. Some particles are their own antiparticles. The photon is one such example: charge-conjugation invariance of the theory implies that the photon changes under C into minus itself since electrons change into positrons; these couple to photons as electrons do, but with the opposite sign.

In a second-quantized formalism the Lagrangian is written in terms of fields, which are themselves linear combinations of creation and annihilation operators. For a charged scalar field $a(k)$ and $b(k)$ are the annihilation operators for quanta of opposite charges, so that, *e.g.*, $a(k)$ annihilates quanta of charge $+1$ while $b^\dagger(k)$ creates quanta of charge -1. In both cases the charge of the system is increased by the action of the operator. One of the types of particles associated with the quanta is called particle and the other antiparticle. As mentioned, some particles, such as the photon, may be their own antiparticles.

There exists a unitary operator $\mathscr{C}$ which takes the fields for particles into those for antiparticles. This is the field-theoretical version of charge conjugation. For instance, the photon field $A_\mu(x)$ transforms into minus itself, *i.e.*,

$$\mathscr{C} A_\mu(x) \mathscr{C}^\dagger = -A_\mu(x). \tag{39}$$

For the charged scalar field

$$\mathscr{C} a(k) \mathscr{C}^\dagger = b(k) \tag{40}$$

In a classic series of experiments in the 1950s, following the suggestion of Lee and Yang (1956), conservation of parity was found to be maximally violated. It was believed at the time that CP, the combined operation of parity and charge reflection, was a good symmetry, but this was disproved by the observation in 1964 of the long-lived kaon decaying into two pions (Christenson *et al.*, 1964).

It is still believed, however, that though T, C, and P are individually not conserved, invariance under the combined operation of TCP holds. The validity of this belief, derived from the existence of local relativistic quantum field theory (Streater and Wightman, 1968), ensures the equality of masses and lifetimes of particles and antiparticles. We discuss tests of these invariances in the last section of the article.

6. INTERNAL SYMMETRIES

We have so far considered symmetries associated with Lorentz transformations. There are also many internal symmetries of systems, generally associated with new quantum numbers. An example is isospin, the symmetry that relates protons to neutrons. By analogy with an ordinary spin-$\frac{1}{2}$ field for which the $S_3 = \pm\frac{1}{2}$ components are related by spatial rotations, we imagine the proton and neutron to be an isospin $I_3 = \pm\frac{1}{2}$ doublet.

The internal symmetries we consider in this section are global symmetries as distiguished from local symmetries; in the former the transformations are independent of space-time, *i.e.*, all protons in a nucleus are rotated by the same amount when we apply an isospin rotation to the state of a nucleus. For local or gauge symmetries, on the other hand, the transformation itself is a function of space-time, *i.e.*, protons in different locations would be rotated by different amounts.

There is another important difference between global and local symmetries: the former are generally broken; in fact many theorists believe there are no exact global symmetries. On the other hand local or gauge symmetries are believed to be conserved in the absence of spontaneous symmetry breaking (this occurs when the Lagrangian is symmetric, but the ground state, or vacuum, of the system is not symmetric). Local symmetries are discussed in Sec. 8.

Taking for granted that the symmetries (from now on in this section we refer to global symmetries) are broken, they may nevertheless be very useful to study, particularly if the breaking is small. Isospin symmetry is a good example; the strong interactions that bind nucleons in a nucleus are believed to be approximately symmetric under an isospin rotation. Electromagnetism obviously distinguishes between protons and neutrons since the former have electric charge and the latter do not. On the other hand electromagnetism usually leads to only small perturbations in nuclei and, after all, the proton and neutron masses only differ by one part in two thousand; isospin is a useful symmetry for nuclei.

In the early 1960s the concept of isospin was extended by Gell-Mann and Neeman (Cheng and Li, 1984) to unitary symmetry, or SU(3), with spectacular success. In SU(3) strangeness, an additional quantum number of hadrons that is conserved in the strong interactions was unified with isospin. The baryons, the pseudoscalar mesons, and vector mesons were found to lie in octet representations, and the baryon resonances in a decuplet representation; and a variety of predictions regarding masses, mixings and decays were found to be true with remarkable precision. Once again symmetry proved a powerful tool.

For the above reasons it is useful to begin by treating these symmetries as if they were exact and look at Noether's theorem (see Sec. 5). We also saw in Sec. 4 how continuous Lie groups were defined. Let us begin to apply some of these notions.

Consider a set of N real scalar fields $\phi_1 \cdots \phi_N$, which we will label as ϕ_i with i running from 1 to N. We assume that the fields belong to a representation of a group G; that is, the fields may be thought of belonging to an N-dimensional vector space acted on by the rotations in G. Calling the Lagrangian density $\mathscr{L}$ as before and assuming that it is a function of ϕ_i and its derivatives, we consider variations of the fields

$$\delta\phi_i(x) = i\varepsilon_a(t_a)_{ij}\phi_j(x) \tag{41}$$

where ε_a is taken to be an infinitesimal quantity assumed independent of space and time. As before, repeated indices are summed over.

If the Lagrangian density is invariant under the rotation in question we have, using Lagrange's equations,

$$\delta\mathscr{L} = \partial_\mu \frac{\delta\mathscr{L}}{\delta(\partial_\mu\phi_i)}\delta\phi_i + \frac{\delta\mathscr{L}}{\delta(\partial_\mu\phi_i)}\partial_\mu(\delta\phi_i), \tag{42}$$

which, on substituting the value for $\delta\phi_i$, implies

$$\delta\mathscr{L} = \varepsilon_a\partial_\mu\left[\frac{\delta\mathscr{L}}{\delta(\partial_\mu\phi_i)}i(t_a)_{ij}\phi_j\right]. \tag{43}$$

Since the Lagrangian is invariant and the above vanishes for any ε_a, we see that the quantity in the square brackets is a conserved current

$$J_{\mu,a} = -i\frac{\delta\mathscr{L}}{\delta(\partial^\mu\phi_i)}(t_a)_{ij}\phi_j. \tag{44}$$

The charges, defined by

$$Q_a = \int d^3x J_{0,a}(x), \tag{45}$$

can also be written, using the definition of conjugate momentum,

$$Q_a = -i\int d^3x \pi_i(t_a)_{ij}\phi_j. \tag{46}$$

Using the equal-time commutation relations between fields and their conjugate momenta, one can easily prove that the charges satisfy in turn the same commutation relations as the generators of the group G, *i.e.*,

$$[Q_a(t), Q_b(t)] = iC_{abc}Q_c(t). \tag{47}$$

The charges are all evaluated at the same time since the commutation relations of the fields and their conjugate momenta are specified at equal times. These relations are called, for obvious reasons, the algebra of charges.

Interestingly enough, since the commutation relations of fields and conjugate momenta hold in any case, these relations hold even if the symmetry is broken. This observation was the starting point for the major development of current algebra in the 1960s (Adler and Dashen, 1968).

This subject is a broad one in itself, but at its roots there is the important identification of the currents associated with the generators of the symmetry with the currents observed in the weak interactions. By this we mean the following: the form of the weak interactions, originally proposed by Fermi in 1934, with suitable modifications, was seen to be an adequate phenomenological description of the weak interactions. It states that the effective

Hamiltonian is

$$H_{weak} = G_F J_\mu J^\mu, \tag{48}$$

where $J_\mu(x)$ is a charged current of the $V - A$ form, namely with equal vector and axial vector parts (Commins and Bucksbaum, 1983).

The initial step was to identify the vector part of this current with the current of the isospin-raising generator; this has many important physical consequences. It not only dictates that the weak current must connect any two particles that lie in an isospin multiplet and differ by one unit of charge (*e.g.*, π^+, π^0), but also specifies the relative normalization of the matrix elements.

This hypothesis, the so called conserved vector-current hypothesis, was confirmed experimentally and extended to an interpretation of the strangeness-changing currents as the currents in the generators of the strangeness operators in the algebra of SU(3). It also became natural then to look for a group-theoretical or symmetry counterpart of the axial currents in the weak interactions.

The algebra of SU(2), with charges Q_a, was extended to an algebra of SU(2) × SU(2) by the inclusion of pseudoscalar charges Q_a^5 with commutation relations

$$[Q_a^5, Q_b^5] = i\varepsilon_{abc}, Q_c \tag{49}$$

$$[Q_a, Q_b^5] = i\varepsilon_{abc} Q_c^5, \tag{50}$$

$$[Q_a, Q_b] = i\varepsilon_{abc} Q_c. \tag{51}$$

This of course can then be generalized to SU(3) × SU(3). This is the historical path. The modern point of view relies heavily on these notions, but incorporates in a central way the notion of spontaneous symmetry breaking, which we turn to next.

7. BROKEN SYMMETRIES AND GOLDSTONE BOSONS

Symmetries of the Lagrangian may be broken explicitly by the introduction of noninvariant terms. More subtly, the Lagrangian may be invariant, but not the physical vacuum or ground state. We distinguish the physical vacuum from what we call the bare vacuum: the former is the true ground state of the system while the latter is the state with no particles or excitations. The physical or true vacuum and the bare vacuum may not coincide, as is the case in, *e.g.*, superconductivity, where the true vacuum contains a superposition of Cooper pairs.

If a continuous symmetry of the Lagrangian is not a symmetry of the physical vacuum, we say that the symmetry is spontaneously broken. To refer back to the case of superconductivity, the Lagrangian has a U(1) symmetry associated with gauge transformations of electromagnetism. The vacuum, on the other hand, does not possess this symmetry since it contains electron pairs.

In general the spontaneous breaking of a continuous symmetry leads to the the existence of massless scalar bosons, usually called Nambu–Goldstone bosons or simply Goldstone bosons (Weinberg, 1995). To see how such a phenomenon arises we can begin by observing that a global rotation of the vacuum (of course here and in what follows we mean the physical vacuum or ground state) costs no energy, or, in other words, vacua differing only by a global rotation are degenerate in energy. Vacua differing by a local rotation differ in energy by the shear energy associated with the deformation of the vacuum. The energy of the shear goes to zero as the wave number goes to zero. In a quantum field theory, there exist states, connected to the physical vacuum by these local rotations, that are degenerate in energy and are populated by quanta whose energy goes to zero as their momentum goes to zero. They are therefore zero-mass bosons, referred to usually as Goldstone bosons. An important caveat, which we discuss in more detail later, is that these massless quanta are not observable in all cases. The number of types or species of such bosons is related to the degree of reduction of the symmetry, *i.e.*, how much less symmetry the vacuum has than the Lagrangian. An explicit field-theoretical example may be helpful.

Consider a theory of scalar fields invariant under the three-dimensional rotation group O(3), now, however, an internal symmetry group. Let the scalars be in the vector, or three-dimensional, representation of the group. The scalars are described by fields $\phi_a(x)$ with

$a = 1, 2, 3$, and an effective potential

$$V(\phi) = -\mu^2\phi^2/2 + \lambda\phi^4/4 \tag{52}$$

with μ a mass and λ a dimensionless coupling constant. As shorthand we have used ϕ^4 equal to the square of $\phi^2 = \phi_a\phi_a$.

The fields ϕ cannot have the usual interpretation as quantum fields since the mass term is negative and hence unphysical. Corresponding to this, the minimum of the potential is not at $\phi^2 = 0$, but rather at $\phi^2 = \mu^2/\lambda = v^2$. Normally in quantum field theory one expands about the minimum of the potential in fields that are described by excitations about the minimum. In this case the minimum of the potential corresponds to a value of ϕ with modulus equal to v, and so the quantum excitations are about this point and not about $\phi = 0$. We say then that in the true vacuum ϕ takes on a nonzero value and the expansion in quantum excitations needs to be made about this value. Pick then a direction in O(3), say the third direction, and let

$$\tilde{\phi}_a = \phi_a - (0, 0, v). \tag{53}$$

The vacuum expectation value (vev) of the field $\tilde{\phi}_a$ is zero while the vev of ϕ_a is

$$\langle 0|\phi_a|0\rangle = (0, 0, v). \tag{54}$$

The fields $\tilde{\phi}_a$ have zero vev and hence may be described in terms of the usual creation and annihilation operators, *i.e.*, they have a standard quantum interpretation. Let us now examine the potential given above as a function of the physical fields. We find, after some algebra, that

$$V(\tilde{\phi}_a) = \mu^2\tilde{\phi}_3^2 + 2v\tilde{\phi}_3\tilde{\phi}^2 + \lambda\tilde{\phi}^4/4 \tag{55}$$

where we have dropped an overall constant and $\tilde{\phi}^2 = \tilde{\phi}_a\tilde{\phi}_a$.

Looking at the quantum fields, $\tilde{\phi}_a$, we see that the first two components are massless while the third has a positive mass. Let us recapitulate what we have found, suitably phrased so that we may generalize our conclusions. We started with a Lagrangian which was explicitly O(3) invariant, but the vacuum was not invariant, as we saw when the field ϕ_3 was shown to have a nonzero vev. This breaking selected a preferred direction in O(3) space which we took to be the third direction, but which was chosen arbitrarily. In terms of canonical or physical fields, we found one massive field, $\tilde{\phi}_3$, and two massless scalar fields, namely the other two components of $\tilde{\phi}_a$.

The symmetry of the Lagrangian, which was O(3), was reduced to rotations about the third axis, so that the symmetry associated with rotations about the 1 and 2 axes was lost. At the same time we saw the appearance of two massless scalar fields. We studied a particular example, but the situation is general. The massless scalars, also known as Goldstone bosons or Goldstone modes, are a general feature of spontaneously broken symmetries. They appear in particle physics, but they also appear in a variety of condensed matter physics problems, *e.g.*, as spin waves in antiferromagnets (Fradkin, 1991).

SU(2) × SU(2) and even SU(3) × SU(3) appear to be good symmetries of the strong interactions. Why is this so? In a simple model of a free proton and neutron, the breaking of vector SU(2) is proportional to the proton-neutron mass difference:

$$\begin{aligned}[Q_a, H] &= i\int d^3x\partial_0 J_a^0 \\ &= \int d^3x\partial_\mu J_a^\mu \sim (M_p - M_n);\end{aligned} \tag{56}$$

but the breaking of the axial SU(2) is proportional to the sum of the neutron and proton masses and hence is apparently not small (Cheng and Li, 1984); however, the symmetry may be spontaneously broken. This requires a triplet of massless pseudoscalars (pseudoscalars rather than scalars since the symmetry is an axial symmetry); they are the Goldstone bosons of the theory. In this case we identify them with the pions. A theory with nucleons and pions can have SU(2) axial symmetry if either nucleons or pions are massless.

One way to understand the smallness of the symmetry breaking is to begin a discussion of the quark model as proposed by Gell-Mann and Zweig (Cheng and Li, 1984). Just as the constituents of nuclei are taken to be protons and neutrons, a doublet or two-component representation of SU(2), so we take the fundamental constituents of neutrons, protons, and other elementary particles to be quarks, the triplet or three-dimensional representation of SU(3).

The three species of quarks are known as the up, the down and the strange quarks or the u, d and s quarks, often written as q_i with $i = 1, 2, 3$. Mesons are bound states of a quark and an antiquark, while baryons are bound states of three quarks. The strong interaction that binds these quarks is taken to be invariant under SU(3) × SU(3) (more about this in the next section) as is the kinetic energy term, so that the only breaking of the symmetry in the Lagrangian, or equivalently the Hamiltonian, is due to the quark masses:

$$\mathscr{L} = \mathscr{L}_{symm} + \mathscr{L}_{mass} = \mathscr{L}_{symm} + m_i \bar{q}_i q_i \tag{57}$$

The success of the quark model has been amply confirmed with the caveat that a free quark has never been seen (more about this in the next section). The values of the quark masses have been found to be

$$m_{\mathrm{u}} \sim 4\,\mathrm{MeV}, \quad m_{\mathrm{d}} \sim 7\,\mathrm{MeV}, \quad m_{\mathrm{s}} \sim 130\,\mathrm{MeV}; \tag{58}$$

so one sees why SU(2) × SU(2) is such a good symmetry [and even why SU(3) and SU(3) × SU(3) are relatively good symmetries]. In the limit of $m_{\mathrm{u}} = m_{\mathrm{d}} = 0$, SU(2) × SU(2) is an exact symmetry of the Lagrangian, broken spontaneously by the vacuum with the appearance of a massless triplet of Goldstone bosons, the pions. In reality the pions have small masses, proportional to m_{u}, m_{d}. It is the smallness of the pion mass which is the true measure of the symmetry breaking.

Of course another puzzle then rears its head, namely how does one build a 940 MeV object out of three objects with masses in the 5–10 MeV range? There is no simple answer to this: quark dynamics create so-called constituent quarks of approximately 300 MeV, while the current-algebra quarks, as described by $\mathscr{L}$, have much smaller values of mass. A major effort to unravel these questions has been embarked on by studies of quarks on lattices (Creutz, 1983).

8. GAUGE SYMMETRIES

So far we have considered rotations of fields by parameters θ_a that are independent of space-time. Can we generalize this notion? The problem is seen immediately by looking at the free Lagrangian of a spin-$\frac{1}{2}$ particle,

$$\mathscr{L} = \bar{\psi}(x)[i\gamma^\mu \partial_\mu - m]\psi(x), \tag{59}$$

which is invariant under the transformation $\psi(x) \to e^{i\theta(x)}\psi(x)$ only for constant θ. If the rotation is space-time dependent, the derivative in $\mathscr{L}$ will introduce extra terms. If we consider not a free theory, but one with minimal coupling to a spin-1 gauge boson, the Lagrangian is invariant under space-time dependent transformations. Minimal coupling means that

$$\partial_\mu \to \partial_\mu + igA_\mu(x) \tag{60}$$

where g is a dimensionless coupling constant. The Lagrangian is invariant under a rotation of ψ by $\theta(x)$ if at the same time we shift

$$A_\mu(x) \to A_\mu(x) - \theta(x)/g. \tag{61}$$

Having introduced the gauge field (photon), we must now include in $\mathscr{L}$ a term for the kinetic energy: this must also be invariant under the gauge transformation and takes the form

$$\mathscr{L}_{\mathscr{A}} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} \tag{62}$$

with the so called field strength defined as

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu. \tag{63}$$

A further requirement for local gauge invariance is that the photon be massless because a mass term in $\mathscr{L}$ for the photon would have to be of the form $M^2 A_\mu A^\mu$ and hence would not be invariant under the translation of $A_\mu(x)$ given in Eq. (61).

Invariance under local symmetry transformations requires the existence of minimally coupled massless gauge bosons.

The example we treated above corresponds to a U(1) gauge transformation, namely the fields were only rotated by a phase $\theta(x)$. Suppose now that we want the more general transformations, as illustrated in Eqs. (9) and (11), to be dependent on space-time, *i.e.*, $\theta_a \to \theta_a(x)$. The solution to this problem was given by Yang and Mills (1954), who showed how to maintain invariance of the Lagrangian when the gauge fields themselves form a multiplet of the group G.

The prescription for invariance under an infinitesimal transformation $\delta\theta_a = \varepsilon_a(x)$ whereby

$$\psi_i(x) \to [1 + it_a\varepsilon_a(x)]_{ij}\psi_j(x) \tag{64}$$

is that ordinary derivatives be replaced by covariant derivatives

$$\partial^\mu \to D^\mu = \partial^\mu + igt_a A^\mu_a \tag{65}$$

where g is the dimensionless coupling constant, and that the gauge fields transform as

$$A^\mu_a(x) \to A^\mu_a(x) - \partial^\mu\varepsilon_a(x)/g - C_{abc}\varepsilon_b(x)A^\mu_c(x). \tag{66}$$

For continuous groups it is sufficient to specify the transformations under infinitesimal transformations. From the above we see that that the number of gauge bosons must equal the number of generators of the group G, or equivalently the gauge bosons must belong to the adjoint representation of G. For instance, if G is the unitary group SU(N), there have to be $N^2 - 1$ gauge bosons, *i.e.*, three for SU(2) and eight for SU(3).

As is the case for electromagnetism, the gauge bosons must be massless. The field strength needs to be of the form

$$F^{\mu\nu}_a = \partial^\mu A^\nu_a - \partial^\nu A^\mu_a - gC_{abc}A^\mu_b A^\nu_c \tag{67}$$

in order for the Lagrangian to be invariant.

The prototype of a gauge theory is the theory of the strong interactions known as quantum chromodynamics. It assumes that each type of quark comes in three species known as colors and that there is a gauged SU(3) symmetry group that acts on them. There is a red, a white, and a blue up type quark and similarly three down quarks and three strange quarks. Since the gauge group is SU(3), there must be eight massless spin-1 particles, the gauge bosons. These are commonly called gluons.

The field strength has terms proportional to the square of the field A^μ_a, and therefore the so-called kinetic term, proportional to the field strength squared, has terms proportional to the third and fourth powers of the field A_μ. This means that $\mathscr{L}$ has nonlinear interactions of the gauge field. This is only true when we have a so called non-Abelian symmetry group, *i.e.*, one for which $C_{abc} \neq 0$. For electromagnetism such terms are not present.

The nonlinear interactions of the gluons cause the effective quark–gluon coupling constant (coupling constant as modified by radiative corrections) to have a very different behavior than the electromagnetic coupling constant. In fact the quark–gluon coupling becomes smaller as one increases the momentum transferred to the gluon; for electromagnetism the electron's coupling to the photon becomes smaller as one decreases the momentum transferred to the photon. These changes in the effective coupling constants are quantum effects due to the dielectric behavior of the vacuum. They are not present in the corresponding classical field theories.

Conversely, quark interactions at small momentum transfer are very strong, leading to quark confinement: only SU(3) color singlet states are observable. For instance, the quark–antiquark potential grows with separation while the electron–positron potential decreases. Since quark interactions become weaker at large momentum transfer, the quarks become almost free, a property known as asymptotic freedom. Both aspects have been confirmed experimentally (Aitchison and Hey, 1989).

As of now the evidence indicates that both the U(1) symmetry of electromagnetism and SU(3) of color are unbroken, or equivalently, unbroken local SU(3) × U(1) is a symmetry of nature.

Gravity is also an unbroken gauge symmetry of sorts. The unbroken symmetry is general covariance, the conserved quantity is the energy-momentum tensor, and the gauge boson is the graviton, a quantum fluctuation of the metric tensor (Weinberg, 1972). Intuitively it is not surprising that if the quantum field that couples to a conserved current has spin 1, the quantum field that couples to a conserved second rank tensor should have spin 2.

The notion that gravity and electromagnetism might be reunited was of course Einstein's dream. This concept is presently being pursued by theorists exploring string theory (Gross, 1995), but that is outside the scope of this article.

We have seen that three of the four fundamental forces (electromagnetic, strong, and gravity) seem to be described by gauge theories with massless gauge bosons as mediators. What about the fourth known force, the weak force that describes beta decay, neutrino interactions, *etc*. Is it like the other three? The answer is that it is indeed similar to the other three forces in that there is a gauge invariance associated with the weak interactions, but there is also an important difference in that, although the Lagrangian is invariant under the corresponding transformations, the physical vacuum is not. This implies, as we shall see in the next section, that the corresponding gauge bosons are massive. In turn, this leads to the conclusion that the force generated by the weak interactions is short range, as opposed to the electromagnetic or gravitational forces.

Equation (48) gives an effective Hamiltonian describing the weak interactions, but we now understand that this is only valid to second order in perturbation theory for an underlying theory with interaction

$$\mathscr{L}_{weak} = gJ^{a\mu}A_{a\mu} \tag{68}$$

where $a = 1, 2, 3$ is the label for a set of three currents associated with the three gauge bosons of the weak interactions. The g and A^{μ} in the above equation are not meant to be confused with those we wrote for the strong interactions.

The breakthrough in understanding the connection of such a model with gauge theories came about with the development of the so-called Glashow–Weinberg–Salam model (Weinberg, 1995). It was realized that the underlying theory was a gauge theory with SU(2) invariance and hence three massless spin-1 gauge bosons and three associated conserved currents.

The quarks and leptons, which constitute the fermionic components of the theory, are placed in doublets and singlets of SU(2), and, of course, the Lagrangian is invariant under SU(2) symmetry transformations. Having the currents conserved is only possible if all fermion masses are zero, since the divergences of the weak currents are, as we have seen, proportional to sums and differences of fermion masses. This is achieved by putting all left chiral fermions in doublets and right chiral fermions in singlets (mass terms connect left to right chiral fields) and, of course, SU(2) invariance forbids direct coupling of doublets to singlets.

The resulting model is elegant, but far from describing nature since neither the mediators of the weak interactions nor the fermions are massless. On the other hand, introducing mass terms in the Lagrangian would break the local symmetry and destroy the renormalizability and hence the finiteness of the theory.

The resolution of this problem using the technique of spontaneous symmetry breaking is explained in the next section. It succeeds in giving masses to the three gauge bosons of the weak interactions: two of them, called $W^{\pm}$, are charged and the remaining one, the Z^0, is neutral. In summary, we say that the so-called "standard model" of the strong, weak and electromagnetic interactions is described by a SU(3) × SU(2) × U(1) gauge theory, spontaneously broken to SU(3) × U(1). At present the "standard model" includes as fermionic building blocks three negatively charged leptons, e^-, μ^-, τ^-, each with its associated neutrino, three charge-$\frac{2}{3}$ quarks, the u, c, and t quarks, and three charge-$(-\frac{1}{3})$ quarks, the d, s, and b quarks. In addition each and every quark comes in three so-called colors, corresponding to the triplet representation of the unbroken color SU(3) group.

An active field of research is the study of whether there exists some much larger gauge group, *e.g.*, SU(5), which spontaneously breaks to the standard-model invariance group (Aitchison and Hey, 1989).

9. THE HIGGS MECHANISM

There is one very important exception to the rule that spontaneously broken symmetries lead to Goldstone modes. This is the so-called Higgs mechanism, anticipated and discussed in the context of condensed matter physics by Y. Nambu and by P. W. Anderson (Weinberg, 1995). If the theory includes minimally coupled massless gauge bosons, they necessarily interact with the scalar bosons because the latter's kinetic energy terms need to have ordinary derivatives replaced by covariant derivatives. For instance, for O(3), we find

$$\begin{aligned}\partial^\mu\phi_a\partial_\mu\phi_a \to D^\mu\phi_a D_\mu\phi_a &= (\partial_\mu\phi_a + ig\varepsilon_{abc}A_{\mu,b}\phi_c)\\ &\quad \times (\partial^\mu\phi_a + ig\varepsilon_{ade}A^\mu_d\phi_e).\end{aligned} \tag{69}$$

If we now introduce into the above equation the vacuum expectation value of ϕ_a, namely the O(3) vector $(0, 0, v)$, we find an effective mass term for the gauge bosons

$$g^2v^2\varepsilon_{ab3}\varepsilon_{ad3}A_{\mu,b}A^\mu_d. \tag{70}$$

From this, we see that the third component field A^μ_3 has no mass term since $\varepsilon_{33a} = 0$ while the other two fields have acquired a mass proportional to gv. This acquisition of mass is puzzling since a massless gauge boson like the photon has only two polarization degrees of freedom while a massive gauge boson can have a longitudinal polarization as well as the two transverse polarizations.

The resolution of the puzzle lies in the Higgs mechanism. We apparently acquired two new degrees of freedom corresponding to the longitudinal modes of the gauge bosons. If we study the problem somewhat more carefully, we find that two massless scalar bosons can be removed from the Lagrangian by a gauge transformation and hence disappear from the spectrum. The colloquial expression is that they have been eaten by the gauge bosons.

Recapitulating, we see that spontaneous symmetry breaking leads to massless scalar bosons: if the scalar bosons are coupled minimally to massless gauge bosons, some or all of the massless scalars may disappear from the spectrum, replaced by the longitudinal modes of the now massive gauge bosons. Gauge bosons coupled to currents associated with unbroken symmetries remain massless. In the O(3) case rotational symmetry about the third axis is unbroken and A^μ_3 remains massless.

For the theory of electroweak interactions our starting gauge theory is SU(2) × U(1) with four massless gauge bosons. In addition we have a complex SU(2) scalar doublet, which transforms nontrivially under U(1) as well, so that there are four independent scalar fields (read and imaginary parts of the doublet). The fermions are left-handed chiral SU(2) doublets and right-handed chiral SU(2) singlets.

To begin with, the gauge bosons are massless, the fermions are massless [left-right couplings are forbidden by SU(2) invariance], and the scalars have a negative squared mass. The symmetry is spontaneously broken from SU(2) × U(1) to simply a U(1) symmetry. This leads to one massive scalar and three massless scalars. The latter are eaten by the four gauge bosons, three of which become massive, and one, the photon, stays massless. The three massive gauge bosons are the $W^\pm$ and the Z^0, the mediators of the charged and neutral weak interactions.

The fermions also acquire a mass, since Lagrangian interaction terms of the form

$$f\bar{q}_{L,a}\phi_a q_R \tag{71}$$

are allowed, and, once ϕ_a acquires a vacuum expectation value equal to v, fermions get masses proportional to fv. The predictions of what has come to be known as the standard model are extraordinarily successful. The $W^\pm, Z^0$ have been discovered at exactly the predicted masses, decay modes agree, *etc.* The one remaining unconfirmed piece of the puzzle is the detection of the single massive scalar, commonly called the Higgs boson.

The Higgs phenomenon has its counterpart in condensed matter physics as well. Let us illustrate this again with the example of superconductivity. The gauge symmetry is U(1), with the photon as the gauge boson. The scalar field is the order parameter, the complex scalar electron-pair wave function, which also transforms nontrivially under U(1) since it has charge −2. The order parameter has a nonzero vev, signalling a phase transition, and the phase of the order parameter is a massless excitation, corresponding to a Goldstone mode. The latter disappears from the spectrum, being eaten by the photon. Inside a superconducting medium, the photon is essentially massive: this is known as the Meissner effect (Weinberg, 1995).

10. EXPERIMENTAL LIMITS ON SYMMETRY BREAKING

We have discussed at some length the notion of symmetry. Let us now consider, at least briefly, some of the experimental limits on conservation laws. Begin with discrete symmetries; *TCP* follows, as we stated, from general principles of relativistic quantum field theory. The best limits on *TCP* invariance come from the equality of the K^0 and the $\bar{K}^0$ masses. The experimental limits on the mass difference Δ are that

$$\Delta / m_{K^0} \leq 10^{-18} \tag{72}$$

at a 90% confidence level. Unless otherwise indicated the experimental results cited in this section are all obtained from the Particle Data Group's compilation (Particle Data Group, 1994). *TCP* also predicts the equality of lifetimes *etc.* for particles and antiparticles. Tests have been performed to compare lifetimes for electrons and positrons, $\mu^{\pm}$ mesons, and so forth. As an example, the lifetimes of the latter are given by

$$\tau_\mu^+ / \tau_\mu^- = 1.00002 \pm 0.00008. \tag{73}$$

Another example is the equality of the anomalous magnetic moments of the electron and the positron. If *TCP* invariance holds, *T* and *CP* symmetries are presumably equal, but again it is worth testing them separately. Experiments in atomic, molecular, nuclear, and particle physics are being conducted to test these symmetries. At present the most sensitive test of time-reversal invariance is probably the limit on the electric dipole moment (edm) of the neutron. The present limit for the neutron is that its edm $< 1.1 \times 10^{-25} e\,\mathrm{cm}$. The bound on the electron edm is comparable to that of the neutron and is a more stringent test of unification theories. It is worth mentioning that a neutron nonzero edm requires violation of both *T* and *P*. Nuclear physics searches for *T* nonconservation are also being pursued (Haxton *et al.*, 1994).

CP symmetry is a vast topic (Jarlskog, 1988) At present the best limits on *CP*-invariance violation come from the analyses of *K* decay. In the neutral kaon system the strength of *CP*-invariance violation relative to the standard weak interactions is characterized by a dimensionless small parameter $\varepsilon \simeq 10^{-3}$. It is crucial to determine if ε is so small because *CP*-invariance violations are very weak or because they involve mixing with heavier quarks, which are only minor consituents of the kaons.

Large experimental facilities in Japan (KEK) and the USA (SLAC) are presently under construction that will provide further tests of *CP* nonconservation and begin to address these questions. An example is the so called BABAR facility at the Stanford Linear Accelerator which will study the B^0-$\bar{B}^0$ system (B^0 is a bound state of a b quark and either a d or an s antiquark).

Baryon-number conservation is presumed to be violated at some level if a grand unified theory that incorporates all known gauge theories exists. The present best limit on baryon-number conservation comes from the stability of the proton, which is known to have a lifetime greater than 10^{31} years.

Baryon-number nonconservation is one of the three key ingredients to the generation of a baryon asymmetry in the early universe, as was pointed out by Andrei Sakharov in a prescient 1967 paper (Kolb and Turner, 1990). The other two are *CP*-invariance violation and a departure from thermal equilibrium. Baryon asymmetry is, of course, present since our known universe is preponderantly made of matter, not of antimatter, but a wholly successful explanation of the asymmetry has not yet been advanced.

Lepton number is tested in neutrinoless double beta decay, particularly in isotopically enriched germanium (Avignone, 1995). The limits state the ratio of neutrinoless decays to neutrino decays to be less than one in a thousand.

The separateness of muon number and electron number is tested by the nonobservation of $\mu \rightarrow e + \gamma$, which has a branching ratio of $< 5 \times 10^{-11}$ to the total decay rate of the muon. The dominant muon decay is into a state of an electron, a neutrino, and an antineutrino. Though it is not obvious, lepton numbers are automatically conserved if neutrinos are massless (technically it would be sufficient if all neutrinos were mass degenerate). There are numerous ongoing searches for evidence of nonzero neutrino mass. Lepton mixing and nonzero neutrino masses may first be observed in so-called neutrino oscillation experiments. In these one species of neutrino, say an electron neutrino, is produced but it then oscillates between that and a second species, *e.g.*, a muon neutrino, while travelling from the source to the observer.

Local gauge invariance requires massless gauge bosons. One obvious verification is the masslessness of the photon. Present limits are

$$m_\gamma < 3 \times 10^{-27}\text{eV}. \tag{74}$$

Trying to set limits on gluon (the presumed mediator of the strong interactions) masses, on the other hand, is very difficult, since gluons are not directly observable. In fact, observation of a free gluon or a free quark would represent a departure from the presently held view that these particles are only observable when combined with other like such particles to form color singlets. Incidentally, all recent searches for free quarks have yielded null results.

Conservation of electric charge is presumed to hold. If it were not, we could imagine an electron decaying into a neutrino and a photon. Present limits on the electron lifetime are $\tau_e > 2.7 \times 10^{23}$ years.

One prominent symmetry we have not mentioned in the text so far is supersymmetry, the unique allowed extension of space-time translation symmetry to a group that includes particle transformations. The symmetry requires paired multiplets, necessarily degenerate in mass, of fermions and bosons. Thus, if supersymmetry exists in nature, it must be spontaneously broken. Some current theories suggest that the partners of the known elementary particles, differing in spin by one half unit, should lie in the mass range of a few hundred GeV. It is therefore an interesting question for the next round of accelerator experiments whether this extended symmetry could be a reality (Wess and Bagger, 1983).

GLOSSARY

Baryon: A strongly interacting particle obeying Fermi statistics, such as the proton or the neutron.

Bravais Lattice: The elementary specification of the location of the units in an infinite crystalline lattice, making manifest the periodic ordering and the translational symmetry.

Charge Conjugation: An operation that transforms a particle into its antiparticle. A theory which incorporates particles and antiparticles in a symmetric manner may then be invariant under the operation of charge conjugation or said to have charge-conjugation symmetry. Similar statements can be made about time-reversal and parity symmetries.

Gauge Boson: A particle of spin 1 that couples to matter in such a way as to maintain gauge invariance, the invariance under continuous space-time dependent transformations. The photon is an example of a gauge boson.

Goldstone Boson: A massless particle of spin 0 that arises when a continuous symmetry is broken spontaneously.

Group: A set of elements and a rule for combining them, commonly called group multiplication. The product of any two group elements must itself be a group element, multiplication must be associative, a unique identity element must exist, and every element must have a unique inverse such that the product of an element and its inverse yields the identity element. Groups may be continuous, such as the full rotation group, or discrete, such as the group of rotations about the z axis by 90°, which has only four elements: rotations through 90, 180, 270 and 360°.

Lepton: The name given to fermionic elementary particles with no strong interactions, as for example the electron and its neutrino.

Quantum Field: The generalization of the concept of a particle satisfying a quantum mechanical equation of motion. Particles are the quantum excitations of the appropriate field, *e.g.*, the photon is an excitation of the electromagnetic field. Quantum field theory allows naturally antiparticle as well as particle creation and annihilation.

Quark: The presumed structureless, *i.e.*, pointlike, elementary fermionic constituents of strongly interacting particles such as the neutron and the proton. Quarks are believed to be bound together by the mediators of the strong force, conventionally called gluons.

Spontaneous Symmetry Breaking: A situation that arises when the Lagrangian and hence the equations of motion of a system are invariant under a continuous symmetry, but the vacuum is not. This comes about because the minimum of the potential and hence the stable point corresponds to a nonzero expectation value of a scalar field.

Standard Model: The term commonly used for the model of matter described as consisting of pointlike fermionic constituents (quarks and leptons) interacting by means of gauge bosons, which in turn are self interacting. The model features an invariance under a set of specified symmetry transformations, corresponding to the group SU(3) × SU(2) × U(1).

INTRODUCTION

Use of shorter-wavelength radiation, like electrons or x rays, provides significantly better spatial resolution than visible-light microscopy (see OPTICAL MICROSCOPY). Although important, a high spatial resolution alone is not sufficient to make a microscope a useful tool. Little can be learned about a sample that is too opaque or too transparent to provide useful contrast. Individual living cells are a few micrometers thick, transparent to visible light, and opaque to electrons. That is why phase-contrast methods are commonly used in visible-light microscopy and sectioning and staining is used in electron microscopy. For soft x rays, however, such cells provide a natural contrast.

The desire for x-ray microscopes arose soon after the discovery of x rays by Wilhelm Röntgen in 1895, but the lack of materials with strong refraction and weak absorption prevented an early development of x-ray lenses and thus of high-resolution x-ray microscopy.

The unique interactions of x-rays with matter were extensively used soon after the discovery of x rays. X-ray spectroscopy, using gratings, was greatly developed by the 1920s. It was realized that x rays in the water window (see Sec. 1.1) would provide a natural contrast mechanism for x-ray microscopy of hydrated biological specimens. The moderate absorption and phase shifts of x rays when passing through matter, which make x-ray microscopy desirable, make it also impractical to build x-ray microscopes based on refractive optical elements.

X-ray microscopes that avoid x-ray optics altogether and record a shadow of the sample were therefore developed first (Coslett and Nixon, 1960). The best spatial resolution of shadow microscopes is achieved by placing the sample in close proximity to an x-ray point source or a high-resolution detector. When the

sample is close to a point source of x-rays, we speak of projection x-ray microscopy. When the sample is placed near the detector, it is called microradiography or contact x-ray microscopy.

Since refractive optics are impractical for x rays, focusing x-ray microscopes rely on reflective or diffractive optical elements. Kirkpatrick and Baez built the first focusing x-ray microscope (Kirkpatrick and Baez, 1948) using an arrangement of two focusing mirrors that operate through reflection at grazing incidence (see X-RAY OPTICS). Zone-plate lenses for x-ray microscopes were first discussed by Baez (1952) and are today used in the instruments with the highest spatial resolution. Present x-ray microscopes exceed the resolution of visible-light microscopes by more than a factor of 5, with further improvements expected in the future. The most complete progress reports on x-ray microscopy are documented in the proceedings of a series of conferences that started in 1984 in Göttingen (Schmahl and Rudolph 1984) and have been held every third year since (Sayre *et al.*, 1988; Michette *et al.*, 1992, Aristov and Erko 1994; Thieme *et al.*, 1998).

1. CONTRAST MECHANISM

Contrast in x-ray microscopy is from the interaction of x-ray photons with the electrons in the sample molecules. The specific dependence of the x-ray interaction with the sample on its elemental composition makes x-ray spectroscopy a very useful tool. When combined with high spatial resolution we speak about spectromicroscopy.

1.1 X-Ray Interaction with Matter

The interaction of soft x rays with matter is described by the complex index of refraction

$$n = 1 - \delta - i\beta. \tag{1}$$

The parameters δ and β are called the refractive index decrement and absorption index, respectively. An electromagnetic wave of wavelength λ passing through a sample with a thickness z will be attenuated in accordance to Beer's law:

$$I/I_0 = \mathrm{e}^{-\beta(4\pi/\lambda)z} = \mathrm{e}^{-\mu\rho z}, \quad \mu = 4\pi\beta/\lambda\rho, \tag{2}$$

and experience a phase shift of

$$\varphi = (2\pi/\lambda)\delta z. \tag{3}$$

The absorption coefficient μ ($\mathrm{cm}^2\,\mathrm{g}^{-1}$) and density ρ ($\mathrm{g\,cm}^{-3}$) are often used instead of the absorption index β.

The refractive index depends in a characteristic way on the photon energy of the x rays and the electronic configuration of the sample. X-ray photons are essentially probing the electronic structure of the molecules in the sample. As an example, we show in Fig. 1 the $1/e$ attenuation lengths of water and a generic protein as a function of photon energy. The absorption increases almost abruptly where the photon energy exceeds the electron binding energies of the elements in the sample. For carbon and oxygen the K-shell binding energies are at 284 and 543 eV, giving rise to the so-called water window, where organic matter absorbs nearly an order of magnitude more than water.

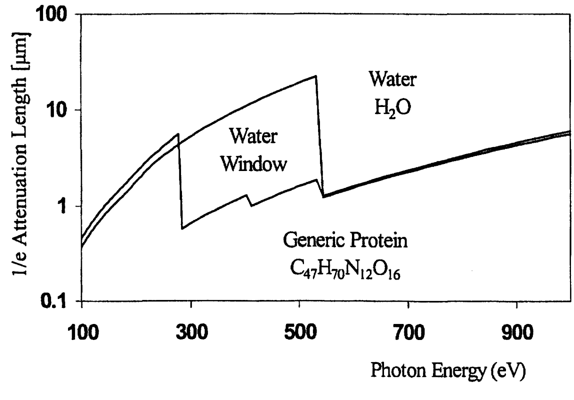

FIG. 1. X-ray $1/e$ attenuation lengths of a generic protein and water as a function of photon energy. The range between 284 and 543 eV is called the water window because water absorbs almost an order of magnitude less than organic material.

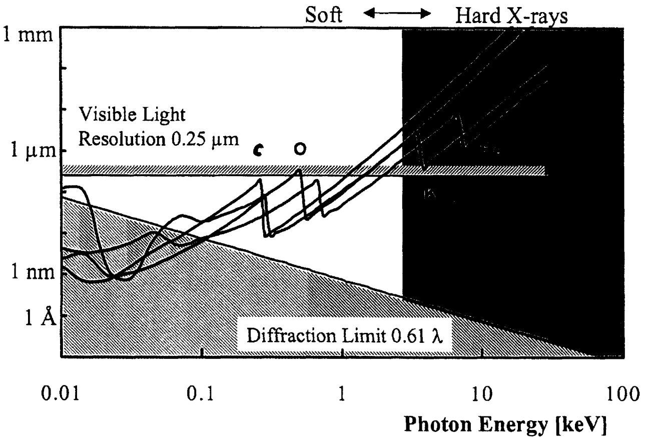

FIG. 2. Material thickness to produce 3% contrast from absorption in a transmission x-ray microscope as a function of photon energy for a variety of elements with a density of 1 g cm^{-3}.

The index of refraction is related to the atomic cross sections f_1 and f_2, which are well characterized and published for x-ray energies away from absorption edges (Henke *et al.* 1993) (see also X-RAY AND NEUTRON REFLECTIVITY):

$$\delta = \frac{r_0 \lambda^2}{2\pi} \frac{N_A}{A} \rho f_1, \qquad \beta = \frac{r_0 \lambda^2}{2\pi} \frac{N_A}{A} \rho f_2, \tag{4}$$

with r_0 the classical radius of an electron, A the atomic weight (g mol^{-1}), and N_A Avogadro's number (mol^{-1}).

Most high-resolution imaging in x-ray microscopy to date uses contrast primarily from photoelectric absorption in the water window, but phase contrast is used as well (Schmahl *et al.*, 1993). For x-ray energies just below the oxygen edge (*e.g.*, 517 eV, $\lambda = 2.4$ nm), the penetration depth of x rays is also ideally suited to image whole cells with a thickness of a few micrometers (see Fig. 1).

The photoelectric interactions of x rays near binding energies are more complex than shown in Fig. 1 and the Henke tables, because the binding state of the electrons affects the cross sections as well. This is used to map the chemical status of the sample.

1.2 Hard and Soft X Rays

The penetration depth of x rays in matter varies significantly throughout the photon energy range that is called x rays. Figure 2, for instance, shows the thickness of a variety of materials needed to produce a 3% absorption contrast. Also indicated are the resolution of visible-light microscopes (approximately $\frac{1}{4}$ µm) and the diffraction-limited resolution due to the finite wavelength of the x rays (0.61 λ). Soft x rays, that is for 100 to 2500 eV photon energy, are ideally suited to provide a spatial resolution exceeding that of visible-light microscopes. Harder x rays, with photon energies more than approximately 2500 eV, do not provide sufficient absorption contrast for high-resolution transmission x-ray microscopy. Phase contrast is also reduced when used with harder x rays, but at a lesser degree. The presence of K-shell absorption edges makes harder x rays also very useful for spectroscopic methods with spatial resolutions down to about 1 µm.

1.3 Dichromatic Microanalysis

The discontinuities of the x-ray absorption cross section are used to produce elemental or chemical distribution maps. Assume that we have two x-ray images I_1 and I_2 of the same sample taken at wavelengths λ_1 and λ_2. The two wavelengths are chosen so that the photon energies are just below and just above an absorption edge of the element to be studied. Further, assume that the cross section μ of this element changes between those wavelengths by $\Delta\mu$, and that the cross section of the other ele-

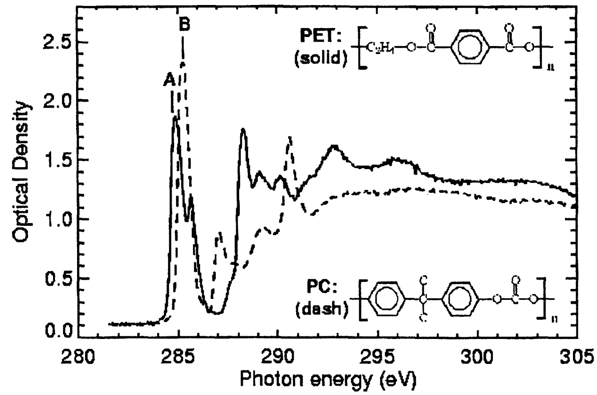

FIG. 3. Carbon NEXAFS spectra from (0.1 μm)^2 areas of a polymer blend. The solid line is from poly(ethylene terephthalate) (PET) and the dashed line from polycarbonate (PC). Images of the polymer blend are shown in Fig. 25. [Adapted from Ade *et al.* (1995), courtesy of H. Ade.]

ments in the sample are constant. Then we can map the areal density (g cm^{-2}) as

$$\rho z = \frac{1}{\Delta\mu} \ln\left(\frac{I_1}{I_2}\right). \qquad (5)$$

The sensitivity of this method is ultimately limited by photon noise. At this limit we can assume $I_1 \approx I_2 \approx I$ and the error of I being $\sqrt{I}$; then the uncertainty of the areal density measurements is

$$\Delta(\rho z) \approx \sqrt{2}/\Delta\mu\sqrt{I}. \qquad (6)$$

It should be noted here that the detectable quantities of the element in question relative to the bulk are on the order of one part in a hundred. If compared with other methods that detect relative quantities on the order of parts per million, this does not appear impressive at first sight. Because of the microscopic nature of the method, however, the absolute quantities that can be detected are quite small. For instance, an iron particle might have a $\Delta\mu = 10^4\,\mathrm{cm}^2\,\mathrm{g}^{-1}$. With a 40-nm spatial resolution and 1000 photons per resolution element detected, we could see 7.2×10^{-17} g of iron or 7.7×10^5 atoms concentrated within the (40-nm)^2 pixel.

1.4 Spectromicroscopy

Closer views of the x-ray spectrum, especially near the binding energy levels, reveal additional structures (see SPECTROMETERS). These structures are based on the energy for promoting electrons into a near-vacuum molecular energy level. Near-edge x-ray absorption fine-structure (NEXAFS) spectra therefore carry information on the chemical environment of the atoms (Ade *et al.*, 1992). Figure 3, for instance, shows the carbon NEXAFS spectra of two polymers: polycarbonate (PC) and poly(ethylene terephthalate) (PET).

The NEXAFS technique is also called XANES (x-ray absorption near-edge spectroscopy).

1.4.1 Orientation- and Polarization-Dependent Contrast The absorption contrast does not depend only on the chemical state of the electrons in the sample, but it is also dependent on the orientation and polarization of the incident radiation. This is especially noticeable with magnetic material. Magnetic circular dichroism provides significantly different absorption of magnetic domains for right and left circularly polarized radiation. The first demonstration of magnetic contrast with an x-ray microscope was done with the Göttingen x-ray microscope at BESSY (Schmahl *et al.* 1996). Ade and Hsiao (1993) have used soft x-ray linear dichroism to map the orientation of polymer molecules in Kevlar fibers.

1.5 Radiation Dose

The photoelectric absorption that provides contrast in soft x-ray microscopy also damages the sample (see BIOLOGICAL EFFECTS OF ELECTROMAGNETIC AND PARTICLE RADIATION), especially at the high doses the sample receives in an x-ray microscope.

The dose, measured in Gray (Gy), is the energy (J) absorbed per mass (kg). The energy of one photon depends on the wavelength and is (h = Planck constant, c = speed of light)

$$E_{\text{photon}} = hc/\lambda. \tag{7}$$

In practical units,

$$E = (1239.8\,\text{eV nm})/\lambda. \tag{8}$$

The dose D at the surface of a sample that is irradiated with n photons per area a (= pixel) is

$$D = (n/a)(hc/\lambda)\mu. \tag{9}$$

For instance, 1000 photons at 2.4 nm wavelength in a (40-nm)^2 size pixel will deposit a dose of 6.7×10^4 Gy ($\mu = 1.3 \times 10^4\,\text{cm}^2\,\text{g}^{-1}$). This is a typical dose for scanning x-ray microscopes. Conventional x-ray microscopes use about an order of magnitude higher dose (see Sec. 3.2.1).

When compared with electron microscopy, x-ray microscopy requires about an order of magnitude less dose to form an image of the same quality from samples that are a couple of micrometers thick (Sayre *et al.*, 1977). This, however, is not low enough to allow direct observation of ongoing living processes (see BIOLOGICAL EFFECTS OF ELECTROMAGNETIC AND PARTICLE RADIATION).

The dose tolerated by a sample in an x-ray microscope before structural changes become visible depends on the exposure time and the sample. Very short x-ray exposure times can be used to investigate initially living samples without limitations to the dose tolerated. At present, however, there are no single-pulse x-radiation sources available that routinely provide the brightness and photon flux needed for images of the quality produced by the best x-ray microscopes, although they are used in x-ray contact microscopy.

Exposure times with x-ray microscopes at synchrotron radiation light sources, which provide the highest-resolution images to date, are on the order of seconds. Sample changes due to the dose during exposure have to be considered with these instruments. The dose tolerated varies widely depending on the sample as well as its preparation. Unfixed chromatin in dried sperm, for instance, is resistant enough to allow imaging at high spatial resolution and good signal-to-noise ratio without visible structural damage. Living green algae can only be imaged, before structural damage degrades the image quality, with a reduced signal-to-noise ratio or spatial resolution.

Chemical fixation—*e.g.*, with glutaraldehyde—and cryogenic fixation are frequently used to reduce the effects of radiation dose to radiation sensitive materials.

2. OPTICS FOR X-RAY MICROSCOPY

X-ray optical elements are essential for focusing x-ray microscopes. Most high-resolution x-ray microscopes use zone-plate lenses, which are covered here. Holographically made zone plates were the first to provide a spatial resolution in x-ray microscopy exceeding that of visible-light microscopy (Schmahl and Rudolph, 1969). Even higher resolution is achieved with electron-beam lithography (Anderson and Kern, 1992). Please refer to X-RAY OPTICS for a more general discussion of x-ray optics other than zone plates.

2.1 Zone-plate Lenses

Zone plates are diffractive focusing elements made of concentric circular zones (see Fig. 4). The radii r_n of the zones $n = 1$ to N are chosen so that mth order diffraction will focus radiation of wavelength λ as shown in Fig. 5 and the equation

$$\sqrt{a^2 + r_n^2} + \sqrt{b^2 + r_n^2} = a + b + nm\lambda/2. \tag{10}$$

When used in a microscope, we can simplify Eq. (10), by assuming $a \to \infty$ and $b \to f$ (focal length), to

$$r_n^2 = mn\lambda(f + mn\lambda/4). \tag{11}$$

For x-ray focusing we can further assume $f \gg mN\lambda/4$, so that

$$r_n^2 = mn\lambda f. \tag{12}$$

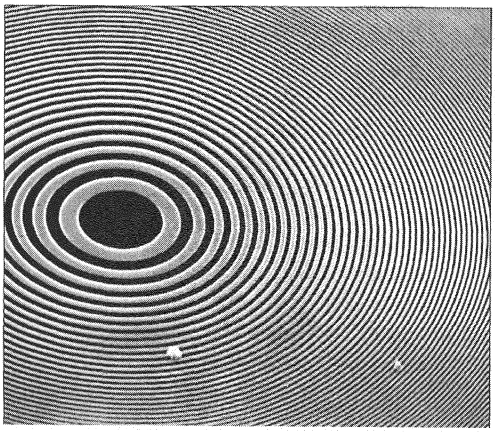

FIG. 4. Electron-microscope image of zone-plate lens with an outermost zone width of 35 nm. The zones are made of nickel and are 150 nm thick. Note: the zones appear elliptical because the lens is viewed at an angle. (Courtesy of E. Anderson.)

The zone width is $\Delta r_n \approx \mathrm{d}r_n/\mathrm{d}n = m\lambda f/2r_n$ and the width of the outermost zone is

$$\Delta r_N = m\lambda f/2r_N. \tag{13}$$

The diffraction pattern of zone plates approaches the Airy pattern of an ideal lens in the limit of many zones. For N bigger than 100, differences can be neglected. The transverse resolution of zone plate lenses is therefore in first order (Born and Wolf 1980)

$$\delta_t = 0.61\lambda/\mathrm{NA} \approx 1.22\Delta r_N/m \tag{14}$$

with the numerical aperture $\mathrm{NA} = \sin(r_N/f) \approx r_N/f$ (see Optical Microscopy). Equation (14) shows that the spatial resolution that can be achieved with zone-plate lenses in first order is approximately equal to the width of the outermost zone, independent of the wavelength. As with thin lenses, the focal tolerance of zone plate lenses in first order is (Born and Wolf 1980)

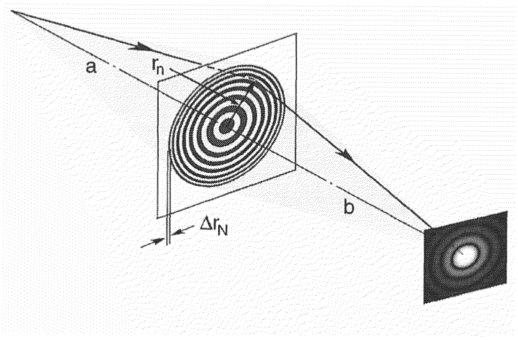

FIG. 5. Geometry of a zone-plate lens.

$$\delta_z = \pm 0.5\lambda/NA^2 = \pm 2(\Delta r_N)^2/m^2\lambda. \tag{15}$$

Zone plates work best with monochromatic radiation. Chromatic aberration is considered negligible if

$$\lambda/\Delta\lambda > mN, \tag{16}$$

with the full bandwidth of the radiation $\Delta\lambda$. A certain amount of chromatic aberration beyond the limit stated in Eq. (16) results in only a modest loss in resolution and is therefore in practice often tolerated.

The efficiency of zone-plate lenses is the fraction of incident radiation that is diffracted into the desired order. The efficiency of an ideally made zone plate with a zone thickness of t made from a material with δ and β as in Eq. (4) is (Kirz, 1974)

$$\begin{aligned} \eta &= \frac{1}{(m\pi)^2}[1+\mathrm{e}^{-2(\beta/\delta)\phi} - 2\mathrm{e}^{-(\beta/\delta)\phi}\cos\phi], \\ \phi &= (2\pi/\lambda\delta)t. \end{aligned} \tag{17}$$

Perfectly made alternating opaque ($\beta \to \infty$) and transparent zones have an efficiency of $1/\pi^2$ or about 10% in the first order. By selection of a proper material and thickness, the efficiency can be improved for a specific wavelength. Efficiencies on the order of 20% can be achieved for soft x rays, and even higher values are possible for hard x rays.

Zone-plate lenses with an outermost zone width of about 20 nm have been under development since 1993 and are used in x-ray microscopes with the highest spatial resolution (Schneider *et al.*, 1995). Similar lenses produce the finest focused spot of electromagnetic radiation of any wavelength (Spector *et al.*, 1997). Present developments focus on the improvement of the fine zone structures required for best resolution and diffraction efficiency. New electron-beam writing machines (Anderson *et al.*, 1995) and nanofabrication tools are expected to provide zone plates that provide 20 nm or better spatial resolution in the future.

3. X-RAY MICROSCOPES

Various instrumental setups are used to take advantage of the contrast mechanisms provided with soft x rays. These include direct-imaging, scanning, contact, projection, and holographic methods. In a scanning transmission x-ray microscope (STXM) the sample is scanned through a small focal spot. The transmitted photons are detected and used to build up a digital image in a computer. The smallest focal spot requires a spatially coherent illumination of the zone-plate lens and nanometer-precision scanning capabilities.

In a conventional transmission x-ray microscope (TXM) setup, the sample is illuminated with incoherent x rays. The transmitted photons are enlarged by a zone-plate lens to form an image on an x-ray–sensitive area detector.

The image formation, which means the relation between the transmission of the sample and the image detected, is partially coherent for both scanning and conventional x-ray microscopes and therefore nonlinear (Jochum and Meyer-Ilse, 1995). The nonlinearity is especially noticeable for feature sizes approaching the diffraction limit. Figure 6 shows the comparison of the intensity across a knife edge, from a theoretical calculation that included partial coherence effects, with experimental data. Indicated is the width of the knife edge from 10 to 90% intensity, which coincides with the Raleigh δ_t in an incoherent imaging system.

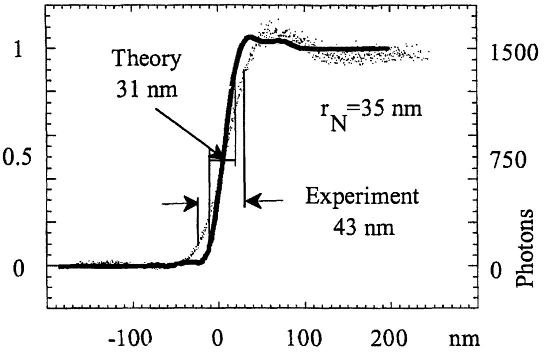

FIG. 6. Spatial resolution of the x-ray microscope XM-1 in Berkeley experimentally determined with a knife-edge test compared with a theoretical calculation that included partial coherence and chromatic aberrations.

3.1 X-ray Sources and Detectors

X-ray microscopes require bright x-ray sources and sensitive detectors for best performance. Synchrotron radiation sources (see Synchrotron Radiation) are used for the most advanced systems. Further development of plasma sources and more common availability of x-ray lasers (DaSilva *et al.*, 1992) might change that in the future.

The most important criterion for detectors in x-ray microscopy is the detection efficiency. A high detection efficiency reduces the dose to the sample and makes best use of the photons available from the source.

Zone-plate microscopes utilize monochromatic radiation, which has to be provided by a suitable monochromator. In this case, the detector will not have to provide information on the energy of the photons detected, because that is already known. With focusing x-ray microscopes, the magnification of the instruments can be designed to match the spatial resolution of the detector. Contact microscopy and x-ray holography, however, require a formidable spatial resolution, generally achieved with x-ray–sensitive photoresist, which is often read out with scanning-probe microscopes.

3.2 Focusing Transmission X-Ray Microscopes

3.2.1 Conventional X-Ray Microscopes Schmahl and collaborators at the University of Göttingen (Niemann *et al.*, 1976; Rudolph *et al.*, 1984; Niemann *et al.*, 1994; see also description in Optical Microscopy) pioneered conventional transmission x-ray microscopes (TXM) with zone-plate optics. The Göttingen microscope is installed at the BESSY synchro-

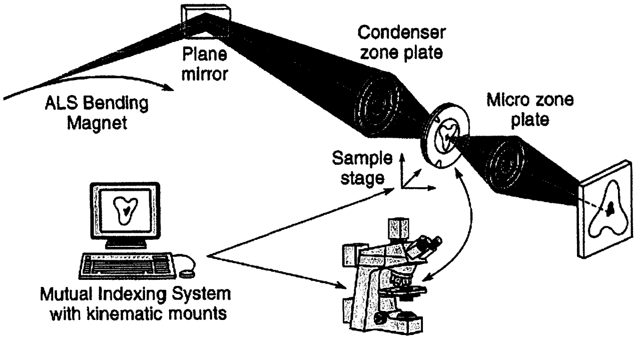

FIG. 7. Optical layout of the conventional x-ray microscope XM-1 at the Advanced Light Source (ALS) in Berkeley. This instrument features a mutual indexing system, which allows one to examine, select, and precisely adjust samples into the focal plane with a visible-light microscope before and after examination with x rays.

tron light source in Berlin. The optical layout is now used in several other places. Figure 7 shows the layout of the microscope at the Advanced Light Source in Berkeley, which also follows the optical design of the Göttingen x-ray microscope.

Conventional x-ray microscopes of the Göttingen type use two zone-plate lenses: a condenser and a micro zone-plate objective. The condenser focuses x rays from a bending-magnet source of a synchrotron facility onto the sample. The chromatic aberrations of the condenser are used to monochromatize the radiation through a pinhole placed in close proximity of the sample. The field that can be imaged is limited to about the size of this pinhole; larger images can be tiled together as shown in Fig. 8. The radiation transmitted through the sample is then enlarged with the objective zone-plate lens onto an x-ray–sensitive area detector. Usually this is a CCD detector (see CHARGE COUPLED DEVICES), which is connected to a computer to generate a digital image.

Conventional x-ray microscopes are relatively uncomplicated as compared with scanning microscopes, but still provide the highest possible resolution achievable with the objective zone-plate lens. These instruments make effective use of the radiation provided, and exposure times are on the order of seconds when used at a synchrotron-radiation facility.

A conventional x-ray microscope setup is also ideally suited for x-ray pulse sources. Both the laboratory x-ray microscope built by the Göttingen group (Niemann *et al.*, 1990) and the first x-ray microscope using an x-ray laser (DaSilva *et al.*, 1992) utilize the conventional setup.

Zernike-type phase contrast (see OPTICAL MICROSCOPY) is relatively easy to do with conventional x-ray microscopes. Figure 9 shows the phase-contrast setup pioneered by Schmahl *et al.* (1993). An example of a alga, *Euglena gracilis*, imaged in absorption and phase contrast is shown in Fig. 10. These images were acquired at low temperature from samples frozen in liquid ethane (see Cryogenic Fixation, Sec. 3.6).

There are two drawbacks of conventional x-ray microscopes. First, the radiation dose to

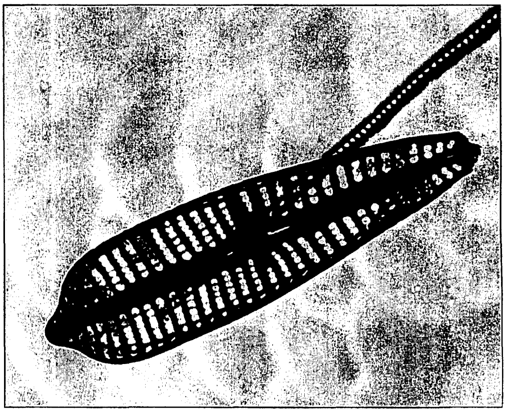

FIG. 8. High-resolution image of a diatom imaged with the conventional x-ray microscope XM-1 in Berkeley. This image contains approximately 100 million pixels of 20 nm size and was tiled together from 36 individual images obtained with a zone plate with 35-nm outermost zone width. The size of this image is 27 by 22 μm. (Courtesy of A. Nair.)

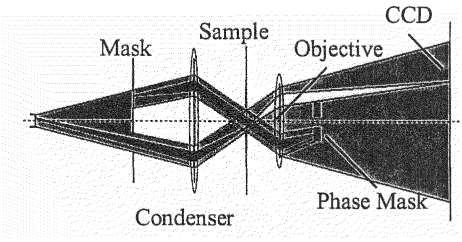

FIG. 9. Zemike phase-contrast setup used in the Göttingen x-ray microscope at BESSY. The condenser illuminates the sample by focusing the source into the sample plane. An annular mask is placed approximately one focal length in front of the condenser. The condenser and objective together concentrate all radiation unperturbed by the sample into the back focal plane of the objective, where it is phase shifted with a phase mask. This leads to image contrast from the phase shift in the sample. In contrast to visible-light microscopes, the phase mask will be absorbent as well and the setup can be optimized for one wavelength only.

the sample is about an order of magnitude higher with a conventional x-ray microscope than with a scanning x-ray microscope. This is because the objective zone-plate lens with its limited efficiency is downstream of the sample. The limitations from such increased dose can be greatly reduced by cryogenic fixation (see below). The second drawback is that the luminescent mode of operation (see below) is not possible at a resolution exceeding that of visible light microscopes.

3.2.2 Scanning X-Ray Microscopes The group of Kirz at the State University of New York at Stony Brook pioneered scanning x-ray microscopy. Their instrument is operated at the National Synchrotron Light Source (NSLS) in Brookhaven at a beam line called X1A. Figure 11 shows the principal setup of a scanning transmission x-ray microscope (STXM). Scanning microscopes were the first to apply spectromicroscopy techniques. The radiation dose to the sample is about an order of magnitude less than with a conventional TXM, because the zone-plate lens is located upstream of the sample. There are several practical advantages of scanning x-ray microscopes. For instance, the field of view can be varied easily, permitting low-resolution overview scans as well as high-resolution scans through computer control.

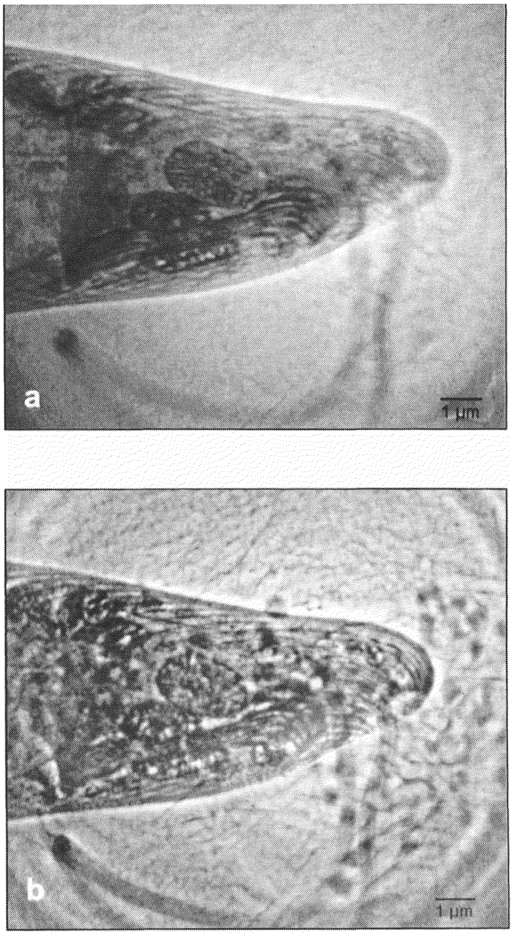

FIG. 10. X-ray micrographs acquired at 517 eV photon energy ($\lambda = 2.4\,\mathrm{nm}$) in (a) amplitude contrast and (b) phase contrast of an alga *Euglena gracilis*, which was shock frozen in liquid ethane. With cryogenic fixation, the organization of the chloroplasts —which are important organelles of photosynthesis—can be analyzed in the intact alga by using solely the natural contrast. Exposure times: (a) 3 s, (b) 15 s. The dose accumulated in vitrified water was about 3×10^6 Gy for either image. These images were acquired with the Göttingen x-ray microscope at BESSY in Berlin. [Adapted from Schneider *et al.* (1998), courtesy of G. Schneider.]

In addition to transmission mode, STXMs are also used to excite visible-light luminescence for high-resolution specific labeling experiments (Jacobsen *et al.*, 1993; Irtel von Brenndorff *et al.*, 1994), and dark-field mode is used to detect silver-enhanced immono-gold labels (Chapman *et al.*, 1996).

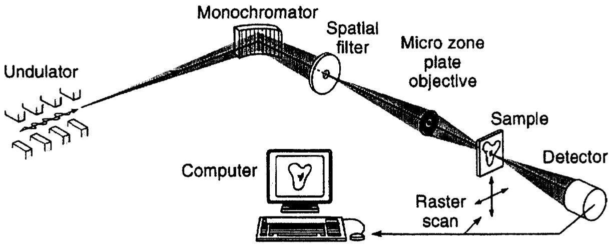

FIG. 11. Optical layout of a scanning transmission x-ray microscope (STXM). Scanning photoemission microscopes (SPEM) and scanning luminescence microscopes differ in the detector arrangement but are similar otherwise.

Scanning microscopes are more complex and demanding on the light source than are conventional microscopes, because they require spatially coherent illumination of the objective zone plate for highest spatial resolution. Exposure times are therefore long, even with today's brightest undulator sources (see SYNCHROTRON RADIATION). Despite this complexity, it is easier to implement spectromicroscopy techniques with scanning x-ray microscopes than with conventional microscopes. This is because high–spectral-resolution monochromators can be realized more easily for the spatially coherent radiation used with scanning microscopes, as compared with the incoherent radiation used with conventional microscopes.

3.3 Examples of Other Focusing Microscopes

The transmission microscopes described above provide the highest–spatial-resolution x-ray images available today. There are other x-ray focusing systems, in general with reduced resolution, that have properties relevant in the context of x-ray microscopy.

3.3.1 X-Ray Fluorescence Microprobes In an x-ray fluorescence microprobe, x-ray optics are used to focus a bright source of x-rays onto a sample of interest. These x-rays excite the characteristic fluorescent x-rays of the elements in the sample, which are detected and analyzed by an energy-dispersive detector such as a Si–Li detector (see X-RAY DETECTORS), allowing an assay of the elements in the sample. Scanning the focal spot over the sample allows the spatial distribution of the elements in the sample to be determined. With a very bright source such as a third-generation synchrotron-radiation storage ring, this method can be very sensitive.

The optics in such an instrument may be regarded as inverted microscopes that form a highly demagnified real image of the source on the sample. Various types of optical element, including zone plates, can be used to achieve this focusing. Another possibility is to use glancing-incidence mirrors in the Kirkpatrick–Baez configuration (Underwood *et al.*, 1988). Coating the surfaces with x-ray–reflecting multilayers (see also X-RAY OPTICS) allows an increase in the glancing angle (and hence a decrease in the aberrations), while at the same time acting as a low-resolution monochromator for the x rays; thus a separate monochromator is not required. The resultant spectral filtering allows selective excitation of the elements of interest and increases the sensitivity of the fluorescence analysis. Figure 12 is a schematic diagram showing the principle of an x-ray fluorescence beam line (Underwood *et al.*, 1996).

This beam line uses a pair of multilayer coated mirrors, shaped into an ellipse by precisely controlled bending, to demagnify the x-ray source (at the Advanced Light Source). With this scheme a spot size of 1 μm is achieved. Using mirrors optimized to focus 12.5-keV x rays, the instrument is capable of analyzing elements with atomic numbers ranging from $Z = 16$ (sulfur) to $Z = 33$ (arsenic) with a sensitivity of tens of femtograms (10^{-14} g). This capability allows the study of a wide range of samples in the fields of materials science, geology, geochemistry, and the life sciences. As an example of the capability of this instrument, Fig. 13 shows a scan of the poison-injecting fang (chelicera) of a garden spider. Interesting features of this scan are the

extremely high concentration of zinc at the tip of the fang and the high concentration of arsenic in the venom duct of the fang. This latter observation is particularly interesting since spider venoms are not inorganic poisons but large proteins similar to snake venom.

Zone plates for hard x rays have been demonstrated as well (Yun *et al.*, 1992) and produce submicrometer size x-ray spots at about 10 keV photon energy. As mentioned above, zone plates have relatively high diffraction efficiencies for hard x rays. This advantage, however, is balanced by the requirement of monochromatic illumination as compared with a microprobe that uses Kirkpatrick–Baez mirrors.

3.3.2 Photoemission X-Ray Microscopes

Photoelectrons generated by x-ray excitation carry information on the electronic structure of the materials involved (see PHOTOEMISSION AND PHOTOELECTRON SPECTRA). Photoemission microscopes use either a small x-ray focal spot to excite the photoemission or electron imaging to provide spatial information.

A variety of photoemission microscopes are installed at several synchrotron-radiation facilities around the world. A review of these is beyond the scope of this article. More information on these systems can be found the proceedings of the x-ray microscopy conference series (Thieme *et al.*, 1998; Aristov and Erko 1994; Michette *et al.*, 1992). The instruments below are described to illustrate the principles of scanning photoemission microscopes.

Two scanning x-ray microscopes are installed at beam line 7.0 of the Advanced Light Source (ALS) in Berkeley (Warwick *et al.*, 1998). One of these instruments is a scanning transmission microscope (STXM); the other is a photoemission microscope (SPEM). Figure 14 shows an image from the SPEM with corresponding energy spectra of the emitted electrons. This SPEM uses a zone-plate lens to

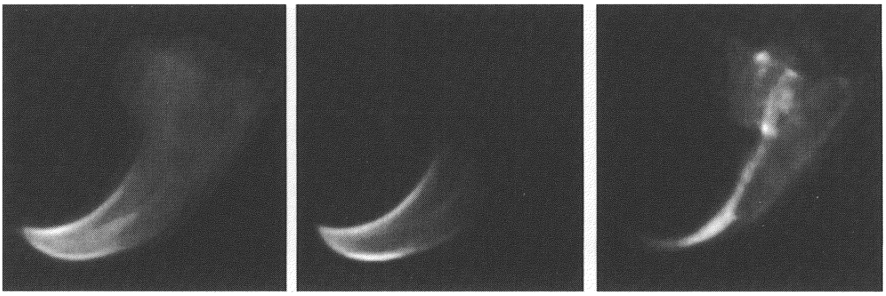

FIG. 13. X-ray microprobe image of a spider fang. The left image shows the x-ray absorption images; the middle and right images show the distribution of zinc and arsenic. (Courtesy of A. Thompson.)

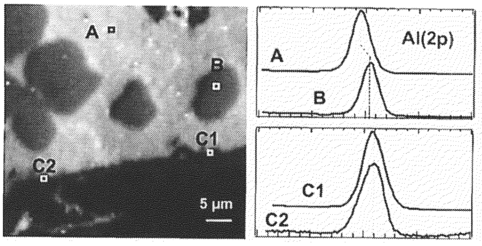

FIG. 14. Scanning photoemission microscopy (SPEM) image and corresponding Al x-ray photoemission spectra (XPS) from a study of Al–Ti melt interactions with graphite. These data were obtained with the SPEM at beam line 7.0 of the Advanced Light Source in Berkeley. (Adapted from Warwick *et al.* (1998), courtesy of T. Warwick.)

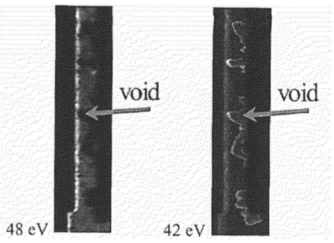

FIG. 15. Photoemission images of an Al–Cu wire on a substrate (4 wt% Cu, 5 μm width) showing electromigration after failure caused by an over-current experiment performed *in situ*. The images are at 42 and 48 eV electron energy. The reverse contrast at 42 eV indicates the presence of charging Al in the voids. The size of the images is $13 \times 60\,\mu m^2$. (Courtesy of J. F. Lorusso.)

excite photoelectrons from a small spot at the sample. The energy of the electrons is analyzed by an electron spectrometer, the image is formed by raster scanning of the x-ray spot. The spatial resolution of this instrument is currently about 0.3 μm; and the exciting photon energy can be varied from 100 eV to 1 keV.

Another scanning photoemission microscope installed at the ALS is called MAXIMUM (Multiple Application X-ray Imaging Undulator Microscope; Ray-Chaudhuri *et al.*, 1993). It uses a multilayer-coated Schwarzschild objective to produce the scanning spot. The multilayer coating (Ru/B_4C) has its maximum of reflectivity at 130 eV photon energy; the emitted photoelectrons are analyzed by means of a cylindrical-mirror analyzer (CMA). This microscope was originally developed at the Synchrotron Radiation Center in Wisconsin and has demonstrated a spatial resolution of 0.1 μm and an energy resolution of 0.3 eV. See Fig. 15 for an example of results obtained with this microscope.

3.4 Nonfocusing X-Ray Microscopes

3.4.1 Contact X-Ray Microscopy Contact x-ray microscopes use laser-produced plasmas to generate short x-ray pulses that are used to illuminate the sample, which is placed directly onto the detector. With short pulse duration, sample damage only becomes apparent after the image has been recorded, so that initially living material can be imaged without any fixation. The spatial resolution however, is limited by diffraction.

3.4.2 Holography and Diffraction When a sample is illuminated with a coherent wave front, the radiation passing through it carries all the information on the absorption and phase shifts from the sample. This is the basis of holography and diffraction methods (see HOLOGRAPHY, OPTICAL; X-RAY DIFFRACTION).

3.5 Microtomography

Information on the three-dimensional structure of the sample can be obtained with stereo and tomographic methods (see X-RAY IMAGING: RADIOGRAPHY AND TOMOGRAPHY; Lehr, 1997).

3.6 Cryogenic Fixation

Cryogenic fixation is the preferred method to prevent sample damage in x-ray microscopes. The first group that built a cryogenic sample stage for x-ray microscopy was the Göttingen group. Their system uses cold dry nitrogen gas to keep the samples at low temperatures. The samples do remain at atmospheric pressure for easy access with visible light microscopy. The amplitude- and phase-contrast images in Fig. 10 were taken at low temperatures. A total dose of 6×10^6 Gy was

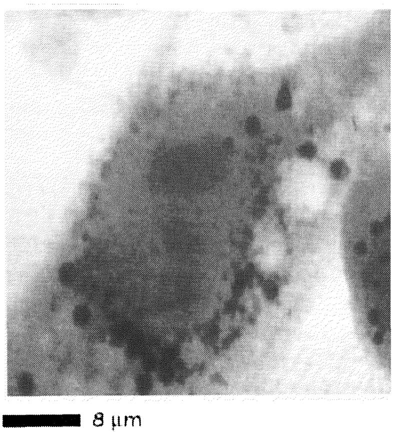

FIG. 16. Frozen hydrated 3T3 fibroblast imaged at 110 K in a cryogenic scanning transmission x-ray microscope. The cultured cell was grown on a Formvar-coated gold electron-microscope grid and plunge frozen from culture medium into liquid ethane. This image was acquired with use of a 60-nm zone plate fabricated by Stony Brook and Bell Labs. [After Maser *et al.*, (1998), courtesy of C. Jacobsen.]

needed to acquire those images. Tests with other frozen algae by the same group showed that an at least three orders of magnitude higher dose could be tolerated without visible damage.

Other groups adapted the cryogenic sample stages available for electron microscopy for their x-ray instruments (Maser *et al.*, 1998 and Lindaas *et al.*, 1998). Figure 16 shows an image obtained at X1A.

3.7 Antibody Labeling

Antibodies that recognize specific proteins can be used to detect and locate those proteins in cells. To do this, either the antibody that recognizes the specific protein is directly tagged with a marker that can be detected in the microscope, or a tagged secondary antibody is subsequently utilized to locate the primary antibody/protein complex. The important point is that in either case the marker selected must be detectable by the type of microscope used. Fluorescent markers are commonly used with visible-light microscopes, and colloidal gold, sometimes enlarged with silver, is primarily used as a marker with electron microscopes.

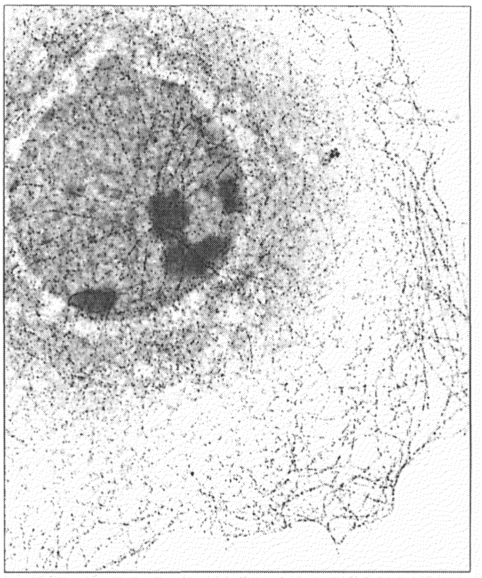

FIG. 17. Part of a hydrated mouse epithelial cell labeled with an antibody against tubulin and 1.4-nm gold markers that were enhanced with silver to about 50–100 nm size. The nucleus and its nucleoli as well as the cell structures in the cytoplasm are visible through natural contrast. Note the strands of labeled tubulin that cross either above or below the nucleus. The images were taken with the transmission x-ray microscope XM-1 at the Advanced Light Source in Berkeley. The size of the image is 26 by 31 μm^2. (Courtesy of C. Larabell, D. Hamamoto, S. Lelièvre, and W. Meyer-Ilse, unpublished.)

Lanthanide-based luminescent markers that can be used in x-ray microscopy are currently under development. Chapman *et al.*, (1996) pioneered the use of silver-enhanced gold markers with x-ray microscopes. The high penetrating power of x rays allows for the visualization of the labels even through or inside the nuclei of unsectioned cells (Fig. 17).

4. APPLICATIONS

X-ray microscopy application cover a wide range of fields. All these fields take advantage of the ability to study hydrated, relatively thick, and often unstained samples with high spatial resolution. The examples shown below were selected to represent the diversity of the field and are not meant to be complete.

4.1 Biology

Biological applications of x-ray microscopy include the investigations of mammalian cells, algae, sperm, spores, chromosomes, parasites, and bone structure (Thieme *et al.*, 1998). Studies of malaria and sperm are given to illustrate the use of high-resolution transmission imaging and elemental mapping, respectively.

4.1.1 Malaria Intracellular parasites like those of malaria are small; hence their morphology is challenging for visible-light microscopy studies. X-ray microscopy combines the advantage of high resolution with penetration of any enclosing structure for studies of intact parasites and their interaction with the host red blood cells.

The development of malaria (*Plasmodium falciparum*) in human red blood cells was intensively studied by Magowan *et al.* (1997). Thousands of x-ray images from malaria parasites were analyzed. In infected red blood cells, the mass redistribution from parasite activity was measured and newly elaborated structures in the cytosol were detected. The changes of the parasite morphology due to potential chemotherapeutic agents (Fig. 18) and from skeletal mutations of the host red blood cells were extensively studied as well. The findings demonstrate conclusively for the first time that constituents of the red blood cell membrane play a role in parasite development and extend our understanding of the relationship between the host blood cell membrane and the parasite.

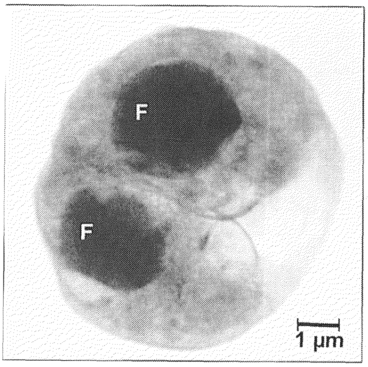

FIG. 18. Two malaria parasites in a human red blood cell. The parasites contain abnormally dense food vacuoles (F) from treatment with a protease inhibitor, a possible chemotherapeutic agent. The images were taken with the transmission x-ray microscope XM-1 at the Advanced Light Source in Berkeley. [Courtesy of C. Magowan, J. T. Brown, and W. Meyer-Ilse; see also Magowan *et al.* (1997).]

4.1.2 Sperm The small size of sperm cells makes them, like the malaria parasite, challenging for visible-light microscopy. Electron microscopy has revealed that DNA is packed so densely inside the nucleus of the mature sperm that electrons cannot penetrate it. X-ray microscopy, combined with atomic-force microscopy, obtained reasonably accurate estimates for the water content of air-dried rat sperm chromatin (DaSilva *et al.*, 1992) and provided the first clear evidence that sperm chromatin must be extensively hydrated, even in its highly compacted state.

Differences between near-edge x-ray absorption spectra of protein, bovine serum albumin (BSA), and DNA make it possible to map these components separately in bull sperm, on the basis of images taken at several energies. Figure 19 shows the spectra of DNA and BSA and Fig. 20 shows the distribution of protein and DNA in bull sperm, based on a series of images taken at different photon energies.

4.2 Environmental Sciences

The ability to study hydrated systems with high spatial resolution combined with the ability to map certain elemental and chemical properties of the sample makes x-ray techniques very valuable for environmental sciences. Notably, reactions that require a certain *p*H to occur cannot be studied with techniques that require introduction of the sample into vacuum.

Of great interest are, for instance, redox reactions that change the solubility of contaminants in our environment. Many species of bacteria can oxidize or reduce transition-metal ions, especially iron and manganese. Imaging with photon energies either above the absorption edges of the transition metal or for carbon-rich microorganisms in the water window provides specific contrast of the metal-containing particles or the organic material. Figure 21 shows x-ray microscope images

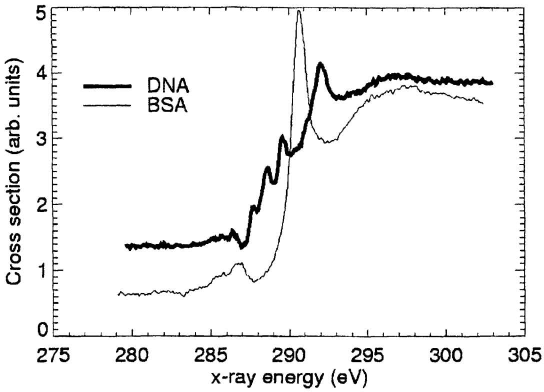

FIG. 19. X-ray absorption spectra of protein, bovine serum albumin (BSA) and DNA make it possible to map these components separately [adapted from Zhang *et al.* (1996), courtesy of R. Balhom].

taken in the same area of a sample, at 646 eV, where x rays are strongly absorbed by the manganese atoms in the needle-shaped particles of manganite (MnOOH), and at 517 eV where x rays are absorbed by the carbon atoms in the bacteria. Figure 22 shows the absorption spectrum of manganese at the L edge. The specific shape of this spectrum indicates that the sample predominantly contains Mn^{3+}. The ability to use spectral analysis illustrates the spatial arrangement of the reactant particles in a nearly natural hydrated state with unprecedented resolution.

The morphology of soil in its hydrated state is of genuine interest in the geosciences. Penetration of water through pores in the soil is responsible for many transport and reaction mechanisms of nutrients and toxicants. Techniques exist to characterize these processes for pore sizes down to about 10 µm. X-ray microscopy is used to study the porous inner structure of soils at a submicrometer scale (Niemeyer and Thieme 1998). Figure 23 shows the microstructure of a dystric cambisol as an example.

4.3 Materials Sciences

4.3.1 Chemistry, Civil Engineering X-ray microscopy has been applied to several problems important to our infrastructure and for industry.

4.3.2 Cement and Concrete In concrete, alkali-metal ions and hydroxyl ions contributed by the cement and reactive silicates present in aggregate can participate in a destructive alkali–silica reaction. This reaction of the alkalis with the silicates produces a gel that tends to imbibe water found in the concrete pores, leading to swelling of the gel and eventual cracking of the affected concrete member. Over 104 cases of alkali–aggregate reaction in dams and spillways have been reported around the world. At present, no method exists to arrest the expansive chemical reaction that generates significant distress in the affected structures. X-ray microscopy has been used to study these alkali–silica reactions *in situ* with high spatial resolution (Kurtis *et al.*, 1998) (Fig. 24).

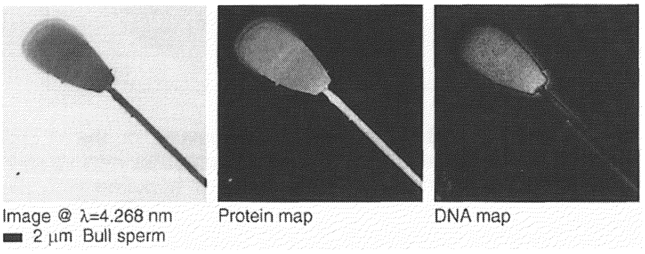

FIG. 20. X-ray microscopy image of a bull sperm taken at 290.5 eV and the distribution of protein (middle) and DNA (right) based on a series of images taken at different photon energies [from X. Zhang *et al.* (1996), courtesy of R. Balhom].

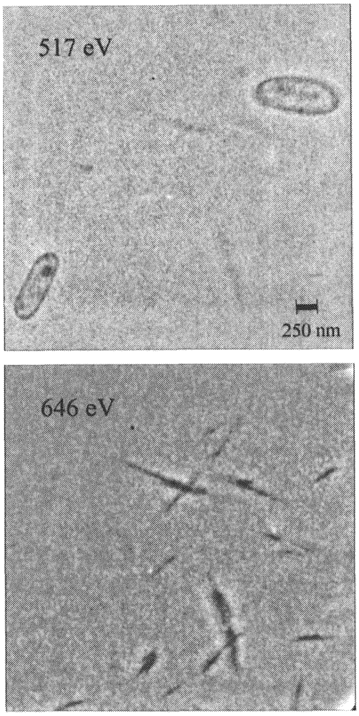

FIG. 21. Hydrated manganese particles and bacteria imaged in the water window (top) and above the manganese L edge (bottom). The images were taken with the transmission x-ray microscope XM-1 at the Advanced Light Source in Berkeley. (Courtesy of B. Tonner and K. Nealson.)

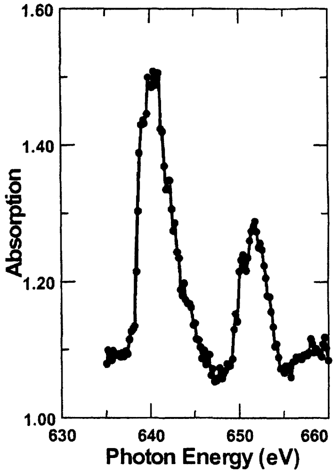

FIG. 22. Spectrum at the Mn L edge from manganese particles as shown in Fig. 21. This spectrum was taken at the STXM at beam line 7.0 of the Advanced Light Source in Berkeley. (Courtesy of B. Tonner.)

4.3.3 Polymers High–spatial-resolution near-edge spectroscopy at the carbon edge is of importance for polymer manufacturing industry. An early example of NEXAFS microscopy is shown in Figs. 25 and 3. The STXM at beam line X1A at the NSLS was used to image the phases from a polycarbonate–poly(ethylene terephthalate) (PC–PET) blend without resorting to heavy-element staining (Ade *et al.*, 1995). The chemical composition of the phases is selectively highlighted with small changes in photon energy. The observed contrast reflects the presence or absence of an electronic resonance between carbonyl groups and the phenylene in the polymers. The spectra of PC and PET as acquired with the X1A-STXM are shown in Fig. 3, along with the chemical structure of the respective polymers. Similar functional groups are present in these polymers, yet the spectra are strikingly different.

4.4 Future Applications

Though it is almost impossible to foresee future applications of x-ray microscopy, it is expected that the techniques described here will be used in a variety of fields not mentioned here. The semiconductor industry, for in-

stance, is developing new lithography techniques to make ever smaller chips. This will require the use of extreme-ultraviolet or soft–x-ray wavelength, as well as the assisting microscopy and microanalysis methods.

GLOSSARY

Areal Density: Mass per area, often measured in g cm^{-2}. Transmission experiments see the areal density.

Advanced Light Source (ALS): Synchrotron radiation facility at the Lawrence Berkeley National Laboratory, California, U.S.A.

BESSY: Synchrotron radiation facility in Berlin, Germany.

Electron Writing Tool: Instrument similar to a scanning electron microscope, which is used to write very small patterns for lithographic processing. Used to fabricate zone plates.

Fixation: Method to stabilize sensitive samples to prevent structural damage from processing or investigations. Chemical fixatives cross-link sample molecules. Cryogenic fixation means deep freezing the sample.

Kirkpatrick–Baez Mirror: Arrangement of two curved mirrors, used to focus x radiation (see X-RAY OPTICS).

Multilayer: Multiple layers of coating to enhance significantly the reflectivity of extreme ultraviolet and x radiation (see X-RAY OPTICS).

National Synchrotron Light Source (NSLS): Synchrotron radiation facility at Brookhaven National Laboratory, Long Island, New York, U.S.A.

NEXAFS: Near-edge x-ray–absorption fine structure. Spectroscopic method to determine chemical properties of the sample.

SPEM: Scanning photoemission microscope (see XPS).

Synchrotron Radiation: Electromagnetic radiation with very high brightness, produced by accelerated charged particles, often electrons (see also SYNCHROTRON RADIATION).

Water Window: X rays of photon energies between the carbon and oxygen K-shell absorption edges. Those x rays provide natural contrast from hydrated organic materials.

XANES: X-ray absorption near-edge spectroscopy (see NEXAFS).

XPS: X-ray photoemission spectroscopy. Spectroscopic analysis of photoelectrons generated by x-ray photon excitation.

Zone-plate Lens: Circular grating structure that acts like a lens, bases on diffraction. Zone plates are used for highest–spatial-resolution x-ray microscopes.

INTRODUCTION

Since the publication of our original article, several noteworthy advances have occurred in acoustical tomography. Improvements in computer technology have made nonlinear diffraction tomography an active research topic. A theoretical foundation has been developed for using acoustical tomography to reconstruct vector quantities. Acoustical tomography has become a mature technology for studying deep-water oceanography. Tomography experiments have produced new insights into deep convection, internal tides, large-scale circulation, and basin-scale temperature variability. More recently, techniques have been developed to study both the water column and the sediment layers in shallow water. Acoustical tomography has been demonstrated in the atmosphere for measuring near-surface temperature and wind velocity.

1. NONLINEAR DIFFRACTION TOMOGRAPHY

In acoustical tomography, a medium of interest is ensonified from several different directions, and the acoustic field is measured for each view. By processing and combining the data in an inversion algorithm, an image of the medium is developed. The inversion algorithm will necessarily depend on a model for the interaction between the sound and the medium. If the model is based on an acoustic wave equation, the process of making the measurements and producing an image is called diffraction tomography.

Mathematically, the scattered field $\psi_S(\mathbf{x})$ is related to the scattering function $F(\mathbf{x})$ describing the medium by an integration over the scattering volume V. Equation (4) from the original article is repeated here:

$$\psi_S(\mathbf{x}) = \int_V F(\mathbf{x}')\psi(\mathbf{x}')G_f(\mathbf{x},\mathbf{x}')\,d\mathbf{x}'.$$

Here, G is the free-space Green's function, or impulse response, that maps scattering from a point $\mathbf{x}'$ in the volume to the observation point $\mathbf{x}$. The total field $\psi(\mathbf{x}')$ is the sum of the known incident field and the unknown scattered field $\psi_S(\mathbf{x}')$. Consequently, the equation is nonlinear; the scattered field appears in a complicated way on both sides of the equal sign. Most algorithms used in diffraction tomography make simplifying approximations to linearize the equation. In the Born approximation, the unknown total field inside the integral is replaced by the known incident field. This is a weak-scattering approximation equivalent to ignoring multiple scattering. Strong scattering is the norm, however, in medical and many other prospective applications. Consequently, tomographic algorithms based on the linearizing Born approximation often produce unsatisfactory results.

In recent years, researchers have proposed various ways to take diffraction tomography beyond weak-scattering approximations. Since

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

linearizing approximations are avoided, the methods are often called *nonlinear diffraction tomography*. In one way or another, these methods rely on numerical solutions to the scattering integral. These methods are usually iterative. Typically, an initial guess is made for the scattering function and the internal field. The integral is then solved numerically for the scattered field that would be measured at the receivers. The difference between the calculation and the observation is used to update the estimates. The procedure is then repeated until the error is below a specified tolerance.

Clearly, nonlinear diffraction tomography is a computationally intensive procedure. At each iteration, the forward-scattering calculation must be repeated. The information from all scattering directions, from all incident field directions, and at all frequencies must be included. When the dimension of the scattering regime is many acoustic wavelengths, the resulting system of equations that must be solved at each iteration can be enormous. Even then, there is no guarantee of convergence.

Borup *et al.* (1992) examined numerical solutions to the scattering integral based on the method of moments. Chew *et al.* (1996) reviewed several other nonlinear diffraction tomography algorithms. These include the distorted Born iterative method. In this procedure, the background medium is not constrained to be homogeneous. This means that a simple analytical representation for the Green's function is no longer possible. A numerical representation is required and must be updated at each iteration. Chew *et al.* (1996) report that the method has improved convergence and can handle objects with a large acoustic contrast.

Nonlinear diffraction tomography remains the subject of active research. As computational power continues to increase, and as more sophisticated algorithms are developed, it is likely that nonlinear diffraction tomography will have a significant influence on measurement technology.

2. VECTOR TOMOGRAPHY

Sound traveling through a moving fluid will be affected by the motion. Recently, tomographic methods have been proposed for characterizing fluid flow. Since the fluid motion has both a local magnitude and a local direction, tomographic methods have been generalized to reconstruct vector fields. Attention is restricted here to cases where the propagation paths are sufficiently short to allow neglect of refraction. This is typically the case in industrial or small-scale oceanographic applications.

Tomographic methods for characterizing fluid flow operate primarily in the transmission mode. As usual, the acoustic travel time from source to receiver will depend on the scalar sound-speed perturbation $\delta C(\mathbf{x})$ of the intervening fluid.In addition, the travel time is also influenced by fluid motion, which can be described by the vector flow velocity field $\mathbf{u}(\mathbf{x})$. The travel time of an acoustic ray propagating along path $\boldsymbol{\tau}$ is a function of $\mathbf{u} \cdot \boldsymbol{\tau}$ integrated along the propagation path. To separate the contribution of fluid flow to travel time from that of sound speed, a reciprocal transmission strategy is used. The travel time is measured along a given path in both directions. Averaging the two measurements removes the effects of fluid motion and yields an estimate of the sound speed. Consequently, when refraction is negligible, the reconstruction of $\delta C(\mathbf{x})$ for a moving fluid reduces to the classic tomography problem detailed in the original article. The projection-slice theorem relates the measurements to the unknown field. The averaged travel-time data from several different directions are combined using the filtered back-projection algorithm to generate the reconstruction.

Taking the difference of the measurements isolates a projection of $\mathbf{u} \cdot \boldsymbol{\tau}$. In contrast to the scalar problem, the reconstruction of vector fields has received sustained attention only in recent years. Initially, the differential travel time was fed directly into the standard reconstruction algorithm. The resulting images, however, were incomplete because components of the flow were invisible. The difficulty is that the differential travel time is sensitive only to that component of the flow vector that lies along the acoustic ray path. Transverse components of the flow are unsampled.

Norton (1988) put vector inversion on a firmer theoretical footing. By means of a vector projection-slice theorem, he showed that only the divergence-free (solenoidal) component of a two-dimensional vector field could be recovered from measured projections. This still gives considerable information about the flow.

The solenoidal component is directly related to the fluid vorticity, itself an important quantity in many areas of fluid dynamics. Instabilities that cause the transition from laminar flow to turbulent flow often exhibit characteristic vorticity structure. A fluid traveling through closely spaced elbows in a pipe, for example, can acquire an unwanted swirling component of motion that can be described in terms of vorticity. Winters and Rouseff (1990) developed a filtered back-projection algorithm for vorticity. Braun and Hauck (1991) successfully imaged flow fields in laboratory experiments.

Rouseff and Winters (1994) proposed using linear diffraction tomography to image flow fields. An appropriately modified wave equation was used to describe acoustic propagation through the flow. They showed that with diffraction tomography it was possible to recover a low-pass filtered version of the complete vector field $\mathbf{u}(\mathbf{x})$. This illustrates an important concept for inverse problems in general and acoustical tomography in particular: to generate a satisfactory reconstruction, it is imperative to include the proper physics in the forward propagation model. To reconstruct the full two-dimensional vector velocity, a ray-based forward model is inadequate whereas a wave-based model provides a more complete inversion.

3. APPLICATIONS OF ACOUSTICAL TOMOGRAPHY

Strictly speaking, most acoustical imaging systems currently used in medicine and nondestructive testing are not tomographic. These systems usually operate in the pulse-echo mode and do not coherently combine data taken from several different directions to form an image. Computer capability and often the underlying science are still not sufficiently advanced to permit practical tomographic imaging systems to be built. Acoustical tomography has found utility primarily in oceanography.

3.1 Ocean Tomography

The results of several recent ocean tomography experiments are summarized here. A review of this field has recently been published by Munk *et al.* (1995).

In the Greenland Sea tomography experiment (1987–1988) the time-dependent three-dimensional ocean temperature was mapped using the tomographic technique. The forward model used to describe the acoustic propagation was based on mode theory. This was the first time that the travel times of acoustic normal modes were measured and used in the inversion process. Given the weakly range-dependent (adiabatic) sound-speed profile, late-arriving acoustic modes sample the near-surface ocean whereas rays sample the deeper ocean. The inversions incorporated point and profile measurements as well as the acoustic measurements. The results provided the first four-dimensional view of oceanic deep convection (Morawitz *et al.*, 1996).

In the Acoustic Mid-Ocean Dynamics Experiment—Moving Ship Tomography (AMODE-MST) project, six transceiver moorings were installed in a pentagonal array south of Bermuda in the Sargasso Sea, where they then "talked" to each other over ranges of 300 to 700 km. During 50 days of the 1-yr experiment, a ship circumnavigated the moored array two and a half times, lowering a vertical receiving array every 3 hours and every 25 km. Although laborious, this provided the large number of ray paths crossing at a multitude of angles required for high-resolution imaging (cf. the projection-slice theorem). One resulting map over a $1000 \times 1000\text{-km}^2$ area is shown in Fig. 1 (AMODE-MST Group, 1994). Because the ocean was changing during this time, the inversion must be explicitly cast in a time-dependent model.

The Acoustic Thermometry of Ocean Climate (ATOC) project has been a major new effort. The principal idea behind ATOC is to use basin-scale acoustic transmissions to measure large-scale variability in ocean temperature (heat content). A prerequisite to doing this is to understand the forward problem. To ranges of 5 Mm, it has been determined that steep ray arrivals are stable, resolvable, and identifiable with predicted rays. The shallow-angle energy described by acoustic modes is more affected by nonlinear mode coupling caused by scattering from ocean internal waves; this has so far made the interpretation of the data difficult. However, the final (lowest mode) cutoff arrival does appear to be stable. Furthermore, a recent experiment using a 28-Hz source (ATOC uses a 75-Hz source) shows

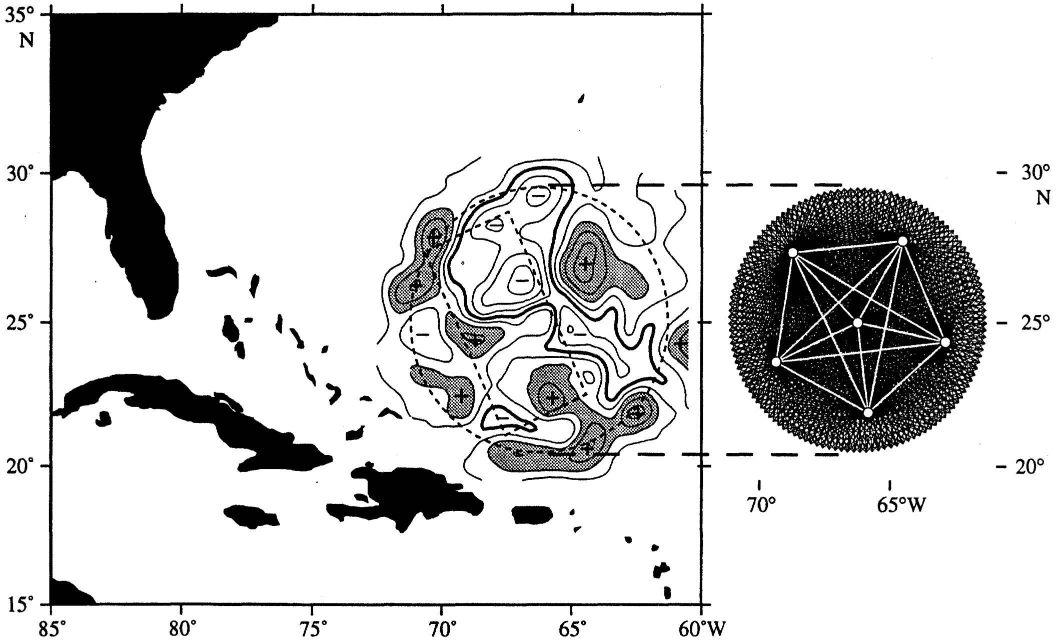

FIG. 1. Sound-speed perturbations from the climatological mean in 1-m/s (0.25 °C) contours at 700-m depth, as measured during the Moving Ship Tomography experiment, 15–30 July, 1991 (AMODE-MST Group, 1994). Five of the moorings are in a pentagon 700 km in diameter, with the sixth mooring in the center. The receiving ship moved around a 1-Mm circle, making 135 receiving stops.Rays from each of the moorings to the receiving stops are shown on the right. The dashed rectangle shows the area surveyed with air-expendable temperature sensors for comparison purposes; the two methods agreed within the expected errors (from Munk et al., 1995; © 1995, Cambridge University Press).

a significant improvement in the acoustic arrival structure, because the lower-frequency, longer-wavelength sound is less affected by the internal waves. The routine use of this and even lower frequencies awaits the development of a more practical transducer.

An acoustic source on Pioneer Seamount off California has been transmitting since the beginning of 1996 to various receivers around the Pacific Basin at ranges up to 10^4 km. The travel times change by as much as 1 s, with clear seasonal cycles (Howe *et al.*, 1996).

A similar, but briefer, experiment was carried out in the Arctic, with a source transmitting to several receivers around the Arctic Basin (Mikhalevsky *et al.*, 1995). As in the Greenland Sea work, the data are most naturally interpreted in terms of acoustic modes. A clear change in mode travel times relative to those that were predicted by use of climatological data indicated a significant warming, which was later verified by intensive *in situ* temperature measurements.

There have recently been several shallow-water tomography experiments. These must by necessity take into account bottom interaction, and therefore the data are much more difficult to interpret; see for instance Jin *et al.* (1996). A moving-source tomography experiment was recently conducted over 2-km ranges in the Haro Straits (Bellingham *et al.*, 1996). Velocity over ranges of 7 km has been determined in water 70 m deep by means of reciprocal transmissions (Kaneko *et al.*, 1996).

Send *et al.* (1995) describe an experiment to measure deep convection in the Mediterranean and are working toward establishing a permanent monitoring system. Groups in Japan are developing new hardware as well as using commercially available systems to begin work off Japan, in the Philippine Sea, and in the equatorial Pacific.

3.2 Sediment Tomography

Tomographic methods have been applied to study the properties of ocean sediment. Yamamoto (1995) adapted seismic cross-borehole techniques for use with propagation paths on the order of hundreds of meters to infer sediment properties like density, porosity, and shear strength. To image smaller scales, Tang *et al.* (1996) developed a U-shaped frame, each leg 1 m long, with 20 transceiver elements on each leg. The two legs are inserted into the sediment and transmission measurements are made. These applications have, to date, been limited to two-dimensional (single-slice) geometries.

3.3 Atmospheric Tomography

In the atmosphere, acoustic tomography has recently been demonstrated by Wilson and Thomson (1994) as a method of measuring the near-surface temperature and wind velocity. Attenuation limits the possible acoustic frequency bands and the range. Their demonstration system consisted of three sources and four receivers with a maximum range of 240 m (their high signal-to-noise ratio implies that longer ranges are possible). An impediment to further development and routine use of such a system is the lack of robust software to pick and track ray-arrival peaks. (This is a problem shared with ocean tomography, but in the latter case, there are presently no requirements for real-time processing.)

3.4 Seismic Tomography

Seismology is concerned with determining the mechanical properties and the dynamics of the interior of the Earth. Because we are limited to only (near) surface measurements of Earth motion, tomography is a natural technique for using the available data to infer the structure of the Earth's interior. Seismic tomography is based on the analysis of body (compressional P and shear S) waves, surface (Rayleigh and Love) waves, and free oscillations (normal modes) as typically recorded on seismographs. The P waves are the "usual" acoustic waves, and thus the connection to acoustical tomography; the presence of the other types of waves complicates (even more) the seismic forward and inverse problems. The literature on seismology and seismic tomography is vast; only a few references are provided here to guide the reader (see also SEISMOLOGY). Nolet (1990) showed how the partitioning of the inverse problem into linear and nonlinear steps can greatly facilitate the interpretation of the large data sets that are commonly used. This work has been extended to include diffraction (Meier *et al.*, 1997) and mode coupling (Marquering *et al.*, 1996). The use of free oscillations to determine the largest scales of the Earth's interior is described by Masters and Widmer (1995).

4. CONCLUDING REMARKS

Many prospective applications of tomography in medical and nondestructive testing require accurate and efficient techniques for modeling the forward problem in highly diffractive or strongly scattering regimes. Progress is being made toward solving this problem, with the most gain expected to come from the ever-increasing computational capability. Deep-water ocean tomography is now a mature technique; applications involving bottom interaction and long ranges are probing the limits of the method. Atmospheric tomography has been demonstrated, but further implementation awaits an efficient method of tracking ray-arrival peaks. It is expected that acoustical tomography will prove to be an elegant and efficient method of measuring ocean sediments in a minimally intrusive manner, particularly at smaller scales. Lastly, acoustical tomography will most likely benefit from the theoretical and numerical development being made in seismic tomography.

1. RECENT DEVELOPMENTS

Since the original article COMPUTER DATABASES was published, significant advances have been made in computer technology. These include the availability of better hardware at lower cost and the appearance of new and more sophisticated software. The overwhelming success of the World-Wide Web (WWW) has revolutionized the way we do business in information. In addition, some changes have occurred as far as the databases described in the original article are concerned.

1.1 Technological Advances

The dramatic changes which have taken place in the distribution, transmission, and access of data of all kind in the last five years were driven by technological advances. In the first instance, the price of mass storage devices for personal computers, work stations, and even mainframes all but collapsed. Whereas personal computers in the beginning of the nineties were fitted with hard discs of about 200 MB, nowadays PCs "off the shelf" have capacities in excess of 1 or 2 GB. Secondly, the prices of random-access memory (RAM) storage chips have dropped considerably. Nowadays, a standard PC is fitted with 16 MB or more of RAM memory compared to 2 or 4 MB a few years ago. Thirdly, hand in hand with these developments, microprocessor speeds increased tremendously—doubling in about every 18 months.

Needless to say, software expanded to these new realities. New software packages invariably use up more hard disc space and need more RAM memory and higher processor speeds in order to perform satisfactorily. Fortunately, their functionality has increased too. Terminals connected to mainframe computers or work stations have been replaced by intelligent front ends (clients) with graphical user interfaces (GUIs). Lately, the idea of "network computers" without hard discs (NCs) was born, with more limited intelligence but running software downloaded from the Internet or a central in-house platform. This greatly facilitates software maintenance, since only a single copy of some product has to be kept up to date.

A few years ago, CD-ROMs were considered somewhat exotic. Drives were slow, and the availability of software or data collections on CDs was low. In the meantime, software and data on CDs have become the rule rather than the exception. It has become possible to produce CDs in small quantities by recording or "burning" them directly in low-cost devices. Master copies can be produced inexpensively for pressing CDs on a large scale.

Furthermore, external magneto-optical storage devices scarcely larger than the well-known $3\frac{1}{2}$-in. magnetic discs have appeared, with storage capacities ranging from 100 MB to 1 GB and good accession times. These new discs have come in handy for information exchange and as storage media for data backups. Being direct-access devices, they have some advantages over the traditional magnetic tape streamers.

Perhaps the most spectacular development happened in the area of communication networks. This is related to the explosive development of the Internet, which consists of a set of linked networks talking the same "language", viz. TCP/IP, the Transmission Control Protocol/Internet Protocol, and its technologies. The Internet is conquering the world

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

and is now commonly used for disseminating and accessing data from places all over the world. This global information infrastructure that has been realized by the creation of the Internet has resulted in a revolution of information behavior in the 1990s. Far from making the traditional hosts superfluous, the Internet offers other and numerous new information possibilities. More and more of the traditional information providers are accessible via the Internet. Almost all researchers now have access to the Internet and are using it daily. In the form of the Intranet the Internet technology is also applied to in-house networks.

1.2 Databases

With the end of 1994 the production of the PHYS database was stopped. The PHYS database was merged with the INSPEC database, resulting in a high-quality database containing all areas of physics and the additional subject fields of electrical engineering, electronics, control, computing, and information technology. The physics subset of INSPEC is now cooperatively produced by the Institution of Electrical Engineers (IEE) and Fachinformationszentrum (FIZ) Karlsruhe. The dissemination of the printed abstract journal *Physics Briefs/Physikalische Berichte*, the content of which was based on the electronic database PHYS, was also terminated and incorporated into the abstract journal *Physics Abstracts*, which is the printed analog of INSPEC for physics. The total number of citations in INSPEC as of September 1996 was about 5.3×10^6 (50% to 60% physics).

The database C13 NMR/IR is not offered anymore. It has been replaced by the database SpecInfo which contains the same data, but in addition more and other types of spectral data as well as more and better retrieval components. It is distributed as an in-house version by Chemical Concepts and online via STN International.

2. DATABASES AND THE INTERNET

The Internet and its associated services, i.e. electronic mail (e-mail), file-transfer protocol (FTP), and in particular the world-wide web (WWW), have revolutionized communications with the outside world. Under the HyperText Transfer Protocol (HTTP), multimedia documents written in HTML, the HyperText Markup Language, are retrieved from special servers (web servers) and displayed locally by use of a web browser such as Netscape. With knowledge of the symbolic address of a web server, or more precisely the so-called URL or Uniform Resource Locator of its HTML files, information may be requested and received world-wide. For example, FIZ Karlsruhe can be reached via the symbolic address http://WWW.fiz-karlsruhe.de.

HTML documents are static documents stored as files on host computers. However, web pages can be made interactive with the user in a number of different ways. First, most HTML documents contain references or links (URLs) to other documents. Selecting highlighted sections of text on a web page is sufficient to obtain access to these documents, which on their own may reside at any location within the Internet. Following these links a user can "surf" through the Internet, starting for example with the Library of Congress and ending in the Vatican while looking at pictures by some famous painter. Second, web pages of HTML documents can be made dynamic with the aid of the CGI, the Common Gateway Interface, which allows user programs to be executed on the web server itself. Third, Plug-Ins and/or Java Applets may be downloaded from the web site and executed on the client computer itself. In this manner web pages can be animated—for example, by rotating figures and graphical elements.

Search engines such as Lycos or Hotbot may be used to find information in the WWW by matching one or more search strings entered by the user. The retrieved documents are ranked according to the degree of overlap with the search terms.

Retrieval of data from centralized databases via the WWW needs HTML forms in which the user can type his requests, and some process on the web server to parse the ASCII strings and pass them through to a database server. The answers from the database have to be passed back via the web server to the end user, who sees the result in the form of a dynamically generated web page. The technical realization of such a system encompasses a number of points that cannot be treated here.

Table 1. Journals on-line.

Physical Review Letters	http://prlo.aps.org/
Applied Physics Letters	http://ojps.aip.org/aplo/
Physical Review C	http://publish.aps.org/
Physical Review D	http://publish.aps.org/

Needless to say, the overall performance loss of such a system with many intervening and interdependent processes can be quite significant when compared to classical in-house database management systems. The situation is improved when the web and database servers are combined in a single unit as, for example, in the Oracle WebSystem. In addition to delays in treating database requests at the host site, the Internet itself may be the cause of poor response times, particularly at certain peak hours of the day. These apparent disadvantages are more than offset by the flexibility and availability of the WWW, so that the number of database providers within the WWW is expected to increase enormously within the next few years. Access to large online databases has recently been demonstrated by STN-International with STN-Easy and EI-Village. Here HTML forms are used for requesting and retrieving bibliographic and other information.

3. PREPRINT SERVERS AND ELECTRONIC JOURNALS

Most physicists are using computers at work today, for writing articles and for communication. The progress in network technology now facilitates the transmission of full-text documents including mathematical formulas, figures, and graphs. Thus, it is no problem to distribute preprints electronically all over the world today. The inexpensive disc storage allows also storage of all these preprints at one place. The first example of a wide usage in physics was the Los Alamos preprint server, which was established by Paul Ginsparg at Los Alamos in 1991 (see Taubes, 1993). The physicist submits papers electronically by e-mail, via FTP, or by using WWW uploaded pages in a prescribed specific format (e.g. TEX) to this server; the system automatically files these papers and sends out abstracts on demand or to a list of subscribers. The physicist can then scan the abstracts, decide which documents are of interest, and download them or require that the preprints be sent to him. This server system is located within the WWW, so that the searching and browsing capabilities of the WWW can be applied. At present examples of such preprint servers are the Los Alamos e-print archive, URL = http://xxx.lanl.gov/, and the CERN Preprint Server, URL = http://preprints.cern.ch/.

This preprint database system allows scientists to publish their results without having to go through a peer review and publication process. This has given the term "desktop publishing" a completely new meaning.

In the meantime also a number of publishers have placed their journals on line with full text and graphics and are offering their printed journals also in electronic form as so-called electronic journals (see Durrani, 1996). In most cases this is done in parallel with the paper version. In this case the usual journal concept, whereby articles are judged and selected within the peer review system and made accessible under subscription, is maintained. Compared with the printed versions these electronic journals have the advantage of allowing full-text searching and hypertext links as well as the printing of an article on demand. Access is possible via Internet or other telecommunication lines. Important examples are given in Table 1.

INTRODUCTION

Computer programming languages are under active development in many areas. For physicists, the most important recent changes in computer programming languages have been extensions to FORTRAN and increased use and availability of C and C++. Increased access to computer networks, high-performance graphics, and databases has led to the increased use of HyperText Markup Language (HTML) and JAVA™ (a special dialect of C++) to create Web pages and forms, use of languages such as TEX™, Postscript™, and Rich Text Format (RTF) for document preparation, and use of languages such as STAR and CIF for database entry preparation. For a more general perspective on recent developments in programming languages, see Bruce (1996), Cardelli (1996), Cohen (1996), Goldberg (1996), Hirschfield and Ege (1996), Schmidt (1996), Wolfe (1996). For a list of freely available language processors, see Robenalt and Sharnoff (1996).

1. THE EVOLUTION OF FORTRAN

FORTRAN remains the dominant language in which scientific computing applications are written. As of this writing, the most popular dialect is the one from 1978 called FORTRAN 77, with gradually increasing use of features from the dialect called FORTRAN 90 adopted by the International Standards Organization in 1991. The language continues to evolve, with a dialect called FORTRAN 95 now available, and the general features of FORTRAN 2000 have been proposed. A guide to the literature can be found in Metcalf (1996), and a detailed description of the current dialects in Metcalf and Reid (1996).

When code portability is an important consideration, it is still best to restrict FORTRAN programs to the subset of FORTRAN 77 described in COMPUTER PROGRAMMING LANGUAGES, but, eventually, many new features from the more recent dialects should be widely available.

FORTRAN was created when the most common computer input medium was the 80-column punch card on which it was simple to keep track of column numbers. Programs are now written with use of interactive editors, many of which do not provide simple mechanisms to track column numbers. Therefore, newer dialects of FORTRAN permit programs to be written in free format, in which statements may be begun in the first character position of a line and use up to 132 character positions of a line. When an exclamation point appears on a line, the rest of the line is treated as a comment. Multiple statements may appear on the same line separated by semicolons. When the portion of a line that is not a comment ends with an ampersand, the FORTRAN statement continues on the next line, which may optionally begin with an ampersand In most cases, blanks are optional, but for most keywords, such as "READ", "WRITE", etc., a blank is required. Full use of free format can cause problems with portability of code. With some care, it is possible to

© 1999 WILEY-VCH Verlag GmbH

ISBN 3-527-29307-8

adopt a style that is accepted by most compilers as either free format or the older fixed-field format by restricting statements to the first 72 columns of a line, reserving columns 1 through 5 for statement labels, reserving columns 6 and 73 for continuation, separating all keywords with blanks, and avoiding multiple statements on one line. Most compilers now accept the exclamation point as a comment character.

Newer dialects accept pointers that allow indirect references to data. This brings to FORTRAN much of the power that languages such as C have in manipulating complex dynamically allocated data structures, but also brings the attendant difficulties in debugging and optimization seen when pointers are used. When code to manipulate linked lists or trees of information is being written, pointers can greatly improve the clarity and reliability of the code produced, but in the writing of code that can be done with equal clarity with arrays, pointers are best avoided.

Newer dialects also allow arrays to be manipulated as easily as scalar variables. All the elements of an array may be moved or manipulated at one time by using the name of the array, instead of having to write an element-by-element loop. An entire array may be given as the value of a function. When a compiler provides such features, not only can the clarity and reliability of the code be improved by their use, but efficiency can be improved as well. When array operations are specified element by element, the compiler is not as free to create optimal code as it is when only the higher-level specification in terms of arrays is given.

There are many other improvements to the language, but one of the most important is the definition of modules, which allows the grouping of subroutines and related data into clearly defined packages. This is a step towards the eventual inclusion of a full range of object-oriented features into FORTRAN (see COMPUTER PROGRAMMING LANGUAGES for more information on "object-oriented" programming).

An important change in the environment for the writing of portable FORTRAN code has been the increasing use of F2C (Feldman *et al.*, 1990), and the availability of G77, a FORTRAN compiler integrated with the GNU project C compiler (Stallman *et al.*, 1996). F2C translates FORTRAN code into C and provides a standard library of operating system interface routines. G77 is a fully operational compiler that produces object code very similar to that produced by F2C but bypassing the need for intermediate C code. G77 and F2C are very popular for FORTRAN compilation on personal computers running variants of the UNIX™ operating system. Subtle differences in the interpretation of language standards (such as in the handling of string concatenation) and in operating-system interfaces and interfaces to routines written in other languages, such as C, has made the creation of portable FORTRAN code difficult, requiring the use of very restricted language subsets and special platform-dependent variations. F2C and G77 have greatly simplified the process of porting codes by providing virtually identical language processors on a wide variety of platforms and clearly defined interfaces to the operating system and to code written in other languages.

2. C AND C++

C has become the standard language for most operating-system programming. With various extensions, C is now the language of choice for building basic systems-level tools, displacing both assembly language and PASCAL. Object-oriented extensions to C have been defined. The most popular is C++ (Ellis and Stroustrup, 1990). Originally provided as a translation program that converted an object-oriented extension of C into C, C++ is now processed as a full-fledged compiled language, and C has evolved to become a compatible subset of C++. The GNU C compiler GCC (Stallman *et al.*, 1996) processes C, C++, and another object-oriented dialect, called "Objective C". C++ supports polymorphism and overloading (see SOFTWARE ENGINEERING), and emphasizes static binding that allows a wide range of potential errors to be detected at compile time. Objective-C emphasizes dynamic binding that simplifies the management of complex code libraries.

An important part of static checking in C or C++ is the use of function prototypes, which carry the important information about how to call a routine without having to provide all the code. Consider the simple FORTRAN function "nblen," which returns the length of a string to the last non-blank character:

```
   function nblen (str)
C  non-blank length of a string
   character*(*) str
   integer nblen,jj,ii
   jj = len(str)
   do ii = 1, jj
     nblen = 1 + jj - ii
     if(str(nblen:nblen).ne.' ')return
   enddo
   nblen = 0
   return
   end
```

When this subroutine is converted by F2C to C or C++, a file called "nblen.P" is created with the statement

```
extern integer
nblen_ (char *str, ftnlen str_len);
```

which says that there is an integer function named "nblen_" (the underscore was added by F2C) with two arguments, the address of a string called "str" and its length "str_len". Programs that use nblen can be compiled using the information in nblen.P to check that the calls that they make are correctly structured. The C or C++ code generated by the loop in the middle of the function looks very much like the original FORTRAN code:

```
jj = i_len(str, str_len);
i__1 = jj;
for (ii = 1; ii <= i__1; ++ii) {
ret_val = jj + 1 - ii;
if (*(unsigned char *)
  &str[ret_val - 1]
  != ' ') {
   return ret_val;
}
}
```

For simple procedural algorithms, there is no special advantage in converting from FORTRAN to C or C++, but in the writing of applications involving complex graphical interfaces and real-time interactions, access to powerful, well-debugged "class-libraries" (predefined libraries of C++ routines and data structures) to perform such tasks as drawing images in windows and passing messages to motor-drivers makes use of C++ highly desirable.

3. HTML AND JAVA™

Much of science is now dependent on the communications infrastructure known as the Internet. Experimental scientists can now start an experiment at a major facility and control it from local or remote terminals using the Internet. The HyperText Markup Language (HTML), augmented by a dialect of C++ called JAVA, is an effective programming language for the creation of applications distributed across a network that can be run on a wide variety of platforms. HTML describes documents. In its most common application HTML documents are presented for viewing in terminal windows by a Web browser. A raw HTML document consists of lines of text marked up by special instructions delimited by angle brackets. The special instructions may flag new paragraphs, headings, lists or other text formatting, may cause images to be fetched, or may cause programs to be executed. The image presented can have areas that respond to mouse clicks to cause another page to be found or, by use of program fragments ("applets") written in JAVA, cause a wide variety of processing actions to occur. There are many competing, evolving, somewhat incompatible dialects of HTML. The most recent "official" version of HTML is version 3.2 (Raggett, 1996). This is a well-supported version to use in writing Web pages. HTML Version 4.0 has been released in draft form and is supported by many Web browsers, but many other Web browsers in use fail to support features of the most recent HTML versions. See SOFTWARE ENGINEERING for more on HTML.

JAVA defines a dialect of C++ that is highly unlikely to cause problems for a computer that downloads an applet from an unknown source. The applet is not allowed general access to memory through pointers, nor to arbitrary files on the host machine. The applet is downloaded in very compact "byte-code" form (*i.e.*, partially compiled to the level of numeric instructions to a JAVA virtual machine). Much of the work of creating powerful applets is taken care of by the existence of comprehensive class libraries and collections of sample applets. For more on JAVA, see Gosling *et al.* (1996).

The process of creating applications to interact with Web pages is greatly simplified by the use of scripting languages, which function interpretively. Two popular scripting languages are TCL and Perl. Perl combines pattern-matching capabilities with C-like programming. TCL allows powerful stand-alone or browser-embedded graphic applications to be built quickly. For more on Perl, see Wall and Schwartz (1990). For more on TCL, see Ousterhout (1996).

4. DOCUMENT-PREPARATION AND DATA-DESCRIPTION LANGUAGES

The transition to electronic presentation of scientific information and the decentralization of computing and document preparation has changed our view of what constitutes a scientific publication. We now need to separate the information to be presented from the mode of presentation, and the languages for the presentation of information have become increasingly important as programming languages. HTML is effective for presentation on a variety of platforms, but does not allow for precise control of the style of presentation in terms of fonts, character sizes, and other layout issues. Currently, the most popular "page description languages" (languages for precise document layout) are TEX™ (Knuth, 1986), which is used internally by many scientific journals, Postscript™ (Adobe Systems, 1990), which is used to create on-line distribution files of many scientific documents with full formatting, and Rich Text Format (RTF) (Microsoft, 1995), which is used for interchange of word-processing documents across systems. An effort is under way to combine precise document layout with HTML by means of "Cascading Style Sheets" (CSS) (Lie and Bos, 1996).

As databases and data archives have become a critical part of scientific research, the need for common languages for capturing data and descriptive information about the data has become clear. One of the most successful efforts in this direction has been the work at the International Union of Crystallography on a Self-Defining Text Archive and Retrieval (STAR) language and a Crystallographic Information File (CIF) (Hall *et al.*, 1991). Based on simple tag-value constructs, these languages have made it possible to gather all the information needed for both a scientific publication and the archival data upon which the publication is based into a common data format. When complex data structures must be described in a precise but machine-independent manner, Abstract Syntax Notation One (ASN.1) is often used. See Gaudette *et al.* (1989, Chapter 2) for an excellent tutorial and references on ASN.1.

It has become clear that these languages are all more than means for expressing the detailed layout of documents or making entries in databases and archives. They are intrinsic parts of an evolving composite language for the control of computers in the transformation of information among many possible representations.

INTRODUCTION

This Addendum discusses developments in inorganic and organic electroluminescence since the publication of the original article ELECTROLUMINESCENCE.

The biggest challenge in inorganic thin-film EL technology today is producing multicolor and full-color displays. Manufacturing of practical color displays was long delayed because of the insufficient luminance of the primary colors (red, green, and blue). Recently, however, progress in the development of the multicolor display structures and color phosphors has made it possible to fabricate commercial multicolor EL displays fulfilling customer's requirements (Cramer *et al.*, 1993), and commercialization of full-color EL displays is close to being a reality (King, 1996a).

Organic thin-film EL devices have been extensively studied since an efficient green emission was demonstrated in 1987 (Tang and VanSlyke, 1987). Substantial improvements in luminous efficiency, color, and stability have been made (Tang, 1996a,b). To a large extent, they have been made possible by use of a multilayer device structure prepared by using vapor deposition and by the discovery of several important classes of organic EL materials that have excellent transport and luminescent properties. These advances have stimulated commercial interest in developing new color displays.

The present review discusses new inorganic thin-film EL phosphor materials with blue and broad-band emissions and their applications to commercial multicolor and full-color EL displays. In addition, recent developments of organic color thin-film EL are discussed.

1. COLOR EL PHOSPHORS FOR INORGANIC EL DISPLAYS

The development of color phosphor for inorganic EL displays has divided into two different material approaches that are based on the structure of the thin-film EL panel. The two basic color thin-film EL structures are the patterned-phosphor structure and the filtered-white structure, also known as the color-by-white structure (see, for example, Ono, 1995, 1996, 1997).

Figure 1 shows practical examples of these two structures. In the patterned-phosphor structure, the development of efficient red, green, and blue primary-color EL phosphors is necessary, and in the filtered-white structure, the development of an efficient white (or broad-band) phosphor that can be filtered to produce a red, green, and blue (RGB) display is necessary. Improved phosphor performances have been the key technological advancement lead-

FIG. 1. Two types of inorganic color thin-film EL structures: (a) patterned-phosphor scheme in a dual-substrate structure; (b) filtered-white or color-by-white scheme in an inverted structure.

ing to the recent successes in both approaches to develop color thin-film EL displays.

In this section, recent developments in red, green, and blue phosphors for the patterned-phosphor structure and broad-band and white phosphors for the filtered-white (color-by-white) structure are discussed.

1.1 Color Phosphors for the Patterned-Phosphor Structure

1.1.1 Red Phosphors. The most efficient EL red emission is produced by the CdS_xSe_{1-x}-filtered ZnS : Mn phosphor (Tuenge and Kane, 1991), whose emission spectrum is very broad, ranging from green to red. The Commission Internationale de l'Eclairage (CIE) color coordinates of $x = 0.65$ and $y = 0.35$ are very close to the red coordinates for color CRTs ($x = 0.624$, $y = 0.337$). Luminance of 70 cd/m^2 at 60 Hz is sufficient for color display applications. These data are summarized in Table 1, which shows a representative list of the best reported EL phosphor performance data. In the table, L_{40} indicates the luminance measured at 40 V above the threshold voltage.

Table 1. Luminance and luminous efficiency of inorganic color EL phosphors.

Phosphor material	Emission color	CIE coordinates x	y	Luminance L_{40} at 60 Hz (cd/m^2)	Luminous efficiency η (lm/W)
ZnS : Mn	Yellow	0.50	0.50	300	3–6
ZnS : Mn/Filter	Red	0.65	0.35	70	0.8
ZnS : TbOF	Green	0.30	0.60	100	1.3
ZnS : Tb,F	Green	0.31	0.60	90	0.6
ZnS : Mn/Filter	Yellow-green	0.47	0.53	160	1.0
SrS : Ce	Blue-green	0.26	0.48	140	1.2
SrS : Ce/Filter	Blue	0.10	0.16	14	0.12
$SrGa_2S_4$: Ce	Blue	0.14	0.10	5	0.02
$CaGa_2S_4$: Ce	Blue	0.14	0.19	10	0.03
$Ca_{0.5}Sr_{0.5}Ga_2S_4$: Ce	Blue	0.14	0.13	4.3	—
ZnS : Mn/SrS : Ce	Yellowish-white	0.49	0.48	470	1.3–1.6

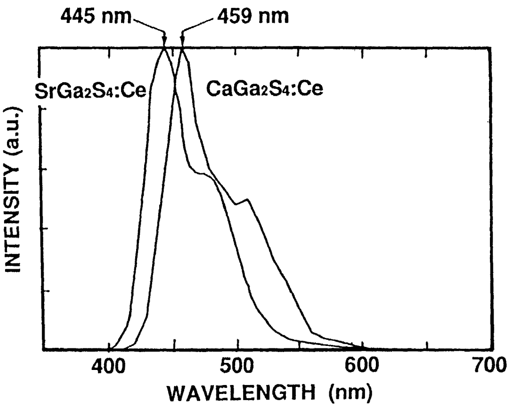

FIG. 2. Inorganic EL emission spectra of $CaGa_2S_4:Ce$ and $SrGa_2S_4:Ce$.

1.1.2 Green Phosphors. For a pure green emission, ZnS:TbOF has the highest luminance and luminous efficiency (see Table 1). The CIE color coordinates of $x = 0.30$ and $y = 0.60$ are close to the green coordinates for color CRTs ($x = 0.312$, $y = 0.597$). Green emission can also be obtained by filtering out the green component of the ZnS:Mn spectrum, which results in a yellow-green luminance.

1.1.3 Blue Phosphors. The first material to show promise as a blue EL phosphor was SrS:Ce (Barrow *et al.*, 1984). However, the broad-band blue-green emission of SrS:Ce requires filtering in order to achieve a blue chromaticity that is acceptable for RGB color displays. The performance of the SrS:Ce phosphor has recently been improved: molecular-beam-epitaxy (MBE)-deposited SrS:Ce was used to achieve a filtered luminance of 14 cd/m^2 with the CIE color coordinates $x = 0.10$ and $y = 0.16$ (Törnqvist, 1997).

Barrow *et al.* (1993) reported a significant breakthrough in blue phosphors. They showed that a group of alkaline-earth thiogallates MGa_2S_4 (M: Ca, Sr) were efficient host materials for the blue EL phosphor when activated with Ce. Figure 2 shows the EL emission spectra for calcium and strontium thiogallate films activated with 1 mol% cerium. Luminance and luminous efficiencies of these thiogallate phosphors are given in Table 1.

The data in Table 1 clearly show that the alkaline-earth thiogallates provide a much deeper blue emission than that of the SrS:Ce phosphor. The $SrGa_2S_4:Ce$ phosphor achieves the deepest blue color with the CIE color coordinates of $x = 0.14$ and $y = 0.10$ and provides a color gamut close to that of the standard CRT display ($x = 0.157$, $y = 0.069$). However, the eye response for the $SrGa_2S_4:Ce$ phosphor emission is nearly a factor of two less than that of the $CaGa_2S_4:Ce$ emission. Thus for equivalent energy efficiency, the $CaGa_2S_4:Ce$ would achieve twice the photopic brightness. The best luminance of 10 cd/m^2 at 60 Hz was obtained for sputtered $CaGa_2S_4:Ce$ using high–dielectric-constant insulators. Very good EL aging characteristics have been demonstrated for the thiogallates (Barrow *et al.*, 1993). Therefore, the thiogallate blue EL phosphors demonstrate the sufficient stability, luminance, and blue chromaticity needed to build a full-color thin-film EL display.

Recently, blue purity has been further improved by mixing Ca and Sr in the host (Tuenge, 1995a, 1995b). The cerium-emission peak wavelength can be continuously shifted from 445 to 459 nm in a mixed calcium and strontium host because these two alkaline-earth thiogallates are miscible over the entire composition range. By optimizing the composition of the mixed host, $Ca_{0.5}Sr_{0.5}Ga_2S_4:Ce$ was found to give a good result with the CIE color coordinates of $x = 0.14$ and $y = 0.13$ and the luminance $L_{40} = 4.3$ cd/m^2 at 60-Hz drive.

1.2 Color Phosphors for the Filtered-White (Color-by-White) Structure

A white-emitting phosphor may be designed either for monochromatic white thin-film EL displays or for multicolor or full-color thin-film EL displays achieved by filtering white light through color filters.

Recently, white emission with the luminance level required for filtered color thin-film EL displays has been achieved by using a stacked ZnS:Mn/SrS:Ce phosphor. The emission spectrum is shown in Fig. 3. This broad-band multilayer phosphor has been investigated by several groups using different deposition processes including multisource deposition (Nire *et al.*, 1992), reactive evaporation (Mauch *et al.*, 1993; Mauch, 1994; Velthaus *et al.*, 1994), and atomic-layer epitaxy (ALE) (Soininen *et al.*, 1993; Soininen *et al.*, 1994; Törnqvist, 1996). The luminance

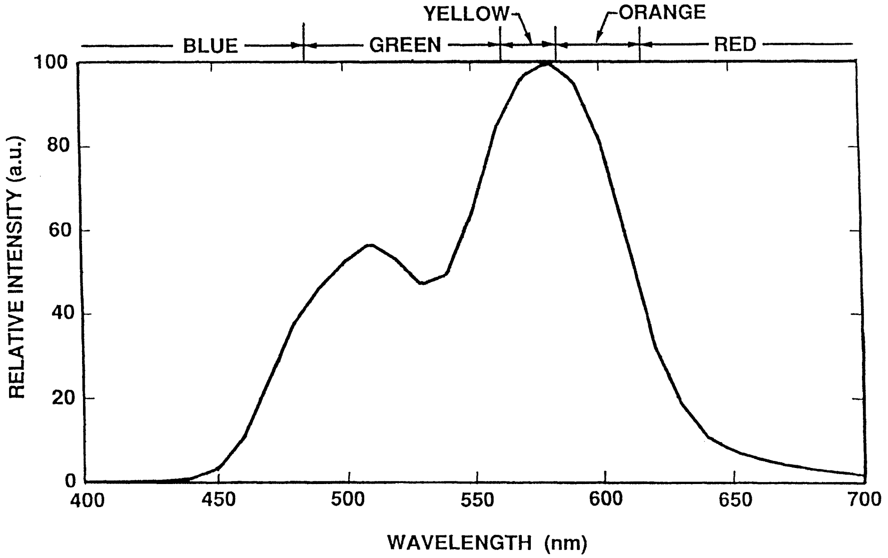

FIG. 3. White EL emission spectrum of ZnS : Mn/SrS : Ce phosphor.

performance of the state-of-the-art ZnS:Mn/SrS:Ce grown by ALE is as follows (Törnqvist, 1997): The filtered red, green, and blue luminances L_{50} at 60-Hz driving are 97, 220, and 11 cd/m^2, respectively. These values are sufficient for RGB multicolor EL display applications. The blue-filtered color coordinates of $x = 0.13$ and $y = 0.36$ need further improvement in order to extend this approach to full-color capability.

The ALE-deposited SrS:Ce films have shown good luminance stability (Soininen *et al.*, 1994), and recently a significant improvement in the stability of evaporated SrS:Ce, Cl films has been demonstrated by codoping them with Zn or Mn (Mauch *et al.*, 1995). These results indicate that by careful control of the defects in the SrS host lattice, the aging characteristics of this material will be sufficient for use in color thin-film EL display panels.

2. INORGANIC COLOR THIN-FILM EL DISPLAYS

2.1 Multicolor Displays

The first RG (red/green) multicolor display (Cramer *et al.*, 1993) employs the filtered broad-band emission from ZnS:Mn in the inverted EL structure [see Fig. 1(b)]. Red and green pixels are generated by use of a patterned color filter plate that is in direct contact with the thin-film stack, thereby eliminating any parallax effects. This structure has several advantages. A very good contrast can be achieved without the use of the traditional circular polarizer, and contrast ratios of 20 : 1 at 500 lx ambient and 10 : 1 at 1000 lx ambient are typical results. In addition, the fabrication of the active thin-film stack can be done with the same equipment line that is now used to fabricate monochrome ZnS:Mn panels, producing very good yields.

In 1994 an eight-color, 10-in. diagonal VGA display (640 × 480 pixels) was brought to the market (Soininen *et al.*, 1994). This multicolor EL panel is an ideal choice for display applications such as industrial control systems and medical electronics, where color highlighting and differentiation of graphics information are needed.

Recently the green color purity of the RG multicolor display has been improved by using $Zn_{0.9}Mg_{0.1}S$:Mn as a broad-band phosphor (Mikami *et al.*, 1996; Mikami, 1997), which has exhibited a pure yellow emission with a peak wavelength of 575 nm. Based on this technology, 4.7- and 9.4-in. diagonal prototype RG multicolor EL displays with a wider color range were fabricated.

2.2 Full-Color Displays

2.2.1 Filtered-White (Color-by-White) Scheme in the Inverted Structure. The simple filtered, inverted multicolor panel structure can be extended to full-color capability by replacing the ZnS:Mn EL phosphor with a ZnS:Mn/SrS:Ce white phosphor. In 1995 a 9-in. diagonal 512 × 256-pixel RGB multicolor panel was fabricated (Haaranen *et al.*, 1995) that demonstrated the performance that meets product requirements. The typical white areal luminance was 21 cd/m^2. The contrast ratio was 40 : 1 in normal office ambient illumination of 500 lx and was 5 : 1 in bright ambient illumination of 10 000 lx. In 1997 a much brighter 5-in. diagonal quarter-VGA (320 × 240 pixels) display was developed (Harju *et al.*, 1997). A white areal luminance of 70 cd/m^2 at 350-Hz driving and contrast ratios of more than 100 : 1 at 500 lx and 7 : 1 at 10 000 lx have been achieved. The CIE color coordinates of the red, green, and blue emissions are ($x = 0.61$, $y = 0.38$), ($x = 0.46$, $y = 0.51$), and ($x = 0.28$, $y = 0.41$), respectively. The color gamut is adequate for applications where the three primary colors must be present but full color is not needed, such as instrumentation applications and automotive displays.

This filtered-white scheme has been applied to develop a 1.5-in. diagonal color VGA active-matrix EL (AMEL) display that is fabricated on single-crystal silicon-on-insulator IC wafers (Aguilera *et al.*, 1996; King, 1996b; Törnqvist, 1997). A filtered white luminance of 555 cd/m^2 was obtained at 4.5-kHz AMEL drive, and filtered luminances were 110, 410, and 35 cd/m^2 for red ($x = 0.63$, $y = 0.36$), green ($x = 0.29$, $y = 0.68$), and blue ($x = 0.12$, $y = 0.20$) emissions, respectively (Törnqvist, 1997). The color gamut of this display should be sufficient for video applications. In 1997 a lower-power, larger–color-gamut, 0.7-in. diagonal full-color VGA display was developed (Tuenge *et al.*, 1997). With field-sequential filtering using a liquid-crystal color shutter, 256 colors have been achieved. The power consumption is typically 2 W. These color AMEL displays are expected to provide a low-cost solution for compact, high-resolution miniature color displays that are suitable for a variety of military and commercial head-mounted and personal viewer applications.

2.2.2 Patterned-Phosphor Scheme in the Dual-Substrate Structure. As shown in Fig. 1(a), the dual-substrate panel structure optimizes the net blue luminance. Blue light is obtained from an unpatterned cerium-doped alkaline-earth thiogallate phosphor. Green light is obtained from a patterned ZnS:Tb phosphor film, and the red component is obtained by filtering the ZnS:Mn emission with a CdS_xSe_{1-x} thin-film filter. The dual-substrate panel structure also allows the drive electronics to be independently optimized for each substrate. Therefore, a higher refresh rate can be used for the blue substrate to increase blue luminance.

In 1993 using the dual-substrate panel structure the first full-color EL display, a 10-in. diagonal VGA prototype display, was reported (Barrow *et al.*, 1993). In 1994 pursuing the same structural approach, a quarter-VGA (320 × 256 pixels) full-color display (FC2) that has a performance sufficient for the first commercial full-color products was introduced (Barrow *et al.*, 1994; King, 1994). In the VGA prototype, $CaGa_2S_4$:Ce was used, and in the commercial FC2 panel, the improved blue phosphor $Ca_{0.5}Sr_{0.5}Ga_2S_4$:Ce was used (Tuenge, 1995a). The color gamut of these full-color panels (VGA panel and FC2) is shown in Fig. 4.

This figure shows that the color ranges of the full-color panels are very close to those of the color CRT. The EL red and green primaries are more saturated than those of the color CRT, whereas the EL blue approaches the CRT blue. A white areal luminance of 30 cd/m^2 with the CIE color coordinates ($x = 0.37$, $y = 0.41$) is achieved at a 180-Hz drive. Filtered areal luminances are 9, 17, and 4 cd/m^2 for red ($x = 0.65$, $y = 0.35$), green ($x = 0.31$, $y = 0.61$), and blue ($x = 0.14$, $y = 0.13$) emissions, respectively. A high contrast of 20 : 1 is realized in a 500-lx ambient condition. This quarter-VGA full-color display is expected to be competitive in price with TFT LCDs and will offer EL's traditional advantages over LCDs, which include undegraded performances over extremes of temperature and a very wide viewing angle.

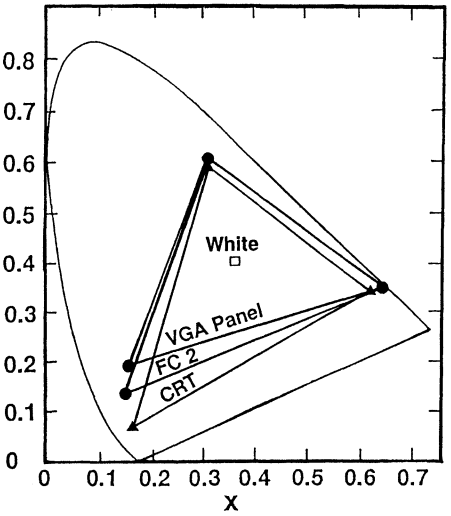

FIG. 4. Color gamut of inorganic full-color EL displays (VGA panel and FC2) and color CRT.

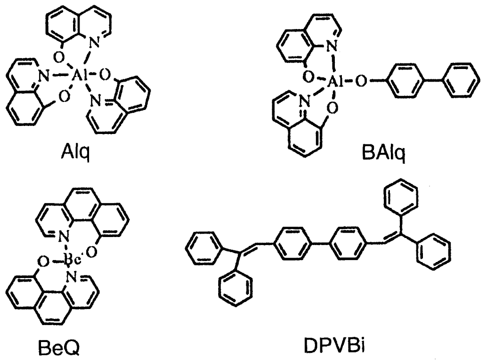
3. ORGANIC COLOR THIN-FILM EL DISPLAYS

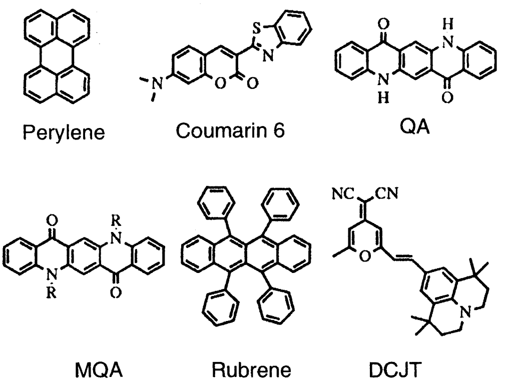
The efficient organic EL devices generally have the three-layer structure with electrodes: anode/hole-transport layer (HTL)/emitting layer (EML)/electron-transport layer (ETL)/cathode (Adachi *et al.*, 1988). The most efficient EL devices use an EML layer consisting of a host material doped with a small amount of fluorescent molecules (Tang *et al.*, 1989). For example, efficient green and orange-red ELs have been obtained from an 8-hydroxyquinoline aluminum (Alq) host using dopants such as coumarin 6, QA, and DCJT (Tang, 1996a, 1996b). Other host materials include distyrylarylene derivatives (DSA), such as 1,4-bis(2,2-diphenylvinyl)biphenyl (DPVBi) (Hosokawa *et al.*, 1995), which are excellent blue emitters. The chemical structures of these organic emitting layer (EML) materials and dopants are shown in Fig. 5.

The EL spectra of a set of organic EL devices emitting in blue, green, and red are shown in Fig. 6 and their luminance characteristics are summarized in Table 2 (Tang, 1996a, 1996b). These EL devices used an EML layer based on doped Alq.

The chromaticity of the green EL is close to that of the CRT green, but the blue and red colors are less pure. Further improvement in the purity of the blue and red emissions is necessary.



(a) Emitting Layer (EML) Materials



(b) Dopants

FIG. 5. Chemical structures of representative organic EL materials: (a) emitting-layer (EML) materials; (b) dopants.

Other combinations of organic materials and dopants were reported to produce excellent efficiencies. The quinacridone-doped Alq device that had green emission exhibited an efficiency 2.5 times higher than that of the undoped Alq device (Wakimoto *et al.*, 1996). For blue EL, the DPVBi class of materials was found to be one of the most efficient. A luminous efficiency of 1.5 lm/W was reported for a DPVBi-doped DSA device (Hosokawa *et al.*, 1995).

Remarkably stable EL devices—in particular, those with emitters based on doped Alq

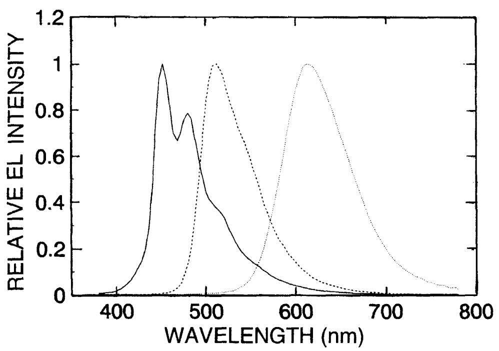


FIG. 6. Organic EL emission spectra of RGB emitters.

and doped DPVBi devices—have been demonstrated. For example, for a green EL device with a modified quinacridone MQA-doped Alq, the half-life exceeded 6000 h (Tang, 1996a,b) and for a blue EL device with DPVBi-doped DSA, the half-life was 5000 h (Wakimoto *et al.*, 1996).

The only approach to have achieved multicolor and full-color displays has been to develop a bright blue-emitting thin-film layer and to obtain green and red emissions by using color-changing media (CCM) (Matsuura *et al.*, 1995; Hosokawa *et al.*, 1997). This has been done by using the CCM made of organic fluorescent materials. The conversion efficiencies of luminance from blue to green emissions and blue to red emissions were 120% and 30%, respectively. A distyrylarylene (DSA) derivative, DPVBi, was used as a blue-emitting layer and an amino-substituted DSA (DSA amine) was used as the fluorescent dopant. These materials showed excellent EL performances. The luminous efficiency was improved to 6 lm/W and the half-life was more than 10,000 hours. Luminances were 40, 150, and 65 cd/m^2 for red (0.63, 0.32), green (0.23, 0.65), and blue (0.12, 0.18) emissions, respectively. The color coordinates of RGB emissions are very close to those of the color CRT.

In June 1997 a prototype 5-in. diagonal quarter-VGA (320 × 240 pixels) full-color EL display, which can display 16.8 million colors, was reported (Yomogida, 1997). The half-life was extended to 20 000 h and the power consumption was only 3.9 W. Furthermore, just six months later, a prototype 10-in. diagonal VGA (640 × 480 pixels) full-color display was demonstrated at the Japan Electronics Show '97 (Komori, 1997).

4. CONCLUSIONS AND FUTURE PROSPECTS

Inorganic color thin-film EL phosphors have been developed to a level that is sufficient for use in initial multicolor and full-color EL display products. The most efficient red and green phosphors, Mn- and Tb-doped ZnS, have been optimized for the manufacturing of patterned color displays. The Ce-doped alkaline-earth thiogallates are the first EL phosphors to provide the unfiltered blue color essential for full-color capability. Improvements in the luminance and aging behavior of the SrS : Ce blue-green phosphor have enabled an efficient and stable broad-band emission that will provide the basis for filtered multicolor EL displays.

A future challenge in the development of patterned color phosphors will be to improve the blue luminance further to enable larger, lower-power displays. In order to reduce panel cost, it will also be important to be able to reduce the blue-phosphor processing temperature. Enhanced emission in the blue spectral region will be required in order to extend the filtered broad-band structure approach to full-color capability.

Table 2. Luminance and luminous efficiency of organic color EL phosphors.

Emisson color	Host material	Dopant material	CIE coordinates x	y	Luminance at 20 mA/cm^2 (cd/m^2)	Luminous efficiency η (lm/W)
Red	Alq	DCJT	0.616	0.381	770	1.3
Green	Alq	Coumarin 6	0.263	0.619	1980	3.9
Blue	BAlq	Perylene	0.163	0.194	355	0.56

Thanks to the improvements in the performance of blue and white phosphors, color thin-film EL displays are now on the market. Based on the color-by-white scheme, the 9-in. diagonal RGB display suitable for instrumentation applications was commercialized and a 1.5-in. diagonal color VGA active-matrix EL display for use in head-mounted displays was developed. The patterned-phosphor scheme in the dual-substrate structure provided the basis for the VGA and quarter-VGA full-color EL displays to be developed, and these are expected to fulfill new flat-panel display applications.

There has been considerable progress in organic thin-film EL devices that are based on a multilayer structure, and it has become possible to make color EL devices with luminous efficiencies much greater than 1 lm/W throughout the visible spectrum. Long operational life has also been demonstrated, and a display with a half-life on the order of 10^4 h has been made. Organic color EL has thus emerged as a new emissive display technology with the potential for a wide range of applications.

INTRODUCTION

The technology of explosives is advancing in a number of areas. The impetus for this work is to improve understanding of

1. how and why explosive materials initiate and detonate,
2. how to make more powerful and safe explosives,
3. what the properties of known explosives are, and
4. how to compute, in detail, the initiation, detonation, and action of explosives on adjacent materials.

Because of space limitations, we only mention some of the more important developments and then concentrate on five specific topics that are representative of recent work.

The five areas that will be discussed in some detail are

1. pure nitrogen explosives,
2. molecular-level measurements of the high-pressure chemistry at detonation conditions,
3. mechanical measurements of reaction-zone properties,
4. detonation-products equation of state (EOS), and
5. initiation measurement techniques and examples of the data obtained.

As in the original article (we assume that the concepts discussed in that article are familiar to the reader), we concentrate on condensed-phase, molecular (rather than mixture) explosives. They are the simplest type and hold the most promise for improved understanding, although mixture explosives are of great practical importance in the mining and blasting area. Because of the short time scales and small space scales under which the chemical reactions in condensed-phase explosives take place, much of our understanding remains phenomenological and is based on studies of one-dimensional (1-D) detonation waves and their interaction with the surrounding "confinement" material. There are many areas in which research on condensed-phase high explosives is being done. Much of the work being published relates to weapon or specialty high-explosive applications.

Research on the synthesis of new explosive materials continues. A current emphasis of this work is the synthesis of explosive molecules that contain a high proportion of nitrogen atoms or that are very insensitive to initiation. A pure-nitrogen explosive, N_8 cubane, is discussed in Sec. 1. Both theoretical and chemical synthesis work is aimed at making and understanding this material, as well as other high-nitrogen explosives.

Understanding the chemical reactions that occur in initiating and detonating explosives continues to be an important area of research. The experiments are costly on account of the extreme pressures and temperatures generated in a detonating sample; this results in the complete destruction of the test assembly and a portion of the experimental probes. The very short time scales involved in detonation phenomena also present difficulties. Additionally, detonating explosives are often opaque to the normal electromagnetic radiations used as spectroscopic probes. Because of these factors,

the work is challenging and progress is slow. In order to produce significant progress a research program must be sustained for 5 to 10 years.

Several recent studies at universities have been done under conditions designed to provide information relating to an initiation or detonation environment. Examples of this are the ring-up shock experiments of Gupta and coworkers (see Constantinou *et al.*, 1994; Gupta *et al.*, 1995), the temperature-jump experiments of Brill and coworkers (see Brill *et al.*, 1992), and the picosecond-spectroscopy experiments of Dlott and coworkers (see Tas *et al.*, 1997). These studies are helpful in bridging the gap between ambient and initiation and detonation reaction conditions but do not completely simulate the high-pressure/temperature regimes. Other workers continue to use gas-phase measurements to calibrate reaction mechanisms, which are then applied to condensed-phase detonation processes; this is almost certainly a gross oversimplification. Some workers believe that the first reactions in a detonation are of the condensation and ionization types (e.g., Blais *et al.*, 1997). Others think that there are "anomalous" phenomena present (Graham, 1979) that cannot be explained by ordinary chemical principles (see Sec. 2). French workers (see Soulard, 1996) have shown that small changes in the chemical makeup of a material can lead to large changes in performance, e.g., deuterated nitromethane has a critical diameter that is roughly twice that of protonated nitromethane, when fired under the same conditions.

Known high-pressure, condensed-phase chemical principles (le Noble, 1988; Issacs, 1981) have not been adequately incorporated into many explosive-chemistry studies, primarily because relatively few explosive workers have expertise in this area. Important research relating to this topic is discussed in Sec. 2.

Safety concerns have motivated many studies. Low-level insults, such as those from impact, flame, heat, etc., can lead to violent explosions and/or detonations. Various experimental setups have been devised to introduce such inputs into explosives, but these are usually not well instrumented and are difficult to interpret. Complex phenomena such as crushing, cracking, heating, shearing, etc. (or combinations thereof) can occur as a result of such insults, and they are difficult to model and understand. Even "cook-off" experiments, in which a material is controllably heated, are not sufficiently reproducible to yield detailed understanding that can be incorporated into computer models. In cook-off situations, heat generated by chemical reaction is competing with heat loss by thermal conduction to produce a runaway heating situation; under these circumstances the size of the explosive charge is important. Nevertheless, work is progressing in all these areas toward the goal of being able to model these phenomena.

Research continues in the area of homogeneous/heterogeneous initiation and detonation propagation. Understanding of the thermodynamic fluctuations in the flow (hot spots) and what causes them is at the root of this work. Again, because of difficulties in separating out the effects of various types of hot-spot phenomena, progress is difficult. Recently, even crystal imperfections in an explosive have been shown to affect initiation behavior (Borne, 1996), as has the orientation of the crystal axes (in perfect crystals) to the direction of motion of an initiating shock wave (Dick, 1997).

Measuring the detonation reaction zone of various explosives is an active area of work. Ideal explosives (molecular explosives in which the full exothermic chemistry occurs in the detonation reaction zone) are usually the explosives of interest. Some work in this area is discussed in Sec. 3. There is considerable current interest in nonideal explosives (usually mixtures of explosives, fuels, and oxidizers). These present an interesting area because the diameter-effect curves of such materials can exhibit very large decreases in detonation velocity before the failure diameter is reached. Furthermore, the extrapolated infinite-diameter detonation velocity is well below what is expected based on equilibrium thermodynamics (Kennedy, 1993).

Computational techniques are rapidly advancing as available computing capabilities increase. This is particularly true in the areas of parallel processing and adaptive meshing techniques. In problems where the explosive is only part of a much larger problem (several tens of centimeters in size) and it is important to resolve the detonation reaction zone (micron-size zoning), these techniques hold hope for meaningful calculations. Such calculations will probably be possible in the next few years.

In numerical calculations, reactivity is generally implemented by using a global rate form to calculate the state that lies between the unreacted explosive and the fully reacted products. This global rate model is usually a mathematically simple form based on initial shock parameters (such as pressure) and contains parameters that are adjusted to match explosive experiments. Reaction models have been developed by a number of workers, including, e.g., Arrhenius rates, Forest Fire (Mader and Forest, 1976), DAGMAR (Wackerle *et al.*, 1978), Ignition and Growth (Lee and Tarver, 1980), HVRB (History Variable Reactive Burn) (Kerley, 1992), and JTF (Johnson, Tang, Forest) (Johnson *et al.*, 1985). Since these are global rates, usually with one forward reaction, they cannot be expected to reproduce the detailed chemical-reaction mechanisms that are present in reacting explosives. Use of such global reaction models in a wave-propagation code often does a credible job of calculating the mechanical phenomena that occur when explosives are shock initiated or detonating explosives push inert materials.

More complicated multiphase flow models have been developed in order to calculate deflagration-to-detonation transitions (Baer and Nunziato, 1989; Bdzil *et al.*, 1997, 1999a,b), and there is a considerable effort to make these models more accurate. Because of the advent of parallel-processor computers, it is now becoming possible to numerically model discrete particles in three dimensions and to compute (and visualize) the particle crushing and hot spots produced by a passing pressure wave (Baer *et al.*, 1997). This type of modeling will undoubtedly become more important as time goes by.

To do credible modeling, accurate high-pressure equations of state (EOS) are required for both the unreacted explosive and the reaction products. Generally a portion of the unreacted Hugoniot is obtained from experiments done well below the detonation pressure; it is then extrapolated to the von Neumann spike point of the unreacted explosive. Reaction-zone profile measurements are helpful in validating unreacted Hugoniot forms at high pressures. Because of safety concerns, there is also considerable interest in the low-pressure (below 1 GPa) EOS of explosives. Work is under way to study the elastic/plastic nature of explosive materials and to determine the ways in which they crack and deform under the action of low-level insults.

The reaction-product EOS is often modeled by use of an empirical form called the JWL (after Jones, Wilkins, Lee) EOS (Lee *et al.*, 1968). It has a number of parameters that are determined by calibration to metal-pushing experiments. Recently, overdriven detonation experiments have been performed on a plastic bonded explosive (PBX 9501) in which the sound speed at the supported detonation state was measured. Such experiments help constrain the EOS form. These experiments are discussed in Sec. 4.

Measurement techniques are continually being refined and new ones developed, thus improving the experimental data available. For example, shock initiation of explosives can be studied by using multiple-gauge techniques in which gauges are built into the explosive system and used to make 1-D measurements. Pressure or particle-velocity measurements can be made (continuously as a function of time) at from one to as many as twelve locations in the explosive material. Pressure measurements are made with manganin and polyvinylidene-difluoride (PVDF) gauges. Particle-velocity measurements are made with magnetic gauges; this technique is briefly discussed in Sec. 5.

Laser velocity-interferometer measurements are made to study reaction zones (see Sec. 3), and these have, in some cases, subnanosecond time resolution. Techniques for measuring detonation velocity at high and low temperatures are being refined to account for the density and internal-energy changes of the explosive as functions of temperature (Hill, 1997). Proton radiography is used at Los Alamos National Laboratory to visualize the reaction zone and to study detonation corner-turning effects (Sarracino, 1997). Sound-speed measurements of detonated explosive at pressure are being made by optical emission techniques (see Sec. 4) to provide additional product EOS information (Fritz *et al.*, 1996).

1. PURE NITROGEN EXPLOSIVES

There is a proposed new class of chemical explosives that has excited considerable theoretical attention in recent years. The unusual feature of this class is that the molecules are composed entirely of nitrogen atoms. Some members of the class are predicted to have markedly superior explosive performance compared to any currently used chemical explosive.

The primary useful feature of condensed-phase explosives is the transient extremely high pressures that they generate and their concomitant ability to do work rapidly on the materials that surround them. Three factors determine a condensed-phase explosive's ability to do work. These are

1. the number of mols of gas per unit mass (G) produced when detonated,
2. its initial mass density (ρ_0), and
3. the amount of heat released per unit mass when detonated (ΔH_{det}).

The most powerful explosive in current use is HMX (cyclotetramethylene-tetranitramine–$C_4H_8N_8O_8$). For this explosive, the values of the three factors listed above are $G = 40.5\,\text{mol/kg}$, $\rho_0 = 1.90\,\text{g/cm}^3$ (crystal density), and $\Delta H_{\text{det}} = -1.5\,\text{kcal/g}$. The corresponding (Chapman-Jouguet—CJ) detonation pressure and velocity at crystal density are 40.5 GPa and 9.14 mm/μs, respectively (Engelke and Stine, 1990).

Property predictions have been made for various pure-nitrogen structures; e.g., the aza forms of tetrahedrane, cubane, cyclooctatetraene, and various linear molecular forms. The most interesting structure is N_8 cubane because of its

1. predicted very good performance as an explosive,
2. being isoelectronic with the experimentally known, very kinetically stable, carbon/hydrogen cubane, and
3. dissociation to N_2 molecules is a Woodward–Hoffmann symmetry-forbidden reaction, which argues for its kinetic metastability.

For N_8 cubane, the predicted values of G, ρ_0 and ΔH_{det} are $G = 35.7\,\text{mol/kg}$, $\rho_0 = 2.45\,\text{g/cm}^3$ (predicted crystal density), and $\Delta H_{\text{det}} = -4.3\,\text{kcal/g}$. The corresponding predicted detonation pressure and velocity are 131 GPa and 14.5 mm/μs, respectively. Note the very substantial improvement of these values over those of HMX. N_8 cubane's predicted ρ_0 value is obtained from accepted phenomenological methods (Stine, 1981). The G and ΔH_{det} values were obtained by assuming that the detonation produces the chemical reaction $N_8 \rightarrow 4N_2$. High-level quantum-chemical techniques were used to compute ΔH_{det} within this assumption (Engelke and Stine, 1990). Perhaps the most important measure of an explosive's performance is its ability to do work on its surroundings. If this criterion is used as the measure of performance, N_8 cubane is predicted to be a ca. 100% better explosive than HMX.

Reliable quantum-theoretical calculations of N_8 cubane's harmonic vibrational spectrum indicate that it is a stable, fairly rigid, bound structure. Therefore, given the right experimental conditions, it is highly probable that it could be produced as a metastable molecular form.

The salient current question is, "Is N_8 cubane sufficiently kinetically stable to be of practical interest?" The search for an answer to this question is a topic of ongoing research. Earlier computations along a high-symmetry reaction path to dissociation indicate a barrier to dissociation of ca. 40 kcal/mol. Improved more recent calculations indicate the actual value may be closer to 20 kcal/mol (Gagliardi *et al.*, 1997). If the true value of the lowest-energy activation barrier to dissociation or reaction of N_8 is much lower than 20 kcal/mol, the material may be uninteresting for practical uses. If it is near this value or higher, then N_8 cubane could be practically used and would bring about a qualitative advance in the performance of available chemical explosives.

2. REACTION-ZONE CHEMISTRY

There has been some recent progress in experimentally examining chemical kinetic processes in materials shocked into the pressure regime characteristic of detonating condensed-phase explosives.

Approximately fifteen years ago, a number of workers suggested that "anomalous" chemical processes occur at or near the shock front in shocked materials (Graham, 1979); supposedly these processes could not be explained by standard chemical theory. This idea has recently been shown to be incorrect. By analysis of shock recovery experiments on a diverse set of materials that undergo a variety of chemical reactions that are pressure hindered, enhanced, or neutral, Davis and Brower (1996) have shown that Eyring transition-state theory suitably augmented with an activation volume term is capable of explaining all their observations. The pressure and temperature range in which their experiments were conducted was 6 to 16 GPa and 900 to 1400 K.

There have also been recent very direct microscopic observations of chemical kinetic processes in detonating condensed-phase explosives and in surrogate materials shocked into the same pressure regime. Two of these efforts used a time-of-flight mass spectrometer, within which one can detonate or strongly shock energetic materials (Blais *et al.*, 1993). Using this apparatus, it has been shown that the cusp in anthracene's principal Hugoniot (at ca. 17 GPa) is the result of a pressure-driven dimerization reaction in which two anthracene molecules cross link (Engelke and Blais, 1994). It is thought that this cross linking is a Diels–Alder process. This same type of process has also been observed (using the same apparatus) in detonating solid TATB and TNT explosives (Greiner *et al.*, 1993). This indicates that an endothermic pressure-driven reaction is occurring in the early detonation kinetics of explosives containing aromatic rings. It is not known whether such reactions are a dominant feature of the detonation chemistry of the explosives containing aromatic rings or are an irrelevant side channel.

A similar mass-spectroscopic study has been made of detonating liquid nitromethane (NM) (Blais *et al.*, 1997). This material is found to have a very short chemical reaction zone; it is estimated to be ca. 50 μm and 7 ns in space and time duration. The most important result obtained was that the new chemical species found within the detonation reaction zone are the result of condensation reactions—i.e., two or more nitromethane molecules are combining to form more massive molecules in the chemical processes that eventually lead to the detonation products. This is completely different from the low-pressure chemistry of liquid nitromethane, where the decomposition chemistry begins with the unimolecular breaking of the CN bond.

In other work relating to the high-pressure chemistry of NM, Winey (1995) found, via optical spectroscopy experiments, that chemically pure NM shows irreversible changes when rung up to 17 GPa and 725 °C. In similar experiments, Constantinou *et al.* (1994) found similar irreversibilities at 10 GPa and 262 °C in base-sensitized NM. Neither of these sets of experiments took the NM explosives into the same temperature regime as occurs in detonating liquid NM.

There is a current hypothesis that ionic processes may be very important in the early detonation chemistry of some explosives. As a test case to examine how such processes occur, shock experiments were carried out to determine how rapidly the equilibrium

$$\mathrm{CoCl_2}X_2 + 4X \rightleftharpoons \mathrm{Co}X_6^{2+} + 2\mathrm{Cl}^- \qquad (1)$$

is reestablished when the material is strongly shocked (Engelke *et al.*, 1997); in Eq. (1), $X =$ ethanol. The pressures utilized in the experiments covered the range 0.8 to 6.7 GPa. The shocked materials were interrogated with time-resolved visible light spectroscopy. In the experiments at the 6- to 7-GPa pressure range, the equilibrium indicated in Eq. (1) was found to be shifted almost completely to the right, indicating the strong preference for the molecules to be ionized at such pressures. Furthermore, even with ligands as bulky as ethanol molecules, it was found that the equilibrium is reestablished in ca. 500 ns. The hydrogen or proton abstraction processes thought to be important in the detonation of some explosives are undoubtedly much faster than this and have not yet been experimentally explored.

3. DETONATION REACTION-ZONE MEASUREMENT

Detonation-wave profiles can be measured by *in situ* particle-velocity or pressure gauges. Interface velocimetry measurements of the particle velocity at the detonating-explosive/window interface provide the highest time-resolution reaction-zone data. Reaction-zone perturbations resulting from this measurement technique are discussed below. Detonation-wave profile experiments, coupled with computer modeling, provide estimates of global reaction-rate parameters.

There are several types of laser interferometry used to make measurements in both inert and energetic materials. These are VISAR (Barker and Hollenbach, 1972; Hemsing, 1979), Fabry-Pérot (Durand *et al.*, 1977), and ORVIS (Bloomquist and Sheffield, 1983); each of them has undergone improvements over time. Time resolution of streak VISAR (Hemsing, 1985) and ORVIS can be as fast as 200–300 picoseconds, while that of VISAR (with photomultiplier tubes and digitizers for recording the fringes) has a time resolution of 2–3 ns. Fabry-Pérot has a time resolution of 5–10 ns.

All these interferometers operate on the same principle: laser light (usually 514.5- or 532-nm wavelength) is Doppler shifted by a moving surface. This Doppler-shifted light is transduced by the interferometer into fringes that change as the velocity of the surface reflecting the laser light changes. The fringe changes are recorded and then analyzed to obtain the velocity–time profile. Such measurements have been made on nitromethane, PBX 9404, PBX 9501, TATB, PETN, and other explosives, although some of these data have not yet been published (Sheffield *et al.*, 1984; Seitz *et al.*, 1989; Tarver *et al.*, 1997).

A difficulty with an interface measurement of the reaction zone is that the wave profiles are perturbed by the mechanical impedance mismatch at the window through which the observations are made. This is not easily correctable because the impedance of the unreacted explosive is different from that of the reaction products; this makes it impossible to have a window impedance match through the entire reaction zone. Interpretation of the measured profiles require impedance matching to the window and/or computer modeling of the interaction process to obtain an estimate of reaction-zone properties. A recent paper used this technique to estimate the reaction zone of PETN to be less than 5 ns (Tarver *et al.*, 1997).

4. DETONATION-PRODUCTS EQUATION OF STATE

A detonation-products EOS is usually developed for a particular explosive by using the JWL form (Lee *et al.*, 1968) and calibrating it to a copper cylinder expansion experiment (using a wave code calculation). The cylinder test consists of a precisely machined copper cylinder filled with the explosive and detonated at one end. The wall expansion at a particular location is accurately measured as the detonation propagates up the tube. Measuring the wall expansion speed vs. time gives an estimate of the detonation products' ability to do work on the cylinder.

Recently, Fritz *et al.* (1996) used explosively driven metal flyer plates to overdrive a detonation in PBX 9501. An overdriven condition results when the flyer plate sustains the explosive at a pressure state higher than the CJ pressure. In the case of PBX 9501, the CJ pressure is 34.8 GPa, and several experiments were done with the support pressure ranging from 30 to 90 GPa. The velocity of the propagating wave was measured and the particle velocity determined by impedance matching to the standard materials in contact with the explosive. In addition, the explosive was in contact with either liquid bromoform or high-density glass, both of which emit light when they are shocked. The amount of emitted light is directly related to the shock pressure (McQueen *et al.*, 1982); higher pressures give more light.

In these experiments the flyer plate produces a pressure pulse in the explosive, creating an overdriven condition that persists until the rarefaction wave from the back surface of the plate moves into the detonation products and relieves the pressure. By use of fiber-optic probes and photomultiplier tubes to measure the light output as a function of time and making the bromoform or glass thickness vary at different positions on the experiment, the overtake time of the rarefaction overtaking the first shock was obtained. From these data, the sound speed at pressure in the detonation products was measured. In these highly overdriven states, chemical equilibrium was assumed, and thus the measured sound speed is taken to be that characteristic of the equilibrium detonation products.

The sound speed ($= c$) at pressure is an important parameter because it is an EOS derivative [i.e., $c^2 = (\partial P/\partial \rho)_s$]. When the experimentally measured sound-speed data are compared to the JWL sound-speed predictions, there is a considerable discrepancy. This method provides a tool that will help make calibrations of the product EOSs more accurate in the future.

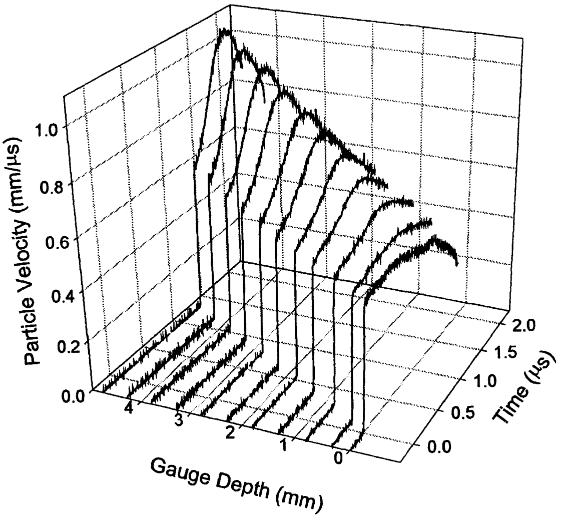

FIG. 1. *In situ* particle-velocity wave forms from a shock initiation in PBX 9501. The first gauge was at the shock input interface and the other ten gauges were embedded in the sample at positions ranging from $\frac{1}{2}$ to 6 mm into the explosive. (Unpublished data of R. L. Gustavsen and S. A. Sheffield, Los Alamos National Laboratory, 1997.)

Measurements on high-carbon–containing molecular explosives have led to a number of predictions that detonation conditions are such that carbon in the reaction products is converted to diamond. In fact, micron-sized diamonds have been recovered from the solid detonation products from confined detonations in some explosives (Greiner and Hermes, 1989). Since the carbon- or graphite-to-diamond transition is an endothermic process, the presence of diamond would be expected to manifest itself in some of the measured mechanical parameters. Indeed, there are slight changes in the product isentropes and other parameters in TNT and TATB that support this prediction. Consequently, this is a current area of both theoretical and experimental activity.

5. INITIATION MEASUREMENTS

Shock-to-detonation (SDT) processes are best measured by *in situ* gauging techniques, which can track the reactive wave growth as a function of time. This provides valuable information to those doing reactive modeling, because it is a rigorous test of the particular global reaction-rate model used to predict the wave growth. Cowperthwaite and Rosenberg (1981) used a multiple-magnetic particle-velocity gauge technique to study nonideal explosives. Both magnetic particle-velocity and manganin pressure measurements are valuable in such studies.

In homogeneous initiation, reactive wave growth occurs well behind the front. In heterogeneous initiation, the wave growth occurs much nearer the front. Most high-density explosives (at 98% or more of theoretical maximum density) exhibit a combination of both types of reactive wave growth.

Particle-velocity wave forms from an *in situ* magnetic gauge experiment (in which PBX 9501 was shock initiated in a gas-gun experiment) are shown in Fig. 1. In this experiment eleven gauges were embedded at different Lagrangian positions in the flow. The wave forms are plotted in 3-D space to allow unambiguous viewing of the details of each gauge measurement. Detailed analysis of the wave forms supports the premise that this high-density explosive exhibits a hybrid homogeneous/heterogeneous nature in the reactive wave growth. The analysis shows that the wave front grows by 15% from the first to the eleventh gauge, and a reactive wave develops behind the front with the intensity increasing as the wave moves into the explosive sample. In fact, the particle velocity of the reactive wave increases until it is double that of the wave front. The maximum in the reactive wave catches the front by about 0.5 μs during the measurement time. The wave developed into a detonation about 10 mm into the sample, well past the last gauge, which was at a depth of 6 mm. These wave forms illustrate the usefulness of *in situ* gauging for examining reactive flow.

INTRODUCTION

Mesoscopic systems cover all types of extremely tiny devices made of semiconducting or metallic materials. The original definition of the mesoscopic device comes, not from its tininess, but from whether electrons in the device behave coherently. Coherence assures us that the device is ruled by quantum mechanics. As was described in the original article, any system will suffer, in principle, more and more from *decoherence* when the number of its degrees of freedom increases. Here, decoherence means processes where quantum systems decohere, *i.e., lose their coherence*, and eventually become *incoherent* systems. In that sense, these tiny devices are expected to behave partially *coherently*.

In condensed matter, any environment of a device is considered to have a variety of degrees of freedom other than those of the electron of concern. All such degrees, more or less, cause the electron to decohere, as long as they subject the electron to *inelastic* scattering, because every electron keeps its coherence if and only if its energy is not changed. These degrees belong to phonons, photons, and even other electrons. Crystalline imperfections such as impurities, grain boundaries, surfaces, and interfaces are considered to cause only elastic scattering.

The original article discussed many possible decohering mechanisms in tiny 3-, 2-, 1- and 0-dimensional devices. However, it did not discuss atomic-scale 2-, 1- and 0-dimensional systems, which have appeared very recently and are attracting increased attention thanks to the use of the scanning tunneling microscope (STM) and related techniques. Readers are referred to TUNNELING MICROSCOPY AND SPECTROSCOPY for details on the observation and fabrication techniques applied for atom-order samples. This Addendum covers atomically small surfaces, wires, and clusters, whose study has become possible only recently.

We can now actually observe images of arrays of atoms in 0, 1, and 2 dimensions using an STM. In one sense these images are related to the spatial distribution of electrons whose energy is situated near the Fermi level. In most cases, the images vary depending on the applied electric potential, even when the gap between the STM probe tip and the sample surface is kept constant. Thus, an STM can be used to perform scanning tunneling spectroscopy (STS). Theories to interpret the observed images are already developed. However, subtle questions still remain as to whether we can observe the electronic wave function itself, including its phase, by means of tunneling microscopy.

An STM can also be used to manipulate atoms one by one (or at least, as very tiny atomic clusters), for example by extracting, moving, or depositing them. Atoms on a sample surface can be extracted from the surface, and similarly atoms on the surface of the probe tip can be deposited onto the surface of a sample by applying a high electric voltage between the tip and sample. This manipulator is often applied to fabricate atomic arrays (1-dimensional quantum systems), atomically small terraces (2-dimensional quantum systems), and atomically small clusters (0-dimensional quantum systems).

These atomic-order–sized electronic devices are often called *atomics*; however, more plausibly, they should be called *atomic electronics* or *atom-electronics*, since the main role for the phenomena of interest is played by electrons, not by atoms.

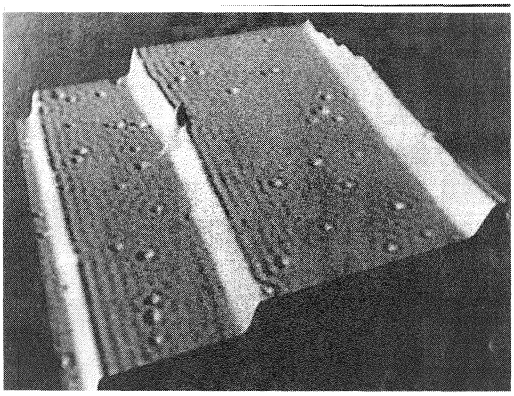

FIG. 1. A 500 × 500-Å^2 constant-current image of a Cu(111) surface. Three monoatomic steps and a few tens of point defects are visible. Spatial oscillations with a period of ~15 Å are evident. The small circles surrounded by circular ripples are point defects on the surface, whose origin is not known. (After Crommie *et al.*, 1993a.)

1. ATOMIC SURFACES

It is well recognized that the Bloch theorem holds formally in a perfect crystal. However, for the Bloch theorem to work, it is implicitly assumed that the crystal system assures that the Bloch states are coherent throughout the system. To have coherent Bloch states, an infinite long-range crystalline order and no decohering mechanisms are needed. Regarding the long-range order of the surface, the situation is the same. Coherence must exist for all the surface Bloch states.

In ordinary bulk crystalline systems, electronic states have the same periodicity as the crystal. In atomically tiny systems, the states are specifically modulated by means of the envelope wave functions according to the boundary conditions the systems are subject to. This situation is very similar to the *charge-density wave* (CDW), where the period is ordinarily incommensurate with that of the crystal, although the CDW is constituted by the Bloch states themselves.

The first astonishing observation of atom-electronics properties on an atomic surface was made by IBM scientists in 1993 (Crommie *et al.*, 1993a; Fig. 1). They used an STM to scan a surface with a few atomic steps (terraces) and obtained an image of electronic states straightforwardly. The surface monatomic step creates a potential step for the surface electrons. The potential step imposes a new boundary condition on Bloch electrons and modulates the wave function so that the distribution probability is affected by this boundary condition; that is, a CDW is created perpendicularly to the potential step, and the electronic charge is distributed in the STM image as a standing ripple wave. The ripple is obviously caused by the interference between the back- and forth-going waves.

Afterwards, the IBM scientists proceeded to create a do-it-yourself boundary condition by utilizing an STM-related technique. Their man-made corral was made of Fe atoms that encircled a certain Cu surface area, and the generated CDW was confined within the corral. Although not displayed here, the co-centered circular CDW ripple is well worth seeing (Crommie *et al.*, 1993b).

Several documents refer to these observed images as a "wave function". Aharonov *et al.* (1993) proposed that it could be possible to observe a wave function itself, if a "protective measurement" is applied to it. However, it is commonly recognized that it is difficult to observe a wave function itself by using an ordinary measurement process. Thus, it is safe to say that what we observe is only a squared wave function that represents the probability distribution of electrons over various states. To establish this ripple, it is necessary to have coherence in two senses. The first is the coherence for a single electron. This assures that wave functions are coherent in their initial and reflected directions. The other means that an ensemble of electrons must be coherent in the same sense as the people in the electron microscope field tell that an electron source is "coherent". This meaning ensures that all the electrons involved in the CDW should be the same as one another, *i.e.*, under the same or very similar quantum conditions. Otherwise, all waves composing a CDW must be randomly added and the ripple would be smeared out.

All these features represent the local density of states (LDOS) defined by

$$\rho(E,\boldsymbol{r}) = \sum_i |\psi_i(\boldsymbol{r})|^2 \delta(E - E_i), \tag{1}$$

where $\psi_i(\boldsymbol{r})$ is the wave function of state i with its eigenenergy E_i.

The atomic reconstructed surface is another interesting example of a 2-dimensional atom-

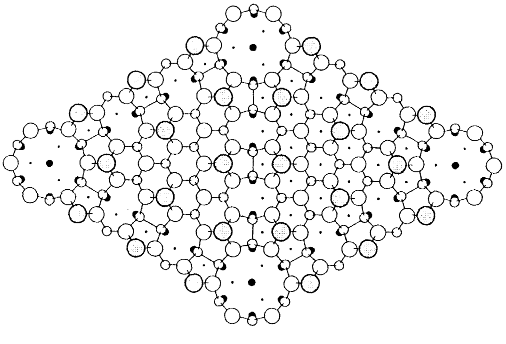

FIG. 2. Schematic representation of Takayanagi's DAS model (after Takayanagi *et al.*, 1985). Four Si atoms on the corners of the lowest layer 7 × 7 rhombus are lacking. The small open circles neighboring small solid circles combine pairwise to form dimers. The next stacking-fault-layer atoms are denoted with larger open circles. Their configurations are faulted between the right and left half rhombus. The darkened large circles are for adatoms on the topmost layer.

electronic system. Under reconstruction, atoms are displaced to construct a new periodicity and the surface Bloch electrons follow the same period.

A marvelous example is related to the complicated reconstruction of Si atoms on the Si(111) surface, as Binnig and Rohrer observed by STM (Binnig *et al.*, 1983). (For more details, see, for example, SILICON, CRYSTALLINE.) It had long been known that the surface constitutes a 7 × 7 structure, and this was later modelled by Takayanagi *et al.* (1985) as a DAS (dimer-adatom-stacking fault) model based on low-energy electron diffraction (LEED) observation. The schematic structure is shown in Fig. 2. This 7 × 7 structure was precisely investigated, again by STM, later on and the structure proposed by Takayanagi was confirmed. Such surface reconstruction is realized as a very long-range order, which tells us that the coherence of the surface Bloch states is also long.

To further investigate and apply the reconstructed surfaces to actual devices, though, it is necessary to manipulate or decorate the surfaces. Hashizume *et al.* (1993) first reported the surface of a Cu(111)-(1×1) sample decorated with C_{60} molecules. These molecules were neatly arrayed forming a triangular structure as shown in Fig. 3.

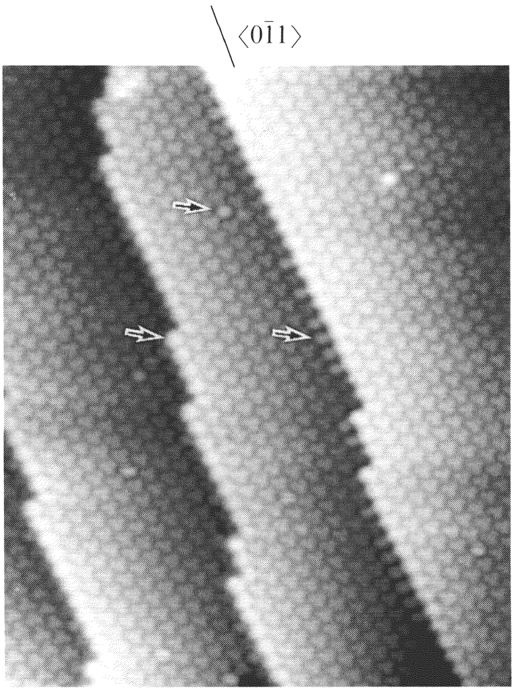

FIG. 3. An STM image of the Cu(111) surface covered completely with a monolayer C_{60} film (area: 300 × 380 Å²). Individual molecules are imaged in a three-lobe clover shape. One lobe of each molecule is oriented either upward or downward along the $\langle 0\bar{1}1 \rangle$ direction. The arrows indicate defects in alignment. (After Hashizume *et al.*, 1993.)

The C_{60} molecules themselves have interesting features. They form an insulating molecular fcc crystal (Kroto, 1985), but if doped with alkali-metal atoms, they can be superconducting. Small alkali-metal atoms are believed to situate themselves between the molecules, and the electronic states are sufficiently modified to force the crystal to be superconductive (Haddon *et al.*, 1991; Hebard *et al.*, 1991; Rosseinsky *et al.*, 1991; Holzer *et al.*, 1991; Chen *et al.*, 1991; Tanigaki *et al.*, 1991).

2. ATOMIC WIRES

An atom is very stable and keeps its coherence, as long as it does not interact with any other degrees of freedom. For example, a hydrogen atom in its ground state remains almost forever in that state, unless it absorbs photons or collides with other high-energy particles, atoms, or molecules. If one goes from an atom to a linear chain of atoms, what happens? A long linear molecule is still coher-

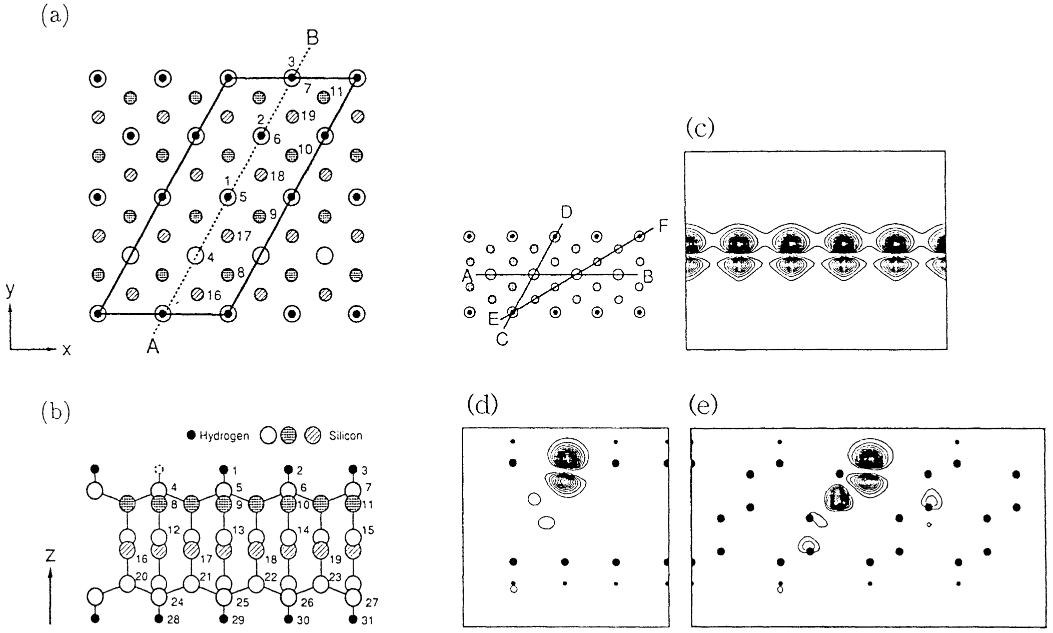

FIG. 4. An atomic wire on the H-terminated Si(111) surface. (a) Top view. A horizontal array of open circles through No. 4 is expected to form a quantum wire of depassivated Si atoms. A rhombus is the 2 × 4 supercell to calculate. (b) Side view along the A-B line in (a). Small solid and larger circles represent, respectively, H and Si atoms. A dotted circle shows the depassivated H site. (c), (d), (e) The charge-density contour maps of the midgap state at the symmetry Γ point (c) along line A-B, (d) along line C-D, and (e) along line E-F. (After Watanabe *et al.*, 1995.)

ent and stable. However, a problem occurs if this system is lying on a substrate, in that a variety of interactions are likely to occur between the chain of atoms and its substrate.

1-dimensional atomic (quantum) wires have been investigated, so far, mostly theoretically, because the fabrication technique is far beyond the present attainable level. In studies on practical quantum wires, the effect of the interaction with the substrate is very important. Readers are recommended to refer to the review paper by Aono *et al.* (1993) and the conference proceedings of Serena and Garcia (1997) and Joachim and Roth (1997).

Quantum wires are most easily fabricated by removing H atoms in one dimension from a fully passivated Si surface. This can be done by applying a high voltage between the STM tip and the passivated surface. This sort of atomic wire is sometimes called a dangling-bond (DB) wire or a depassivated (DP) wire. Watanabe *et al.* (1995) tried a pseudopotential, density-functional approximation calculation for a DB wire on an Si(111) surface and showed that the wire becomes truly conductive (Fig. 4).

How to obtain a p–n junction utilizing these quantum wires, something not yet achieved, is an important question from a practical viewpoint. It is also very interesting from a device-physics viewpoint. In an earlier study on what dopant concentrations are needed, to realize n- or p-type atomic-scale conductors (Murayama, 1995), the author reasoned as follows. Doping is effective in conventional bulk semiconductors when its level is something like $(a/a_B)^3$, where a is the lattice constant and a_B is the appropriate Bohr radius of a hydrogenlike dopant atom, which is on the order of several tens of angstroms. This means that 1 ppm or a slightly larger dopant concentration works quite well in the bulk case. However, in 1-dimensional wires, a/a_B means approximately 1%, so that a great quantity of dopants is needed for the wire to work well. This large quantity may lead to a severe stability problem in such heavily doped semiconducting substances.

3. ATOMIC CLUSTERS

The original article already reviewed 0-dimensional quantum systems, where conductance is characterized by the Coulomb blockade, the single-electron tunneling (SET) oscillation, the turnstile effect, and so on. Studies that should be referred to in this field include Fulton and Dolan (1987), Delsing *et al.* (1989), Geerligs *et al.* (1990), and Averin and Likharev (1991). The main point of the underlying physics is that electrons can be transferred via tunneling only under the correlation effect, which is efficient for ultrasmall tunnel junctions. In larger tunnel junctions, the electron wave function spreads, and then the correlation effect is diminished in the same manner that makes it almost insignificant in bulk metals.

A unit of charge q is defined by CV, where V is the applied electric potential and C is the capacity of the tunnel junction. In ordinary capacitors, the charge q or $-q$ on each electrode is kept fixed. In contrast, in tunnel junctions, one unit of charge e can tunnel and eventually annihilate to give $q-e$ and $-(q-e)$. However, if a charge q between $-e/2$ and $e/2$ is diminished by one unit e via tunneling through the junction, the electrostatic energy of the capacitor $(q-e)^2/2C$ becomes larger than before, say $q^2/2C$. That is, the energy is increased rather than decreased by tunneling. This is in accordance with the Coulomb repulsion energy, as first suggested by Likharev (see Averin and Likharev, 1991). In other words, tunneling conductance is suppressed. This phenomenon is known as the Coulomb blockade.

From a device-application viewpoint, the Coulomb blockade effect applies to few actual nonlinear quantum devices. This is mainly because the electrostatic energy is too far below the ambient thermal energy kT (25 meV at room temperature). If kT is equated to $e^2/2C$, the capacity C must be as small as 3 aF ($= 3 \times 10^{-18}$ F). This value corresponds to a $3 \times 3\text{-nm}^2$ capacitor with a 3-nm gap and a dielectric constant $\varepsilon = 4\varepsilon_0$ (ε_0 denotes the permittivity of vacuum). Such a small capacitor cannot be fabricated with conventional photolithographic techniques. For this reason, plausible devices could initially only be operated at low temperatures (Nakazato *et al.*, 1993).

However, Yano *et al.* (1994) first observed room-temperature operation of the Coulomb blockade phenomena within granular polycrystalline Si ultrathin films. The device structure they examined was similar to the conventional electrically alterable MOS (EAMOS), or a floating-gate nonvolatile-memory device, since the thickness of the granular Si film was so thin that the potential produced by the gate voltage randomly varied from grain to grain. When the gate voltage was high enough, percolation channels formed. Otherwise, the channels were broken into pieces of quantum dots. In the latter case, every dot would have acted as an island for the Coulomb blockade capacitor. The size of these islands seems to have been sufficiently small compared to the size of the above mentioned 3-aF capacitor.

Figure 5(a) shows a model for an ultrasmall MOS with a floating island embedded inside the gate insulator. In this device, an increase in the gate voltage V_g causes the "write-in" into the floating island (the floating gate) to be changed. As suggested in Fig. 4(b), the floating charge shifts the effective gate voltage by a specific amount. This shift in V_g is given by the relationship

$$\Delta V_g \sim \frac{q}{C_{gc}}, \tag{2}$$

where C_{gc} is the capacitor specific to the circuit. Thus, the original V_g-vs-I_d characteristic where I_d is the drain current becomes a shifted $(V_g + \Delta V_g)$-vs-I_d characteristic as shown in Fig. 5(c). The most significant part of this phenomenon is that the shift in V_g is quantized. Certainly, a single floating charge seems to block a single conducting channel. As described in the original article, the Landauer formula gives the conductance in terms of the number of channels. With more channels, the device becomes more conductive. A further increase in V_g may reduce the number of channels one by one, depending on whether the islands are charged in a floating manner. The observed data are shown in Fig. 6.

linear resistor and "single-electron memory" with a *nonlinear* shunting resistor are compared in Fig. 7. The voltage at the floating dot exhibits a hysteretic behavior as shown in the figure, indicating that operation as a single-electron memory device is possible. This type of memory operation was first observed by Nakazato *et al.* (1993), but at a low temperature.

The device introduced here has a strong advantage in that it works at room temperature. However, how the gate voltage can be precisely controlled is another formidable problem. In the experiment, the ultrathin Si film unexpectedly produced a network of floating islands. Therefore, the gate voltage itself varied a great deal from sample to sample. In contrast, the shift in the gate voltage was definite as a result of the Coulomb blockade effect with an integral number of floating charges, which is the biggest advantage of this device.

4. FUTURE PROSPECTS

likely to flourish in the next century, thanks to the STM-related fabrication technologies.

The size of the devices described so far seems to be just between the photolithographically processable size and the atomically maneuverable size. The size of an atom is on the order of 0.1 nm, while an approach from a macroscopic size using photolithography is possible only down to a few hundred nanometers. The two approaches have a gap in size amounting to a ratio of about a hundred, since actual devices are expected to be, at least, on the order of ~10 nm. On a smaller scale, the devices may not work stably, even though the packing density of the devices would be increased.

For example, an array of single atoms in a chain would be too fragile to manipulate without damaging it by, for example, electrostatic discharging. It must work as if it is a "quantum fuse". This effect was a particularly annoying nuisance in conventional tiny MOSFETs. This reliability problem will be the last, but may be the most serious, obstacle in the development of atom-electronic devices.

How we can access these devices is also a serious problem. Maneuverable leads to devices are on the order of ~1 μm. However, actual devices are sized to only ~10 nm in this case. The ratio of the two scales is again ~100. Thus, we must gradually expand the scale of the leads from ~10 nm to ~1 μm.

When atomic clusters are intended to be used as a 2-dimensional memory array, how to achieve rapid access and how long is needed to "write-in" and "read-out" are the critical engineering bottlenecks.

In the early years of the next century, many nanoscale devices will be proposed. However, the study will have to continue mainly from a purely scientific view for a while, rather than from actual application-oriented interests. Nevertheless many breakthroughs are still expected, because today's prevailing Si devices are so tough and seem likely to survive longer than once expected. The realization of practical nanoscale devices may be considerably later than had once been hoped.

This atomic-scale device technology, however, has a promising future and an important role to play in human technological development. The ultimate goal is to mimic the human brain with a network of nanoscale devices on the order of synapse size! In addition, although nobody knows whether these devices will work *coherently* or not, coherent operation could make the "quantum computer" attainable.

INTRODUCTION

The last years saw some highlights in the research on muonic, pionic, and antiprotonic atoms and on the muon-catalyzed-fusion cycle. Especially in the field of exotic-atom binding energies and of the formation of exotic atoms some completely new results emerged. They are here briefly described. Reference to the original article will be marked by a roman I.

1. ENERGY LEVELS IN EXOTIC ATOMS

1.1 Electromagnetic Binding Energies

Progress continues both in theory *and* in experiments on the electromagnetic binding energies in exotic atoms. Attention in this field has turned more and more to the simplest systems, muonic protium (protium is the most abundant isotope of hydrogen, with only one proton as nucleus) and antiprotonic He. This has to do partly with the fact that laser-resonance techniques have been applied or are planned to be employed to determine binding-energy differences in the atoms with unprecedented accuracy. All experiments of this kind proceed in roughly the same way: An exotic atom is formed in a sufficiently long-lived state; the muonic protium atom $p\mu$ in its $2s$ state (principal quantum number $n = 2$, angular-momentum quantum number $l = 0$) is used as an example (cf. Fig. 1). Afterwards a light pulse from a laser system is applied. If the wavelength corresponds to the energy of the transition [in the case of $p\mu$, the transition from $2s$ to $2p$ ($n = 2, l = 1$)], the laser pulse is long enough, and the laser power is sufficient, a transition to the final state is induced with high probability. In order to detect that the

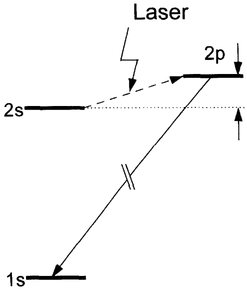

FIG. 1. Scheme of the lowest levels in the $p\mu$ atom.

resonance condition has been met and hence a transition has occurred, the daughter state has to be short-lived and must be depopulated by radiation that can be easily detected. In our example the $p\mu(2p)$ state has a lifetime of only a few picoseconds and is depopulated to the $p\mu(1s)$ state by quantum radiation of about 1.9 keV energy, not too hard to detect with low-energy semiconductor detectors. If the resonance condition is fulfilled a detector signal is registered in coincidence with the laser pulse. Relative errors for the transition energies as low as a few ppm (parts per million) may be achieved.

1.1.1 Muonic Hydrogen. In the case of the lowest levels of muonic hydrogen the uncertainty of all QED corrections turned out to be at the few-ppm level. QED, quantum electrodynamics, is the quantum theory of the electromagnetic interaction, the most important of the four interactions in the universe known up to now: strong, weak, and electromagnetic interactions, and gravity. The interest in muonic hydrogen is easily explained: In electronic hydrogen the accuracy of the $2s - 2p$ energy difference, a very stringent test of QED, is limited at the moment not by a lack of experimental accuracy but by the uncertainty of the proton radius $r_p = 0.862 \pm 0.012\,\mathrm{fm}$, which strongly influences the theoretical interpretation of the experimental results (Pachucki, 1996). In the muonic counterpart of the hydrogen atom the uncertainty in r_p plays a much larger role—the muon orbits much closer to the proton than the electron in the electronic hydrogen atom and therefore probes its dimension much more thoroughly. A precision determination of the $2s - 2p$ *difference* in muonic protium allows a much better determination of r_p and hence a test of QED on the normal hydrogen atom with an orders of magnitude better accuracy.

A direct test on the QED corrections in *muonic* atoms aiming at a precision much better than the present 10^{-3} has been proposed by an ENEA–Neuchatel–Paul Scherrer Institute–Trieste collaboration (Chatellard *et al.*, 1993). In this case the energy difference $3p - 3d$ in muonic hydrogen is to be determined with very high precision; this will be achieved by stimulating the $3p \rightarrow 3d$ transition during the muon cascade in μp with a laser and thus—in case the laser is on resonance—changing the intensity pattern of the x-ray transitions in the Lyman series compared to nonresonance. As no s level is involved, the influence of the proton radius is drastically reduced. A comparison with the results from electronic hydrogen allows one to draw conclusions about the μ–e universality.

1.1.2 Metastable Antiprotonic Helium. Metastable antiprotonic He, $^{3,4}\mathrm{He}^{++}\bar{p}e^-$, is a very special exotic atom, half-way between atom and molecule. Some years ago it was shown (Iwasaki *et al.*, 1991) that about 3% of all $\bar{p}$He atoms formed exist in such metastable states (lifetime several microseconds), in total contrast to conventional wisdom, which predicts the cascade in this exotic atom from the states populated immediately after atomic capture to the states from which annihilation occurs to be completed within picoseconds to nanoseconds, even in gaseous targets at moderate pressures. The metastability of the $\bar{p}$He atoms (their lifetime in liquid helium is more than *five* orders of magnitude larger than expected) may be explained by the formation of circular $(l = n - 1, v = n - l - 1 = 0)$ or nearly circular states $(v \leq 3)$ of the $\mathrm{He}^{++}\bar{p}e^-$ system (cf. Fig. 2) which can be depopulated neither by Auger effect with moderate angular-momentum transfer nor via Stark mixing with lower-l states, from which fast deexcitation may occur. Only radiative transitions are allowed, which are slow. Irradiation of the system with laser light of suitable wavelength, however, leads to stimulated deexcitation of some metastable states to short-lived ones, which is followed by the usual fast cascade of the $\bar{p}$ to states from which annihilation occurs. In this case the signal for a resonant transition is the prompt emission of charged and neutral pions following the annihilation of the $\bar{p}$ (Ya-

mazaki *et al.*, 1993). A typical setup for such an experiment is shown in Fig. 3.

The laser spectroscopy of highly excited, metastable states of the $\mathrm{He}^{++}\bar{p}\mathrm{e}^-$ system—besides offering other benefits to be described later—opened the way to investigate the binding energies in this simple three-body system with a He nucleus, an antiproton, and an electron. As already pointed out, this special system may be viewed either as an antiprotonic atom with the nuclear charge partly shielded by the electron or as a special electronic molecule with one partner having negative charge. Such a system is perfectly suited to test the existing techniques for the calculation of atomic and molecular wave functions and energies. The most recent calculations are in agreement with the outcome of the experiment at a 5-ppm level. Table 1 shows the transitions detected by laser spectroscopy and their experimental and calculated wavelengths (Morita *et al.*, 1994; Hayano *et al.*, 1994; Maas *et al.*, 1995; Ketzer *et al.*, 1997).

1.2 Hadronic Atoms: the Strong Interaction

1.2.1 Pionic Atoms. The successful development of new crystal-spectrometer techniques [cylindrically bent quartz (110) crystals, position-sensitive CCD detectors] has stimulated research on the strong interaction of pions in low-lying states of pionic hydrogen (protium or deuterium). A measurement of shifts and widths of transitions to the 1*s* state gives direct access to the fundamental pion–nucleon scattering length, a quantity governing the pion–nucleus strong-interaction potential (cf. I, Sec. 4). An improvement of the energy resolution of these spectrometers by a factor of six to about 0.7 eV at 2.8 keV and an increase in the beam current in the modern meson factories (e.g., at Paul Scherrer Institute, Villigen, Switzerland) made it possible to determine the strong-interaction shifts and widths of the $3p \rightarrow 1s$ transitions in π^-p (Sigg *et al.*, 1995) and π^-d (Chatellard *et al.*, 1995) with hitherto unknown accuracy. The values are listed in Table 2, together with deduced experimental and theoretical (Bernard *et al.*, 1995) scattering lengths. The agreement is good.

Successes have been reported also from the very heavy pionic atoms. The lowest levels in these atoms are inaccessible to research via formation of and cascade in the pionic atom, because the pion is absorbed by the nucleus long before it reaches these levels. Knowledge about the deeply bound atomic states (cf. Fig. 4), however, is extremely interesting because there the pion is practically inside the nucleus and probes the nuclear matter density as well as changes in the strength of the pion–nucleon interaction caused by the nuclear medium. It has been argued that the strong-interaction potential in heavy nuclei should become repulsive (*i.e.*, decrease binding) on account of the action of the nuclear medium. This would result not only in a reduction of the binding energy of the pion but also in a smaller width ΔE of the lowest π-atomic levels: the pion is pushed outward by the repulsive force, so that its interaction with the nucleus decreases and with it the width of the level.

Table 2. Shifts and widths of the $3p \rightarrow 1s$ transition in pionic protium and deuterium, together with deduced experimental and recently calculated π-nucleon s-wave scattering lengths. Experiment and theory agree quite well now.

Pionic atom	Energy shift ε_{1s} (eV)	Linewidth Γ_{1s} (eV)	Scattering length a (fm)
$p\pi$	-7.13 ± 0.05	0.97 ± 0.11	$(0.086 \pm 0.002)m_\pi^{-1}$ (Experiment)
$d\pi$	2.48 ± 0.07	1.02 ± 0.21	$0.088 \leq am_\pi \leq 0.096$ (Theory)

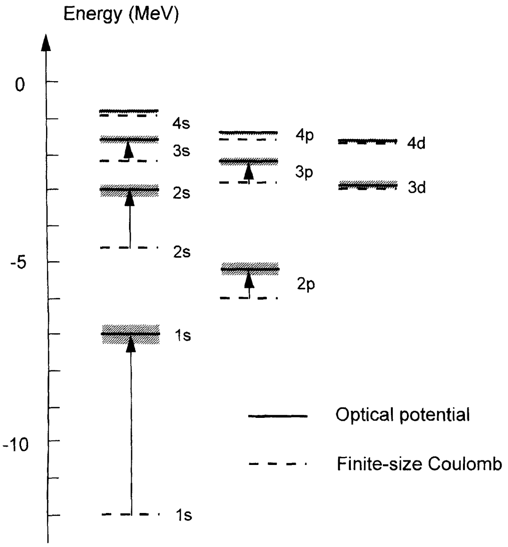

FIG. 4. Scheme of the lowest bound levels in pionic ^{207}Pb. Full lines: level energies calculated taking electromagnetic and strong interactions into account; dashed lines: level energies calculated taking only the electromagnetic interaction into account.

For the first time ever an experiment succeeded in populating directly the $2p$ level in $\pi^{-}\,{}^{207}\mathrm{Pb}$ via the high-energy reaction $^{208}\mathrm{Pb}(d, {}^{3}\mathrm{He})\pi^{-}\,{}^{207}\mathrm{Pb}$ (Yamazaki *et al.* 1996). The pion is created by the reaction of the deuteron with the lead nucleus and at the same time a neutron is picked up from this nucleus to make the momentum and energy balance favorable for the pion to stay bound. From the experiment the binding energy of the pion in the $2p$ level was extracted to be only $5.4 \pm 0.2\,\mathrm{MeV}$, much smaller than expected from purely electromagnetic binding (cf. Fig. 4). This experimental finding corroborated the suspicion that the strong low-energy pion–nucleus interaction indeed becomes repulsive towards the center of the nucleus in heavy nuclei. The small value of the level width (estimated to be $\Delta E < 0.8\,\mathrm{MeV}$) results from the pion being driven out of the center of the nucleus, markedly weakening its interaction with the nucleons. More experiments are planned for the coming years, which aim at detecting other low-lying levels, like $2s$ and even $1s$.

1.2.2 Antiprotonic Atoms. The experimental basis for levels and shifts in antiprotonic atoms was only slightly enlarged and no new data were taken for other exotic atoms with particles heavier than antiprotons. A new attempt was made (Batty *et al.*, 1995) to reproduce a representative subset of the $\bar{p}$-atomic data (for elements between carbon and praseodymium) by the full nonlocal potential used for pionic atoms (cf. I, Sec. 4) and a *density-dependent* scattering length:

$$(\mu/2\pi)\,V_{Strong}(\boldsymbol{r}) = (1+\mu/M)\left\{\left[b_0+B_0\left(\frac{\rho(r)}{\rho_0}\right)^{\gamma}\right]\rho(\boldsymbol{r})+b_1\delta\rho(\boldsymbol{r})\right\} - \boldsymbol{\nabla}\alpha(\boldsymbol{r})/[1-(4/3)\pi\zeta\alpha(\boldsymbol{r})]\boldsymbol{\nabla}, \qquad (1)$$

where $\delta\rho(\boldsymbol{r}) = \rho_{\mathrm{n}}(\boldsymbol{r}) - \rho_{\mathrm{p}}(\boldsymbol{r})$. Such a density-dependent parametrization of the scattering length was triggered by the observation that the $\bar{p}$–nucleus potential is repulsive for the free-antiproton–nucleon interaction whereas it becomes strongly attractive inside a nucleus even at the low nucleon densities that prevail at its periphery.

Antiprotonic atoms were also recently applied to probe espeically the difference between neutron and proton densities at the nuclear periphery. To this aim antiprotons were shot into isotopically pure samples. They form antiprotonic atoms and are annihilated. As the annihilation is very peripheral, it may happen that all annihilation products (mostly pions) miss the nucleus. In this case the nucleus with mass number $A-1$ that is produced after annihilation has either $N-1$ neutrons (annihilation of the $\bar{p}$ on a neutron) or $Z-1$ protons (annihilation on a proton). Here Z and N are the atomic number and the neutron number, respectively, of the original nucleus. If the nuclei generated in this way are radioactive they may be detected with high sensitivity via their decay. If the neutron distribution extends to larger radii than the proton distribution more annihilations take place on neutrons than if both nucleon distributions are the same. Such an effect has been detected for a number of nuclei (Lubiński *et al.*, 1994). Figure 5 shows the correlation of this enhancement with the binding energy of the most loosely bound neutron. Apparently a smaller neutron binding energy means a neutron localized more at the

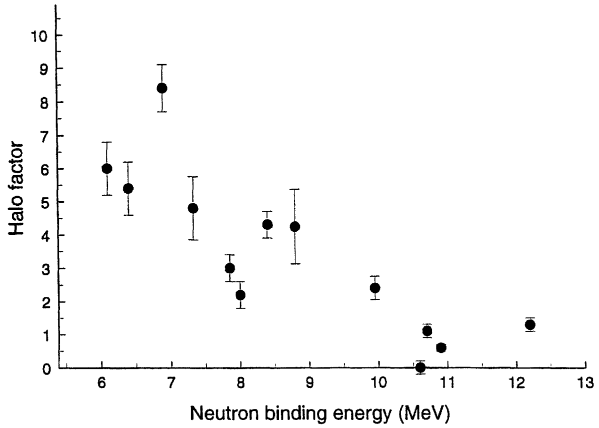

FIG. 5. Halo factor as a function of the binding energy. The halo factor is defined by

$$h = \frac{n(N_T - 1)}{n(Z_T - 1)} \frac{\mathrm{Im}(a_p)}{\mathrm{Im}(a_n)} \frac{Z_T}{N_T}.$$

Here N_T and Z_T are the numbers of neutrons and protons, respectively, in the target nucleus. $n(N_T - 1)$ denotes the number of nuclei generated with one neutron missing, $n(Z_T - 1)$ the number of nuclei generated with one proton missing. Finally, $\mathrm{Im}(a_n)$ and $\mathrm{Im}(a_p)$ are the scattering lengths for annihilation on a neutron and a proton, respectively.

periphery of the nucleus and hence a larger probability for peripheral annihilation on the *neutron.*

2. FORMATION OF EXOTIC ATOMS

Three fundamental questions may be raised about the formation of exotic atoms:

1. What is the kinetic energy the exotic particle has before it enters the atom it is finally captured by?
2. What is the energy the exotic atom gains immediately after capture?
3. Which are the bound states in the exotic atom populated immediately after Coulomb capture? The phrase "Coulomb capture" indicates that only Coulomb-like forces are acting during atomic capture.

2.1 Kinetic Energy of the Exotic Particle Before Capture

The simplest exotic atom one could envisage is the muonic hydrogen atom: only nucleus and muon. It is formed in the following way: The muon approaches a hydrogen atom; its charge screens the nuclear charge until finally the electron becomes free. Proton and muon start orbiting around their common center of gravity if the muon kinetic energy is low enough. If the energy of the emitted electron energy stays low—and there is good reason to assume this, as the momentum transfer of the comparatively heavy muon to the light electron should be small—the momentum of the muon (mass m_μ) before capture and of the $p\mu$ atom generated (mass $m_{p\mu}$) are roughly the same. Then the $p\mu$ kinetic energy is given by $T_{p\mu} = T_\mu(m_\mu/m_{p\mu})$, with T_μ the kinetic energy of the muon before capture. The kinetic energies of the exotic particle before and the exotic atom after capture are hence strongly correlated for this especially simple case.

The situation is somewhat complicated by the molecular structure of hydrogen and the measurement is made more difficult by the cascade processes taking place after capture (cf. Sec. 3.2). The *density-dependent* collision processes (Coulomb deexcitation, Auger effect and elastic collisions, cf. I, Sec. 3) may change

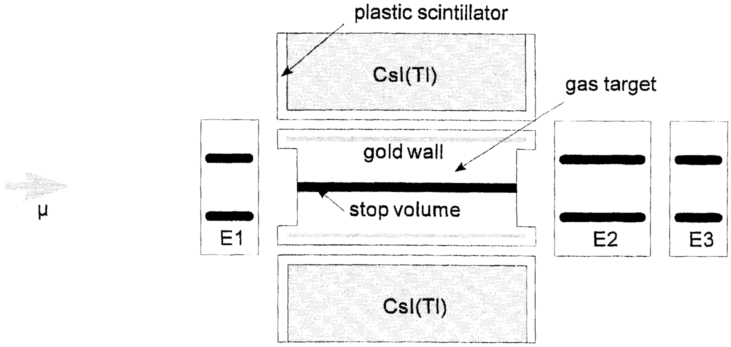

FIG. 6. Setup for the determination of the velocity of muonic hydrogen atoms after formation and cascade. The negative muons coming from the left are forced to travel to and fro between the electrodes E1, E2, E3 which are switched to high voltage at the right moment. The particles are finally stopped in the "stop volume". The $p\mu$ atoms formed travel to the walls of the cylindrical target; there they transfer the muon to the atoms of the "gold wall". Muonic X-rays from the gold walls are detected by the "CsI(Tl)" scintillation counter. Electrons from muon decay which also hit the CsI(Tl) counter are vetoed by the "plastic scintillator".

the kinetic energy of the $p\mu$ system. By working at the lowest pressures (below 0.1 hPa) they may be made small enough not to disturb the measurement of $T_{p\mu}$.

2.2 Kinetic Energy of the Exotic Atom After Capture

A series of experiments has been performed to study specifically the diffusion of the $p\mu$ atom after capture without any side effect due to collisions with hydrogen. To this end the pressure was lowered down to 0.062 hPa (which corresponds to a fraction $\varphi = 8.1 \times 10^{-5}$ of the atomic density of liquid hydrogen, 4.26×10^{22} atoms/cm^3); at these pressures collisional processes do not play a role for flight paths in the centimeter region: if we assume the reaction cross-section to be the geometrical cross-section $\sigma = \pi a_\mu^2 n^2$ the probability of a collision for a 1-cm flight path is below 0.001, even for $n = 14$. The velocity was determined via a time-of-flight measurement of the $p\mu$ system (Hartmann *et al.*, 1996) with a setup shown in Fig. 6. At this low pressure the $p\mu$ energy was found to be significantly smaller than 1 eV. From this the energy of the muon *before* capture can be estimated to be below 10 eV, in accordance with predictions from semiclassical calculations (Cohen, 1983).

2.3 The First-Populated States in the Exotic Atom

New knowledge about the characteristics of the first bound states in the simplest atoms came as a highly welcome by-product of the laser experiment on metastable antiprotonic He atoms, described in Sec. 1.1.2. By comparing experimental and calculated transition energies in these atoms more than a dozen transitions in $\bar{p}$-^{4}He and $\bar{p}$-^{3}He were unambiguously identified to proceed between levels with $n \approx 38$. Even the populations of some levels were deduced. The $\bar{p}$ really is captured into orbits around $n = 38$. The finding is the very first experimental proof for the long-standing assumption that the exotic particle is preferentially captured into those states for which the dimensions of the orbit of the ejected electron and that of the exotic particle after capture are roughly the same.

Experiment and latest calculations (Beck *et al.*, 1993) agree in their predictions about the circular or nearly circular character of the formed metastable states. Disagreement, however, exists about the percentage of the metastable atoms formed: whereas the experiment found a fraction of only 3%, theory estimates this fraction to be as high as 30% with most of the $\bar{p}$ initially populating the levels with $n \approx 40$. From these more loosely bound levels, however, the antiproton is predicted to be immediately quenched by collisions with other He atoms (Beck *et al.*, 1993). Mechanisms for this quenching process have been elaborated; quantitative results are still missing. As, naturally, this process is a collisional process it may be efficiently suppressed by going over to low pressures or even by storing the atoms in a trap. In these cases the probability for forming metastable antiprotonic atoms may be drastically increased, making these atoms a perfect laboratory for the research on electromagnetic interaction (three-body Coulomb interaction $He^{++}\bar{p}e^{-}$), fundamental physics (magnetic moment of the $\bar{p}$), and atomic collision processes.

3. THE EXOTIC-ATOM CASCADE

Knowledge about the exotic-atom cascade has developed mostly in the field of the lightest species, exotic hydrogen and helium. In these atoms no electrons are present from formation on or very soon afterwards, and some special effects already described earlier are present that make e.g. muonic hydrogen interesting for muon-catalyzed fusion. Before turning to the cascade in muonic and pionic hydrogen we say a few words about the progress in the understanding of the cascade for exotic atoms with $Z > 2$.

3.1 The Exotic-Atom Cascade in Elements with $Z > 2$

Absolute intensities of x rays from pionic atoms with $Z > 2$ have been measured recently for elements between $Z = 3$ and $Z = 83$ (Shinohara *et al.*, 1994). From the data "initial populations" of the angular-momentum sublevels at $n = 14$ of the form $p(l) \propto (2l + 1)\exp(\alpha l)$ have been deduced. Please keep in mind that these distributions at $n = 14$ have little to do with those at formation time but are rather a snapshot of the cascade pretty well towards its end. Nevertheless a remarkable correlation of α with the maximum angular momentum $\boldsymbol{L}_{\max} = \boldsymbol{r}_{\max} \times \boldsymbol{p}$ brought in by the exotic particle was found. Here $\boldsymbol{r}_{\max}$ is half the next-neighbor-atom distance in the solid and $\boldsymbol{p}$ the pion momentum corresponding to a kinetic energy equal to the ionization potential of the respective element (this is a rough estimate for the energy at which the exotic particle is Coulomb-captured into the atom).

The large number of Auger transitions during the exotic-atom cascade leads to a peculiar phenomenon: The exotic atom may be completely stripped of electrons during the cascade if electron refilling from the outside is suppressed by a lack of collisions (cf. Sec. 2.1). Such an exotic atom is an ideal laboratory for research on the electromagnetic and, if present, strong interaction between nucleus and exotic particle: No electrons are around disturbing this interaction. That those naked exotic atoms can be really formed with gases at low pressure has been recently shown by measuring the antiprotonic x-ray cascade in noble gases at pressures around 20 hPa (Simons *et al.*, 1994). Only transitions between circular orbits were observed and all lines had, after correction for the detection efficiency of the measuring device (a Ge detector) the same intensity: Because lack of electrons allows only radiative transitions with maximum $|\Delta n|$ (see I, Sec. 3.1), circular orbits are populated with high probability, and the antiproton cascades down the ladder of these orbits by radiative transitions only.

3.2 Acceleration During the Cascade

Even more than in the velocity of the exotic atom at formation time, one is interested in the velocity at the moment when the particle has reached the ground state or some might-be long-lived excited state (like the $2s$ state; cf. Sec. 1). The reason is that the velocity determines the chance to prepare certain states of the $p\mu$ system in pure form [e.g., the singlet hyperfine state of the $p\mu(1s)$ level (in this state the spins of proton and muon are antiparallel)] or the speed of some process (e.g., the transfer of the muon from deuterium to tritium in the muon-catalyzed dt-fusion cycle). Calculations (Markushin, 1994b) and experiments (Kraiman *et al.*, 1989; Aschenauer *et al.*, 1995; Hartmann *et al.*, 1996; Abbott *et al.*, 1997) give a roughly consistent picture: At pressures between about 1 kPa and 78 MPa the *mean* kinetic energy of the $p\pi$ and $p\mu$ system after reaching its ground state is several electronvolts. This kinetic energy comes from acceleration effects during the cascade (preferentially Coulomb deexcitation; cf. I, Sec. 3.5). The velocity is thus increased compared to the energy immediately after atom formation (cf. Sec. 2.2). Such an energy is, e.g., high enough to allow transitions between the $p\mu(1s)$ singlet and triplet (spin of proton and muon parallel) states by collision to occur (the triplet state lies 182 meV higher in energy than the singlet state). Precision measurements of the rate of nuclear capture (a weak-interaction process) from the $p\mu$ singlet state are thus hindered by the existence of $p\mu$ atoms in the triplet state with much smaller nuclear-capture rate.

3.3 Transfer Processes

During the last few years the *excited-state* transfer from muonic hydrogen to atoms with higher Z has gained more and more interest. The cross section for such transfers is considerably larger than for ground-state transfer, as the radius of the muon orbit increases with the square of the principal quantum number n, $r_n = a_\mu n^2/Z$; hence transfer, which has to proceed via level crossings in the correlation diagram (cf. I, Sec. 3.4) in order to become really fast, is possible already for larger impact parameters. Furthermore the higher polarizability of the $p\mu$ atom in the excited state gives rise to an additional attractive potential. Transfer from the $p\mu$ atom to argon, as an example, was calculated to be more than 20 times faster from the 2s level than from the $1s$ level. Such a fast transfer, together with effects of the deceleration of the $p\mu$ atom, served to explain the unusual time spectra observed for transfer from hydrogen to oxygen in a 15-bar hydrogen-SO_2 mixture. Such time distributions are obtained by registering muonic x rays from the element to which transfer occurs (the cascade in this element is fast). In normal cases transfer proceeds at one constant rate, and the distribution of transfer times follows the simple exponential law known from radioactive decay. In the mixture mentioned above, however, the time distribution of transfers to oxygen had a double-exponential shape, whereas for transfer to sulfur it was single exponential with a rate roughly corresponding to the smaller of the rates valid for oxygen. This may be explained (Schneuwly, 1994; Werthmüller *et al.*, 1996) by the population of higher $p\mu$ states, from which (faster) transfer is possible to oxygen but not to sulfur (because of a lack of level crossings).

4. APPLICATION OF EXOTIC ATOMS

4.1 Application of Muonic X Rays in Diagnostics

An experiment was reported only recently which applied muonic x rays to the nondestructive analysis of vertebral body trabecular bone (Hosoi *et al.*, 1995). It showed that quantitative information may be obtained about the elemental composition of deep-lying well-localized regions inside the human body. Muons were stopped in the lumbar vertebral bones (vertebra L3–L4) from patients of different ages (16 to 72 years), who had died from various diseases. The results for the elemental composition (Ca and P) found from the intensity of muonic x rays and from atomic absorption analysis were found to be strongly correlated, showing the x-ray method to be applicable for nondestructive analysis of the human body. Multiwire proportional chambers were again proposed (cf. I, Sec. 6.2) to trace muon-decay electrons back to their creation point and to localize better the place where the muons stop, but an experimental verification of this method is still missing.

5. MUON-CATALYZED FUSION

5.1 Basic Knowledge

The progress in our knowledge about muon-catalyzed fusion has slowed down somewhat during the past three years. Muon-catalyzed *deuterium-tritium* fusion is still in the center of research (cf. I, Sec. 7.6). Calculations and measurements, even if they aim at clarifying the processes in other types of fusion, are undertaken with the goal of obtaining further insight into the muon-catalyzed *dt*-fusion cycle.

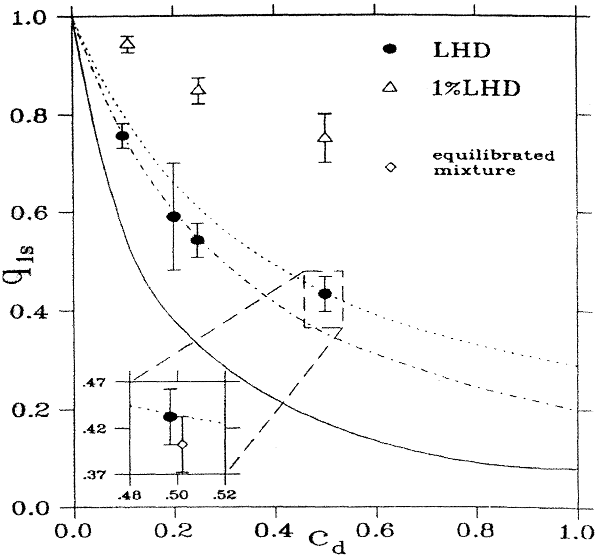

FIG. 7. Probability for excited-state transfer (Lauss *et al.*, 1996): q_{1s} for a protium-deuterium mixture as function of the deuterium concentration c_d at different target densities. LHD = liquid-hydrogen density. Equilibrated mixture: the concentration of HD molecules has been reached according to equilibrium in the reaction $H_2 + D_2 \rightleftharpoons 2HD$, which naturally depends on c_d. The curves show the results of calculations on q_{1s}. Full line: Markushin (1994b); dotted line: Czaplinski *et al.*, (1994); dash-dotted line: Markushin (1994a).

5.1.1 Atomic Capture. The latest results on Coulomb capture have already been presented.

5.1.2 Slowing Down. The complex interplay between acceleration and slowing down during the $p\mu$-atom cascade has already been described in Sec. 3.2. As soon as the muonic hydrogen atom reaches its ground state the only reactions capable of changing its velocity are elastic collisions. Here the structure of the collision partner (atomic or molecular) has a strong influence on the cross-sections. Especially at low $p\mu$ energies the molecular structure of hydrogen plays a more and more important role (Adamczak *et al.*, 1996). The cross section for interaction with a hydrogen molecule is not just twice the atomic cross section, as one might expect: Depending on the orientation, one of the atoms in the molecule may lie more or less in the shade of the other one. More important, the electron cloud between the covalently bound partners has a strong influence on the interaction.

5.1.3 Transfer. The implication of excited-state transfer has already been indicated in Sec. 3.3. In the case of hydrogen mixtures it tends to speed up the fusion cycle. It has become customary to characterize the excited-state transfer in hydrogen mixtures by the quantity q_{1s}, which simply means the fraction of muons captured in the lighter isotope (deuterium for instance) that reach the ground state without being transferred to the heavier isotope (e.g., tritium). As soon as the muons reach $\mu d(1s)$ they are trapped because the transfer from there is much slower than that from the excited states. At the lowest concentrations of the heavier isotope q_{1s} approaches unity as the number of collisions goes to zero. With increasing concentration the competition between cascade transitions and transfer tends more and more towards transfer, which makes q_{1s} decrease. An increase in density naturally has the same effect. Figure 7 shows results of a calculation for q_{1s} in HD mixtures together with experimental values taken only recently by just comparing the intensity of muonic x rays from $p\mu$ and $d\mu$ (they may be disentangled because their energy differs because of the difference in the muon reduced mass; cf. I, Sec. 1).

5.1.4 Molecular Formation. In the field of molecular formation, the main bottleneck in the dt-fusion cycle, attention has turned more and more to the possibility of epithermal resonant molecule formation. In this process the resonance condition for molecule formation [cf. I, Eq. (11)], playing an important role in dt fusion, is met for a large number of energies beyond thermal energy through which the tμ atom passes on its way down from the large kinetic energies attained after transfer. This is true for different excited states of the electronic (i.e., nonmuonic) hydrogen molecule that the *dt* molecule is part of and may considerably speed up molecular formation and hence the whole fusion cycle (Jeitler *et al.*, 1995).

5.1.5 Nuclear Fusion and Sticking. No new results are to be reported in the case of nuclear fusion rates. As this process is very fast in the *dt* cycle it is of restricted interest there, anyhow. Much more interesting is the fraction of muons finally sticking to the ^{4}He nucleus after fusion. Three different kinds of measurements have been performed:

1. Measurement of the number of neutrons emitted per muon. At high density, when the fusion cycle becomes faster, this number is limited by the loss due to sticking (Petitjean *et al.*, 1993).
2. Detection of muonic x rays from ^{4}Heμ, the fusion reaction product. The smaller this intensity the larger the number of cycles and the lower sticking (Bossy *et al.*, 1987).
3. Direct comparison of the He^{++} (no sticking) and Heμ^+ (sticking) ions generated. Such a measurement has been performed at low tritium concentrations (Petitjean *et al.*, 1993).

Combining these methods the sticking coefficient ω_s was evaluated to be $\omega_s = (0.51 \pm 0.05)\%$. Sticking really limits the possible number of catalyzed *dt*-fusion cycles to less than 200 (cf. I, Sec. 7.6). Schemes to revitalize the muon *after* sticking are highly desirable. Some proposals have been made, which, however, could not yet be tested.

5.2 Applications of Muon-Catalyzed Fusion

5.2.1 Generation of 14-MeV Neutrons. A design study has been finished for the μCF-based neutron source sketched earlier (cf. I, Sec. 7.8). Such a source is needed to test the neutron robustness of materials to be used in a *thermal-fusion* reactor (e.g. ITER). The study (Petitjean *et al.*, 1994) gave the following results: With a 12-mA beam of 1.5-GeV deuterons on a carbon target one may expect $10^{16}\,\pi^-$/s, which results in about $10^{15}\mu^-$/s in the DT mixture (volume 800 cm^3) and 0.5×10^{17} to 1×10^{17} 14-MeV neutrons per second. The test surface in this case would be 800 cm^2, resulting in roughly 10^{14}n/cm$^2 \cdot$ s. This is expected to be about the flux of neutrons hitting the walls of a future fusion reactor. The advantage of using the same fusion reaction as in the thermal fusion reactor would be to have the same neutron-energy spectrum in the test facility *and* in the future reactor. The technological difficulties for such a source, however, are large.

5.2.2 Generation of Low-Energy Muons with the Help of Muon-Catalyzed *dt* Fusion. The muon-catalyzed *dt*-fusion process was proposed to be employed to generate low-energy muons (i.e. muons with energies around and below 10 keV). In this process the muon is, in more than 99% of the case, only a spectator and is released with about 10 keV to catalyze another fusion (see above). In the proposed scheme a fraction of the MeV-muon beam is stopped in a thin layer of a solid protium-tritium mixture with small tritium content. The muons captured by protium are transferred to tritium, and the muonic tritium atoms (energy about 45 eV) travel into a second layer made of deuterium and tritium. Here fusion takes place and a fraction of the spectator muons leaves this layer with low energy. Those muons that are stopped in the layer catalyze another fusion and again have the chance to escape from the DT layer, making the conversion efficiency rather large. In an experiment at TRIUMF, Vancouver, the feasibility of the method was shown using protium-deuterium mixtures, which are much easier to handle than those with deuterium and tritium (Strasser *et al.*, 1996).

INTRODUCTION

The distinctions between neurobiophysics and other areas of neuroscience are becoming progressively more difficult to discern. Attempts to understand how the nervous system functions have been made from a variety of different scientific perspectives, and a consensus approach appears to be developing that involves some mathematical modeling and attempts to elucidate physical principles, but which is more focused on elucidating physical mechanisms.

1. STRUCTURE AND FUNCTION

Recent evidence suggests that gap junctions play an important role in regulation of the nervous system. Gap junctions are composed of transmembrane protein subunits called *connexins*, 4 to 6 of which form a pore that constitutes one half of a gap junction, the other half of which is formed by a similar structure on an adjacent cell. Heterology among the connexin subunits allows for differences in permeability, conductance, and gating of gap junctions by voltage or various ligands (Kumar and Gilula, 1996).

Flux through gap junctions in retinal cells was visualized in the form of Ca^{2+} waves induced by electrical, chemical, or mechanical stimuli that caused no change in cell-membrane potential (Newman and Zahs, 1997). The Ca^{2+} waves, which could propagate for more than 10 s and as far as 180 μm from the initiation site, may constitute a previously unrecognized form of neural communication.

A form of Charcot-Marie-Tooth disease (a hereditary peripheral neuropathy) has been attributed to the production of nonfunctional connexin subunits (Spray and Dermietzel, 1995), thereby underscoring the importance of electrotonic conduction between cells in the functioning of the nervous system.

2. ION CHANNELS

X-ray diffraction of most types of ion-channel proteins is presently not possible because of the difficulty in producing suitable crystals. *Site-directed mutagenesis* studies, however, have provided insight into structural features of ion channels such as the location of the ion-selective filter for voltage-gated Na^+, Ca^{2+}, and K^+ channels (Guy and Durell, 1995). The filter appears to lie in the channel's pore-lining segments (P segments). By changing specific amino acids in the P segments, the permeant-ion profile of Na^+ and Ca^{2+} channels can be interchanged. Even though the primary structures of K^+ channels are more heterogeneous, location of the selectivity filter has been narrowed down to a three-amino-acid motif in the P segment where mutations have invariably disrupted function (Navarro *et al.*, 1996).

Just as ion channels seem to share a common structural and functional domain for ion

selectivity, all known voltage-gated channels sense voltage changes with a protein subunit called the S4 segment. This segment has been identified as the voltage sensor of K^+ channels on the basis of measurements of the gating current (Mannuzzu *et al.*, 1996). A span of at least seven S4 amino acids was exposed extracellularly during activation of K^+ channels in a *Xenopus* oocyte model system. This suggests that during activation either the S4 amino acids moved extracellularly, or they remained static while the rest of the channel protein moved intracellularly.

The basis of the gating current in Na^+ channels was studied using hydrophilic cysteine-modifying reagents (Yang *et al.*, 1996). The procedure (systematic replacement of each S4 residue with cysteine followed by use of the membrane-impermeant reagents to modify the cysteines and detect any changes during activation) permitted a determination of precisely how many S4 amino acids and their accompanying charges moved from the intracellular to the extracellular compartment during channel activation, and the distance through which they moved. The total gating current was found to consist of the movement of about 10 positive charges through a distance of 4.5–11 Å. Since the cell membrane is normally 40 Å thick, the observation of (at most) only an 11-Å displacement between the extracellular and intracellular compartments suggests that the geometry of the cell membrane is radically altered in the vicinity of ion channels.

3. NEURONAL SYSTEMS

3.1 Dendrites

The role of dendrites was traditionally thought to be limited to that of supporting the passive unidirectional propagation of current, but new evidence suggests that dendrites can also integrate and process bidirectional information. Back-propagation of axon-derived action potentials (*antidromic action potentials*) was demonstrated in the hippocampus (Magee and Johnston, 1997) and neocortex (Markram *et al.*, 1997), and shown to be necessary for long-term potentiation. Subthreshold synaptic inputs that were followed within about 100 μs by the arrival of back-propagating action potentials facilitated amplification of subsequent subthreshold synaptic inputs. Timing differences above the window fundamentally altered the plasticity of the synapses (Sejnnowski, 1997). Thus, it appears that dendrites may have an important and previously unrecognized role in synaptic plasticity.

3.2 Neural Networks

Neural networks have been developed as useful interpretative tools. For example, they have been used to determine secondary structure of proteins (Rost *et al.*, 1995), putative coding sites in DNA, and chromosome classification (Leon *et al.*, 1996). Networks can even outperform human beings in some diagnostic judgment tasks, including diagnosis of acute myocardial infarction under the high stress and time constraints of the emergency room (Baxt and Skora, 1996) and interpretation of breast biopsies (Baker *et al.*, 1996). However, the original promise of neural networks, that they could accurately model the actual mechanism of biological learning, has not been fulfilled. It is becoming increasingly more clear that information processing within the central nervous system is more complicated than that embodied in the neural-network approach.

3.3 Volume Transmission

Movement of information in the central nervous system can occur via nonsynaptic mechanisms (volume transmission). One type of such information flow occurs when potentials produced by groups of cells propagate in the electrically conductive extracellular fluid and induce effects in distant cells—for example, synchronizing firing or altering firing probability (Bullock, 1997). The physiological significance of signalling by means of volume electrical conduction is still problematical, but diffusion of neuroactive substances through brain tissue from their point of secretion to distant binding sites is increasingly being recognized as an important mechanism for regulating cell activity.

Neuropeptides (a subset of neurotransmitters) are usually cosecreted with a classic neurotransmitter (biogenic amines, amino acids, and acetylcholine), but at lower levels. Neuropeptides are good candidates for volume transmitters because they are present in the extracellular fluid for relatively long periods and have relatively high affinity for their receptors. For example, when mossy fibers of the cerebellum were stimulated, dynorphin (a neuropeptide that was cosecreted with glutamate) inhibited the effects of glutamate in unstimulated mossy fiber tracts as a result of diffusion through the extracellular fluid (Weisskopf *et al.*, 1993). Comparable results were found in other studies (Chen *et al.*, 1995; Kolaj *et al.*, 1995).

Nitric oxide (NO) is also a possible signaling agent because it is produced in both neurons and glia and can quickly diffuse through the extracellular fluid. NO depressed voltage- and Ca^{2+}-dependent currents in hippocampal slices from Sprague-Dawley rats (Erdemli and Krnjevic, 1995), again suggesting a mechanism whereby distant groups of cells could interact with one another.

In addition to isotropic diffusion, evidence has been found for the occurrence of preferential extracellular diffusion along fiber bundles within the brain. Channel-like pathways that paralleled myelinated fiber tracts in rats were demonstrated using fluorescent-labeled dextrans and confocal microscopy (Bjelke *et al.*, 1995). The label reached the contralateral side of the neostriatum, indicating that long-range routes were possible.

Classically, it has been taught that neurotransmitters are released through calcium-dependent fusion of neurotransmitter-laden vesicles at neuronal presynaptic membranes (highly specific regions that form one of the boundaries of the synaptic cleft). Atwell *et al.* (1993) showed that *uptake carriers* can reverse direction and actually secrete neurotransmitter (Fig. 1). This secretion is nonvesicular, usually occurs away from the synaptic cleft, does not require Ca^{2+}, and can be demonstrated in glial cells as well as neurons. Thus, the phenomenon of reverse uptake provides a possible source of diffusable neuroactive agents.

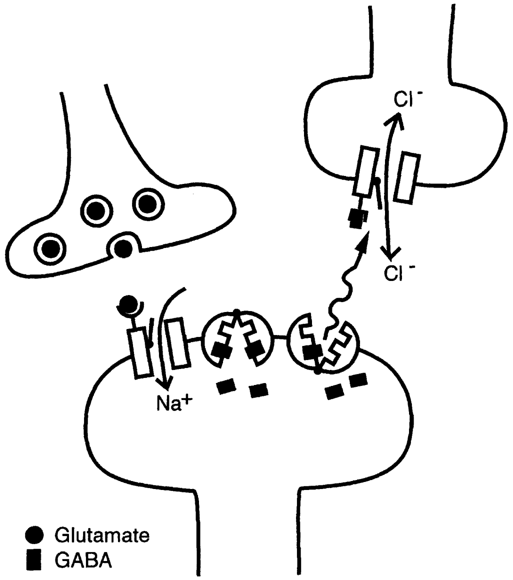

FIG. 1. Reverse uptake and volume diffusion of GABA (Atwell *et al.*, 1993). Glutamate is released by a presynaptic neuron and stimulates its receptors on either glial or neuronal cells, resulting in an Na^+ influx. The increased intracellular Na+ causes GABA uptake carriers (which normally couple the influx of GABA and Na^+) on the postsynaptic cell to operate in reverse and extrude GABA from intracellular stores. The extracellular GABA can then diffuse and affect other cells having appropriate receptors.

3.4 Memory

Memory must somehow be mediated by a relatively permanent physical change in the nervous system, but the responsible mechanisms have not been delineated. One possible explanation involves the irreversible activation of a calcium-calmodulin-dependent kinase (CaMKII), which is abundant beneath presynaptic and postsynaptic membranes. After Ca^{2+} activation, CaMKII can phosphorylate and regenerate itself independent of Ca^{2+} (Fig. 2). Mathematical models have predicted that spontaneous reversion to the inactive state would be highly unlikely, and the active Ca^{2+}-independent state could potentially last a lifetime (Lisman and Goldrign, 1988). The kinase could, therefore, mediate long-term changes in synaptic function by phosphorylating another protein, for example synapsin I (Nayak *et al.*, 1996).

The role of the kinase in mediating memory was demonstrated in animal studies. Mice were genetically engineered to express a permanently activated form of CaMKII (CaMKIIα) whose expression was regulated by a promoter in the forebrain and by a transactivator (tetracycline) (Mayford *et al.*, 1996). Thus, expression of the transgene (the foreign-DNA gene) was con-

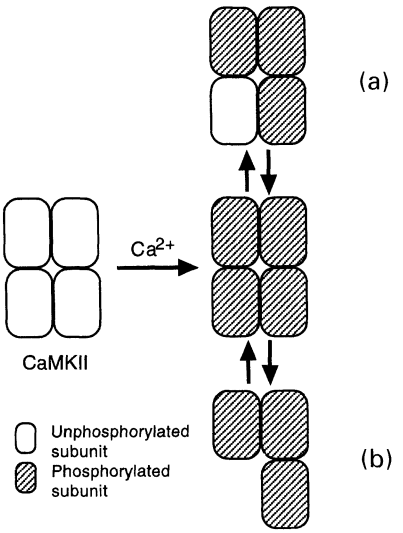

FIG. 2. Irreversible activation of CaMKII (Hanson and Schulman, 1992). In the inactivated state. CaMKII's subunits are unphosphorylated. Stimuli that induce memory activate CaMKII by Ca^{2+}-dependent phosphorylation of the subunits, after which autophosphorylation occurs independent of Ca^{2+}. Thus, if (a) a phosphatase dephosphorylates a subunit, Ca^{2+}-independent activity rephosphorylates it and returns CaMKII to full activity. Furthermore, when (b) a subunit becomes unbound or degraded by normal protein removal processes, the subunit is replaced and phosphorylated independent of Ca^{2+}, resulting in fully activated CaMKII.

fined to the forebrain (the only location of promoter) and was turned off only when tetracycline (T) was added. Tetracycline regulation of the transgene allowed some important observations. The transgenic mice learned and retained memory the same as normal mice when the transgene was inhibited (+T). Expression of the transgene (−T) impaired memory. The impaired memory was reversible by inhibiting the transgene (+T), and memories acquired while the transgene was inhibited could be extinguished by expressing CaMKIIα (−T).

Other studies in which CaMKII was inactivated also showed impairment of various aspects of memory (Glazewski *et al.*, 1996). Thus, inhibiting *or* activating CaMKII results in significant changes in memory storage, indicating that the kinase is at least partially responsible for information storage in the central nervous system.

GLOSSARY

Antidromic Action Potential: Movement of an action potential in a direction opposite to that of normal propagation. Backpropagation.

Connexin: Protein subunit of a gap junction.

Long-Term Potentiation: A relatively permanent change in a neuronal system.

Site-Directed Mutagenesis: A form of genetic engineering that permits changes in specific nucleic acids in a given gene.

Transgene: A foreign-DNA gene incorporated into an organism's genome early in development, and inherited by offspring in an Mendelian fashion.

Uptake Carrier: Membrane protein that facilitates uptake or release of ions and other substances.

24.1
Introduction

The basic principles and instrumentation of Raman spectroscopy are reviewed. Emphasis is placed on fiber-optic probes and microprobes. Applications to a wide range of problems in several industries, as well as to forensic applications are surveyed. Applications to the arts and sciences, including the life sciences, are also reviewed. Literature references provide the reader with links to more detailed discussion of the theory of Raman spectroscopy, to the methodology used in each of the surveyed areas, and to the details of the Raman spectra of many materials.

24.2
Raman Spectroscopy Basics

24.2.1
Theory

Raman spectroscopy is a widely employed tool in physical science, life science, and engineering. Consequently, there are numerous monographs and chapters in monographs that address the fundamentals and applications for different audiences. Good introductory surveys are available (Smith and Dent, 2005; Lewis and Edwards, 2001).

Raman scattering is a form of inelastic light scattering. In general, the lasers that are used to excite Raman scatter have photon energies lesser than the energy of the first electronic excited state. The weak interaction between the exciting laser photons and the molecule results in scattering, with light scattered at a new, lower frequency (expressed in wave numbers) according to Eq. (24.1) as follows:

$$\overline{\nu}_{\text{scattered}} = \overline{\nu}_{\text{exciting}} - \overline{\nu}_{\text{vibration}} \qquad (24.1)$$

Where $\overline{\nu} = 1/\lambda$. The scattered light is red-shifted and is called *Stokes-scattered*. It is assumed that all of the molecules are in the ground vibrational state. That is not quite true, especially for low frequency vibrations. If the scatter originates from a molecule in an excited vibrational state, then light is blue-shifted by the same frequency. Because this effect called *anti-Stokes Raman scattering* is weak, it is rarely used. Generally, most workers report Raman spectra as plots of intensity vs. $\overline{\nu}_{\text{vibration}}$ of scattered light.

The quantum efficiency for Raman scattering is low. Generally, it is between 10^{-7} and 10^{-9}. Although this number

Encyclopedia of Applied Spectroscopy. Edited by David L. Andrews.

ISBN: 978-3-527-40773-6

sounds low, it should be noted that a 1-W laser operating at 800 nm outputs about 4×10^{18} photons per second. Raman spectroscopic instruments use lasers that provide 0.01–0.5 W at the sample. Therefore, even with 0.01-W laser power and 10^{-9} quantum efficiency, there should be about 10^7 Raman-scattered photons generated per second. Even with very low collection efficiency, the experimental problem is often not the absolute intensity of Raman scatter but rather the presence of an intense background signal from fluorescing molecules. Because fluorescence quantum efficiencies are often at least 0.01 and can approach 1, fluorescence intensity even from impurities in a matrix can exceed Raman scatter intensity by 2 or 3 orders of magnitude.

The wavelength dependence of the intensity of Raman scatter is approximated by Eq. (24.2).

$$\overline{\nu}^4_{\text{exciting}} = \frac{1}{\lambda^4_{\text{exciting}}} \tag{24.2}$$

If only the intensity of the Raman signal governed the choice of exciting wavelength, spectroscopists would choose as blue a wavelength as possible. In fact, the choice of wavelength is usually governed by the need to circumvent fluorescence background. If the material to be analyzed or its matrix is fluorescent, then red or near-infrared lasers are used. This is usually the case for most industrial organic compounds and most polymers and virtually all tissue specimens and human, animal, or bacterial cells. On the other hand, many inorganics, including ceramics and semiconductors, have little or no fluorescence. In this case, green lasers are usually used. Ultraviolet lasers are used only in special cases, both to avoid photochemical damage and to preserve compatibility with glass optics and sample containers.

The selection rules for Raman scatter are different from those for infrared absorption. A vibration is Raman active if the vibration causes a change in the dipole moment of the molecule induced in an external electric field. This quantity is proportional to a parameter called *polarizability*, *P*. By contrast, a vibration is infrared active if there is a change in the dipole moment of the molecule when the vibration is excited. These different selection rules mean that different types of vibrations are intense in the Raman and in the infrared. In many cases, a vibration that has an intense band in one mode of observation will have a weak band in the other. For example, stretches and bends of highly polar functional groups are intense in the infrared and weak in Raman scatter. On the other hand, stretches of unsaturated moieties are intense in Raman scatter and weak in infrared absorption. Significantly, the OH stretching and bending modes of water are strong in the infrared, but weak in Raman scatter. The stretching and bending modes of Si–O moieties are also intense in infrared absorption and weak in Raman scatter. Indeed, compatibility with aqueous solutions, glass, or fused silica containers and optics has long been major reasons for use of Raman spectroscopy rather than infrared spectroscopy.

24.2.2
Enhancement

There are two general enhancement mechanisms that result in great increases in Raman intensity, resonance enhancement, and surface enhancement. The corresponding methodologies are usually called *resonance Raman spectroscopy* (*RRS*) and surface-enhanced Raman spectroscopy (SERS) (Smith and Dent, 2005; Lewis and Edwards, 2001).

Resonance enhancement occurs when the exciting laser wavelength is coincident or nearly coincident with the electronic absorption band of a molecule. For colored molecules, resonance enhancement occurs at visible wavelengths. Examples of practical interest include hemoglobin, and dyes, especially those that are red or orange and absorb 532 nm light, the frequency-doubled wavelength of the very common Nd : YAG and Nd : VO_4 lasers. Of course, several molecules absorb in the ultraviolet. Resonance enhancement occurs at UV wavelengths; but for practical reasons, only a small number of specialist laboratories make use of this effect.

Surface enhancement occurs when the wavelength of the exciting laser is coincident with the wavelength of the surface plasmon of a metal on which the molecule is absorbed. For specially structured surfaces of silver or gold, the surface plasmon wavelengths are in the visible or near infrared. In theory, enhancement factors can exceed 10^{10}. In practice, enhancement factors of 10^3-10^5 are observed. Although surface enhancement can be observed with easily prepared gold or silver colloids, current practice has been moving toward structured surfaces prepared by photolithography because these provide more reproducible enhancement. Increasingly, gold is preferred over silver because gold surfaces are more stable than silver surfaces. The potential user is cautioned that the technique is limited to the monolayer of molecules that are actually in contact with the surface or, but with greatly reduced enhancement, to the monolayer and one or two layers directly above it. The dynamic range of SERS is, therefore, limited and it is largely a trace or an ultratrace analytical method.

24.2.3
Subsurface Measurements – Spatially Offset Raman Spectroscopy (SORS)

An important recent development has been the use of spatially separated laser illumination and collection regions to probe beneath the surface of a turbid medium, such as a polymer, a powdered material, or tablet or a human or animal tissue (Matousek, 2007). Generally, delivery of laser and collection of Raman scatter is by optical fibers, which may be arranged in any number of different geometries. The spatial separation of illumination and collection regions allows the collection of light that has been multiply scattered as it propagates through the turbid medium. Low definition images have been acquired with SORS-type systems (Schulmerich *et al.*, 2006; Schulmerich *et al.*, 2007) and even Raman tomography has been reported (Schulmerich *et al.*, 2008).

24.2.4
Instrumentation

24.2.4.1 Laser Safety

Standard laser safety protocols should always be enforced. In particular, users should wear appropriate laser safety glasses. Depending on the laser power, door interlocks and warning signs may be necessary. American laboratories follow the guidelines of the ANSI Z136.1–2007 standard (Laser Institute of America, 2007). Similar standards for laser safety apply in other countries.

24.2.4.2 Basic Instrumentation

A standard Raman spectroscopy system comprises a laser source, a sample illumination and collection system, a single stage spectrograph with a holographic or dielectric prefilter to reject laser light, and a charge-coupled device (CCD) imaging detector. Many types of devices are available to illuminate the sample and to collect the scattered light. The majority of users employ either fiber-optic probes or microscope-based microprobes. A common accessory is a motorized stage to facilitate spectroscopy of multiple samples, including samples in microliter plates and similar systems.

Frequency-doubled Nd : YAG and Nd : VO_4 lasers, which operate at 532 nm, are preferred for nonfluorescent or weakly fluorescent samples. They are compact, stable, and have no special electrical service requirements. For fluorescent materials, diode lasers operating at 785 nm, or for many biomedical applications, those operating at 830 nm are preferred. Where the excited fluorescence is low enough, 785 nm is preferred. It is the deepest red standard wavelength diode laser for which Raman shifts of C–H stretches (i.e., below about 3100 cm^{-1}) can be observed with a CCD or other silicon photodetector. The recent development of InGaAs-based imaging detectors has made Nd : YAG 1064 nm lasers a viable choice.

Several different spectrograph configurations are used. Czerny–Turner systems, usually with toroidal mirrors for astigmatism correction, are common. On-axis designs are frequently used for their superior imaging performance. The axial transmissive spectrograph (Battey *et al.*, 1993), which uses lenses instead of mirrors for collimation and focusing and a transmission grating instead of a reflection grating, is the most prevalent.

The detector in most Raman spectroscopy systems is a slow-scan (also called *scientific*) back-illuminated CCD (Janesick, 2001). The deep depletion version, which is fabricated from high resistivity silicon, has superior quantum efficiency above 800 nm, and is used in conjunction with 785 and 830 nm lasers. Replacement of conventional output amplifiers with a chain of avalanche breakdown stages yields an electron-multiplying charge-coupled device (EMCCD) (Coates *et al.*, 2003; Denvir and Conroy, 2003). The EMCCD has high gain (up to 1000 X), is capable of single photon detection and can be operated at high read-out rates (greater than 1 MHz) with very little excess noise. The electron-multiplying technology has not yet been successfully implemented on deep depletion CCD's and so has not been useful with deep red or NIR diode lasers.

As the size of solid state lasers and CCD detectors has decreased, so has the size of laboratory bench-top Raman spectroscopy systems. Modern systems generally have a footprint that is slightly higher than 0.5×0.5 m and many are smaller. Of course, the addition of a microscope or a stand for a fiber-optic probe or some other specialized accessory may increase the overall size of the instrument.

The increasing use of Raman spectroscopy for chemical process control has encouraged vendors to develop versions of their instruments for use in the factory environment. These instruments are usually packaged in enclosures for high dust, vibration, and electrical noise environments and may contain rugged versions of some components and subsystems.

Recently, several companies have introduced handheld, battery-powered instruments for off-site use in incoming materials inspection and for geological, environmental, homeland security and forensic applications. These instruments can operate for several hours without recharging. They typically are low-resolution (8–10 cm^{-1}) instruments and may have on-board databases and software for matching spectra to commonly encountered materials.

24.2.4.3 **Fiber Optic Probes**

An obvious advantage of the fiber optic probes is that the laser, spectrograph, and CCD can be some distance away from the sample. In the laboratory, 3–5 m is considered as the typical fiber length. Often, longer lengths are found in industrial process control to minimize the effects of noise and vibration on the instrumentation. Two general designs of fiber-optic Raman probes are in widespread use: the N-around-1 probe and the bifurcated filtered probe.

In the N-around-1 design laser, light is transmitted through a central optical fiber and Raman scatter is collected from a circular bundle of fibers that surrounds it. These are cemented into a metal, ceramic, or plastic holder and the ends are cut and polished. However, as the laser light propagates through the excitation fiber, it generates a silica Raman signal. This usually causes no problem in measurements of clear liquids. If the sample is a turbid fluid or a solid, some silica Raman scatter is reflected back into the collection fibers and becomes a background, which increases with the length of the fiber used. The background problem can be reduced if filters are placed at the ends of the optical fibers. An example is shown in Figure 24.1 (Motz *et al.*, 2004). Of course, the filters add cost and complexity to the probe.

In the bifurcated filtered probe, a single excitation fiber and a single collection fiber are used. A dichroic mirror, notch filter, or other wavelength-selective optic are used to combine the excitation and collection light. Delivery of laser light to the sample and collection of Raman-scattered light from the sample are through a single lens. Auxiliary filters may be used to remove silica Raman scatter from the excitation light and to prevent laser light from entering the collection fiber, resulting in very low silica background. In addition to the basic, general purpose designs, available probes include models with sampling optics designed for immersion in liquids or for operation at elevated or low temperatures.

24.2.4.4 **Microprobes**

Raman microprobes are used because they are applicable to opaque materials and water-containing materials (such as plant or animal tissue or cells) and offer lateral spatial resolution that is similar to resolution obtainable with light microscopes, about 0.5–1 µm. Operation in this wavelength range gives the Raman microscope better spatial resolution than is available with infrared microscopes. Additionally, most employ a confocal geometry to improve axial resolution and reduce background scatter and fluorescence. Depth profiling by Raman microscopy is well established (Reinecke *et al.*, 2001; Adar, 2001; Fleming and Kazarian, 2004). It should be cautioned that the spherical aberration induced by refractive index changes can distort

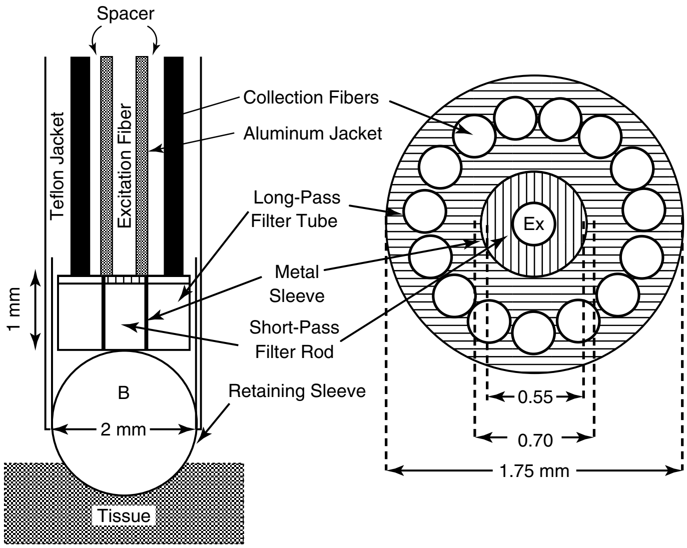

Fig. 24.1 An N-around-1 fiber-optic Raman probe. In this probe design, dielectric filters are used to block silica Raman scatter generated in the excitation (laser delivery) fiber and to block backscattered laser light from entering the collection fibers. A ball lens is used to focus the sample onto the specimen, which is skin tissue. (Reprinted by permission from reference (Motz *et al.*, 2004).)

depth measurements (Everall, 2000a,b). Index matching and the use of immersion objectives are needed to minimize this problem (Everall *et al.*, 2007).

Almost all commercial systems are constructed around standard epi-fluorescence microscope frames made by the major microscope makers. Coupling optics are added, but the microscope hardware is usually unchanged. For safety reasons, it is not common for a Raman microprobe to include binocular eyepieces. A video camera is used for viewing the sample and focusing the instrument. Because Raman microprobes operate in the visible or near-infrared, the spectroscopist has ready access to the wide range of specialized objectives used for light microscopy. Temperature-controlled stages and many other accessories made for the microscope frame can also be used.

A schematic Raman microprobe is shown in Figure 24.2. Coupling optics bring laser light to the microscope objective and direct Raman scatter to the spectrograph. Direct (i.e., with lenses and mirrors) coupling is common. Some vendors offer fiber optic coupling, which provides greater flexibility in component positioning and facilitates using the same spectroscopy optics with other sampling systems. However, to retain the spatial resolution of the direct-coupled instrument, it is necessary to use a single mode optical fiber to deliver the laser light to the microscope. A multimode fiber can be used to direct the Raman scatter to the spectrograph.

A basic instrument operates as a single point microprobe. Mapping is

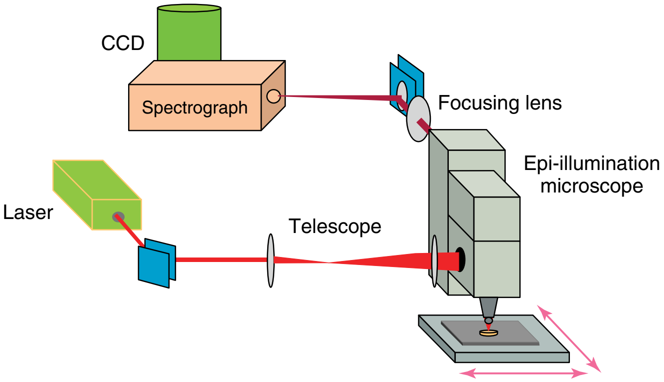

Fig. 24.2 Schematic of a Raman microprobe. Light from the laser is shaped by the telescope and focused on the sample by a microscope objective. Raman scatter is collected through the objective and focused onto the entrance slit of the spectrograph. In this simple design, a manual or motor-driven stage can be used to build up a Raman map pixel by pixel.

provided by motor-driven or piezoelectric *XY* stages, or by scanning mirror systems similar to those used in confocal microscopy. Motor-driven *XY* stages have a settling time that can approach 1 second, and this dead time can limit the speed at which point–point images can be acquired. Piezoelectric stages settle in less than 1 ms. The combination of a piezoelectric stage and an EMCCD allows very fast mapping, at least with green laser excitation. Line-focusing of the exciting laser can be used to acquire an entire line of spectra simultaneously, while increasing the total power that can be safely focused on the sample. In this case, only one-dimensional scanning is needed to generate an image, and the total image acquisition time can be much shorter than if point-point scanning is used.

24.2.5
Data Reduction

Raman spectroscopy is often used for material or contaminant identification. Visual inspection or computer-aided matching to a spectrum in a database of Raman spectra is often all that is needed. Because the intensity of Raman scatter is directly proportional to the number of molecules interrogated, quantitative analysis using band heights or areas and standards of known concentration is satisfactory. However, inaccurate subtraction of fluorescence or background can introduce errors into this seemingly simple operation. The merits and problems of background subtraction protocols remain contentious.

In industrial process control, small changes in complex materials are frequently sought. Tracking the change in the height or area of a single band or of a band height or area ratio is often not satisfactory. In such cases, a multivariate model, typically a partial least squares model, is used instead. Models contain contributions from throughout the Raman spectrum and thus strongly depend on reproducible instrument and process conditions. They can yield erroneous results if the process conditions or instrument parameters change, even if the change is small.

24.3
Identification and Quantification of Inorganic Materials

24.3.1
Introduction

Characterization of inorganic materials by Raman spectroscopy has been reported in topics ranging from surfaces of nanocrystals to characterization of bulk geological minerals. Since the late 1990s, there have been many applications of Raman to new classes of materials and novel approaches to examining existing classes of materials. More recently, fundamental studies of phonons in reduced dimensions have been investigated using Raman spectroscopy. Most reports fall under three broad topics: chemical identification, quantification, and spectroscopic response to mechanical or chemical perturbation (Lyon *et al.*, 1998; Pitt *et al.*, 2005). A comprehensive review of the theory of molecular vibrational spectroscopy and Raman spectroscopy of small inorganic molecules provides both a theoretical and experimental basis for examining a wide variety of inorganic molecules (Nakamoto, 1997). A wide variety of materials, including silicate glasses, cements, catalysts, clay minerals and ceramics (Potgieter-Vermaak, Potgieter and Grieken, 2006; McMillan, 1984; Bartlett and Cooney, 1987; Butler and Frost, 2006), have been examined using Raman spectroscopy. Mineral-based inorganic pigments, forensic physical evidence, nanoscale semiconductors and carbon nanotubes have been recently explored using Raman. In this chapter, Raman identification and quantification in these broad classes of inorganic materials are reviewed. Finally, a case study using Raman spectroscopy as a real-time industrial process control tool is presented.

24.3.2
Minerals

Examination of geological minerals is one of earliest applications of Raman spectroscopy, and it remains a vibrant field of study. A review of the major Raman bands from a wide variety of geology samples was provided by (Griffith, 1987). Various modes of Raman (resonance Raman, Raman microscopy, isotopic substitution) were reviewed and spectroscopic data was presented from two broad families: nonsilicates and silicates. A wide variety of nonsilicate minerals, such as diamond, carbonate minerals, and gypsum, and silicate minerals, such as clay minerals, micas, and olivine, were included in this chapter. Modern Raman applications of geology minerals include astrobiology remote sensing and planetary exploration (Villar and Edwards, 2006; Lipschutz *et al.*, 2007; Wang, Haskin and Cortez, 1998; Sharma *et al.*, 2002; Haskin *et al.*, 1997). Effects of high temperature and/or high pressure on Raman spectra of minerals have been extensively studied (Gillet *et al.*, 1993; Butler and Gilson, 1997; Gillet, Hemley and McMillan, 1998; Butler and Frost, 2006).

24.3.3
Art, Archaeology, and Architecture

Raman spectroscopy is used to examine mineral-based inorganic pigments in works of art, architectural buildings, and archaeology samples. Recent reviews highlighted the many applications of Raman spectroscopy in art and archaeology (Vandenabeele, Edwards and Moens, 2007; Edwards, 2004). The primary usage of Raman spectroscopy is the identification of pigments, corrosion products, or contaminants in manuscript and paintings. Ceramics, glasses, enamels, glazes, minerals, and gem artifacts are also examined with Raman spectroscopy. Spectral libraries of reference inorganic pigments are available in journals (Bell, Clark and Gibbs, 1997; Vandenabeele, Edwards and Moens, 2007) and online. Table 24.1 presents some spectral libraries available online.

Raman spectra of artifact pigment samples are typically collected in a confocal microscopy mode, because of sample heterogeneity and minute sample sizes. The choice of laser wavelength is influenced by sample fluorescence and the nature of the artifact. Many studies use multiple wavelengths to examine a single artifact. Pigments are typically examined using a near-infrared laser while metal corrosion is examined using 514.5 or 532 nm lasers. White pigments were commonly used as wall paint and as a base for the addition of colored pigments. Figure 24.3 shows the commonly used white pigments: (a) gypsum, (b) calcite, (c) barium white, and (d) bone white, adapted from UCL spectra library as described by Bell *et al.* (Bell, Clark and Gibbs, 1997).

Mixtures of mineral particles, resulting from artist blending pigments in the original composition or subsequent restoration efforts, complicate the interpretation of Raman spectra taken from paintings. Carbonaceous particles from soot or dirt contaminate artifacts and are a source of fluorescence. However, they are easily distinguishable in light microscopy images because they are often black particles and Raman spectra of carbon particles do not interfere with the identification of mineral-based inorganic pigments. A complicating issue is pigment degradation, either through environmental-induced or laser-induced pathways. Mixtures of lead corrosion products, such as lead oxide, lead sulfate and lead nitrate, were quantified using Raman spectroscopy (Black, Allen and Frost, 1995). Raman spectra of lead carbonates identified the presence of

(http://www.chem.ucl.ac.uk/resources/raman/index.html.)

adducts and unstable corrosion products (Brooker *et al.*, 1983; Ciomartan *et al.*, 1996).

Raman spectra of paint layers complement historical data on the pigment. These data can be used to estimate the painting's age or direct restoration strategies (Edwards, Farwell and Brooke, 2005). In a study of architectural paint samples, cross-sections of eight paint layers were examined using Raman spectroscopy, light microscopy, and scanning electron microscopy with energy dispersive spectroscopy (SEM–EDS) (Kendix, Nielsen and Christensen, 2004). Raman spectra indicated that each paint layer had its own mixture of pigments, and the Raman data correlated with results from SEM-EDS. The dominant white pigments were calcium carbonate, white lead, titanium dioxide, and barites.

In another study, layered samples paint and stucco were recovered from a preserved Mayan temple found within the Rosalila building (Goodall *et al.*, 2006). Paint/stucco samples from the temple and a stucco mask were examined using Raman, micro attenuated total reflectance infrared spectroscopy (ATR-IR and scanning electron microscopy (SEM) (Goodall *et al.*, 2006). The nature of the green paint was a key finding. Raman bands associated with plagioclase and celadonite were found in green particles, but the bands were too broad and noisy to be definitive. ATR-IR of the same particles reveal a celadonite-based mixture (also called *Terra Verte*), which was confirmed by SEM and micro X-ray. Spectroscopic studies of the Rosalila samples revealed the use of the green Terra Verte pigment, and this pigment was not found in samples collected from another Mayan temple (Vandenabeele *et al.*, 2005).

24.3.4
Forensics

Applications of Raman spectroscopy for nonbiological forensic evidence primarily fall under sample identification. Physical evidence in criminal cases is often in trace amounts, or on a large support structure such as a car panel. Many reports cite flexibility in sampling modes (e.g., microscopy or fiber optics systems), small sample requirements and the nondestructive nature of Raman spectroscopy as an advantage of the method for analysis of trace-level evidence. A 2007 applications review on forensic science highlighted the use of Raman spectroscopy to identify automobile paint, pen ink, and explosives (Brettell, Butler and Almirall, 2007). Raman spectra are primarily used to distinguish physical evidence found at a crime scene from evidence collected from a suspect. Raman spectra of automobile paints identified inorganic fillers or binders, such as magnesium silicate or talc, and inorganic pigments, such as titanium dioxide, lead chromate, or calcite (Buzzini, Massonnet and Sermier, 2006; Zieba-Palus and Borusiewicz, 2006; Gelder *et al.*, 2005). Pigments from spray paint or house paint were also examined by Raman spectroscopy. In one case study, Raman spectra collected from red paint splattered on a suspect's shoe was undifferentiated from spectra of red paint stain on a wall. Raman spectra identified two red paints: (i) Iron oxide using 785 nm excitation and (ii) either chrome orange (lead (II) chromate) or molybdate orange (lead molybdate chromate) in stains at the crime scene. Raman spectra of paint droplets collected from the suspect's shoe also contained bands from the two paint pigments and it was concluded that the shoe was in contact with the paint used to damage the wall (Buzzini, Massonnet and Sermier, 2006). As seen in Figure 24.4, Raman spectra collected from a suspect's shoe indicated a mixture of two red paints, which were similar to the spectra collected from the crime scene.

Proof of concept for metals and anions identification in gunshot residue was shown by (Stich *et al.*, 1998). Gunshot residues were produced from 10, 20, or 30 cm from the paper substrate. Residues left on a paper substrate were examined under a Raman microscope ($\lambda = 633$ nm) in three domains surrounding the impact point. Raman spectra showed heterogeneity in the chemical composition of residues, which was dependent on the distance of the particle from the impact site. In the region closest to the impact site, barium carbonate was the dominant component. In regions farther from the impact site, a mixture of lead-based and barium-based particles were found, and the oxidation state (carbonate or oxide) also varied.

24.3.5
Nanoscale Semiconductors

A review of Raman studies from 1995 to 1997 that characterized semiconductor surfaces was provided by (Lyon *et al.*, 1998). Later reviews in 2003 and 2004 provide a theoretical basis of analyzing fundamental semiconductor properties such as phonon interactions, doping, strain, crystallinity, and surface composition; resonance Raman and polarized Raman were also reviewed (Jimenez, Wolf and Landesman, 2003; Nakashima, 2004). As seen in Figure 24.5, Raman bands are sensitive to local environments and differences in band shape, intensity, or width can be used to differentiate regions on a semiconductor surface.

Since 1998, two nanoscale materials have emerged that have unique electronic properties: single-wall nanotubes (SWNTs) made from carbon and quantum dots (QDs) composed of semiconductor materials. QDs are nanoparticles composed of semiconductor materials, typically with a

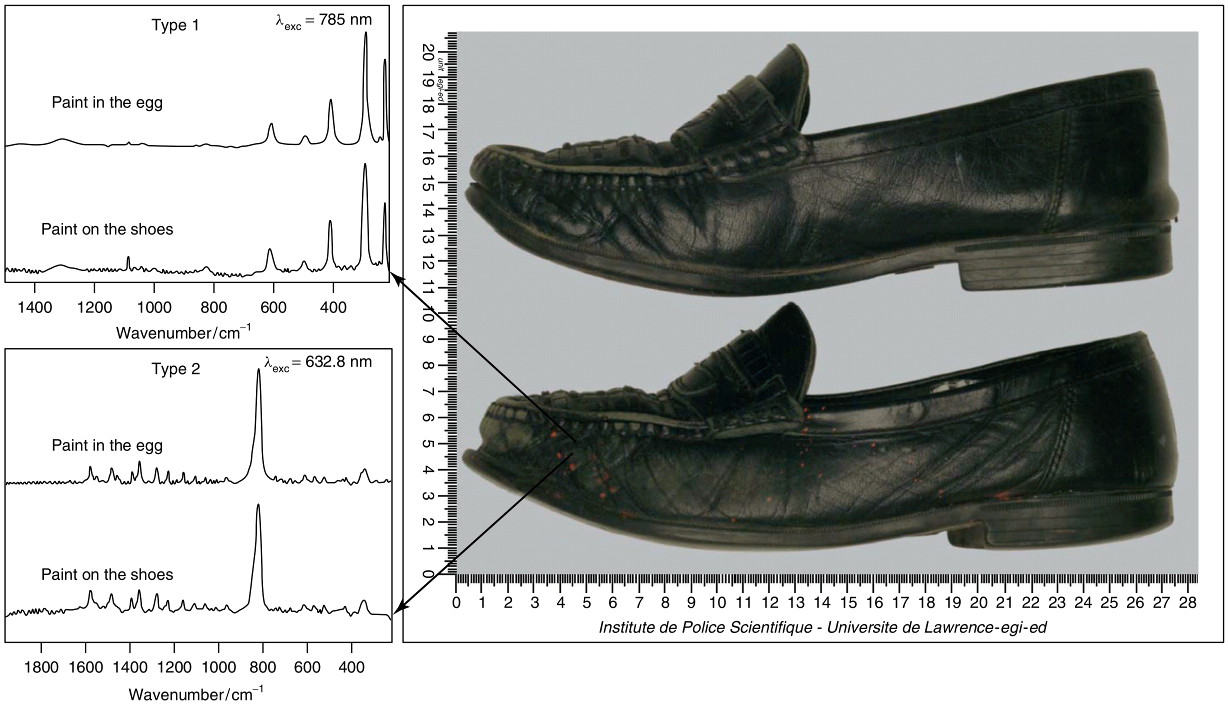

Fig. 24.4 Raman spectroscopy used in forensic evidence analysis shows correlations between evidence collected at a crime scene and evidence collected from a suspect. Paint was thrown onto the wall of a home in small ''eggs,'' and Raman spectra of the splattered paint showed a unique mixture of two red/orange pigments. Raman spectra collected from paint evidence on a suspect shoe were undifferentiated from spectra collected from a crime scene. (Reprinted by permission from reference (Buzzini, Massonnet and Sermier, 2006).)

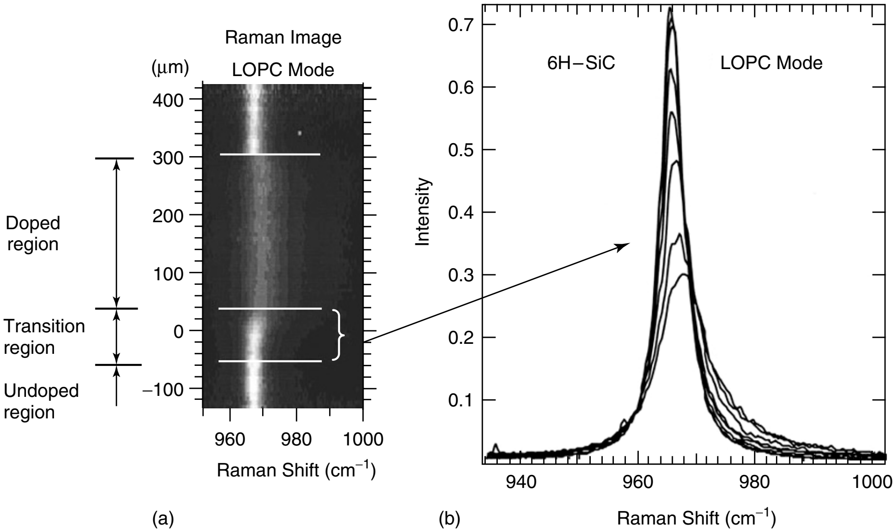

Fig. 24.5 (a) shows a Raman image of a modulation-doped 6H-SiC semiconductor surface and (b) shows Raman spectra of the longitudinal optical phonon plasmon coupled (LOPC) mode in the transition region. Raman band position and band width varied in the transition zone as a result of starting and stopping of carrier gas used in modulated doping experiments. (Figure is reproduced with permission from reference (Nakashima, 2004), copyright Institute of Physics.)

cadmium/selenium core, with potential applications as laser sources, storage materials, fluorescent dyes, and sensors (Voronin, 2006; Cottingham, 2005; Murphy, 2002). Exciting applications in diffusion, flow cytometry, and biomechanics experiments show the broad applicability of QDs in biological fluorescence or luminescence imaging (Dahan *et al.*, 2003; Gao and NIe, 2004; Golcuk *et al.*, 2007).

Raman spectroscopy has proven valuable in characterizing the chemical and electronic properties of QD's. Raman spectroscopy was used to understand the fundamental phonon behavior in reduced dimensions, characterize QD surfaces after chemical doping or mechanical strain, and measure the effects of temperature on longitudinal optical (LO) or transverse optical (TO) phonon frequency. Rolo and Vasilevskiy reviewed theoretical and experimental results of optical phonon modes using Raman spectroscopy (Rolo and Vasilevskiy, 2007). Resonance Raman spectroscopy and nuclear magnetic resonance (NMR) spectroscopy monitored exciton-phonon interactions; results showed improved sensitivity at the molecular level for single QDs and QDs in an ensemble (Gammon *et al.*, 1997).

Carbon nanotubes, multiwalled or single-walled, are frequently investigated by Raman spectroscopy because graphitic structures have intense Raman bands (Barbarossa *et al.*, 1991; Everall and Lumsdon, 1991; Lespade *et al.*, 1984; Gibson, Ayorinde and Wen, 2007). These nanotubes are proposed as reinforcing materials in polymer composites (Coleman *et al.*, 2006; Bokobza, 2007). Raman spectroscopy has emerged as a preferred method for characterizing these materials and has been suggested as a method for monitoring their manufacture (Degamber and Fernando, 2002). In particular, single-walled carbon nanotubes (SWCNTs) have unique electronic, mechanical, and chemical properties; their uses as a composite material or electronic device have been reviewed (Popov, 2004). Raman spectra of SWCNTshave provided valuable insight into the electronic and the phonon properties of SWCNTs. Raman spectra of SWCNTs are sensitive to tube diameter, functionalization, and mechanical strain (Dresselhaus *et al.*, 2002, 2005; Graupner, 2007). A recent study of whole-body Raman imaging using surface-enhancing carbon nanotubes indicates exciting applications of SWCNTs in biomedical imaging (Keren *et al.*, 2008).

24.3.6
Industrial Process Control

High specificity, spatial resolution, molecular identification, and ease of use are features that make Raman an attractive technology for monitoring inorganic chemical production (Workman *et al.*, 2001; Workman, Koch and Veltkamp, 2003). Raman has been used to examine chlorosilane streams as a complementary technique to gas chromatography (GC) analysis (Lipp and Grosse, 1998). A fiber-optics Raman system has been used for direct monitoring of the corrosive stream, where several species were identified and quantified. Raman PAT monitored fluctuations in stream components that indicated poor performance of distillation columns.

Direct monitoring of titanium dioxide production using a fiber-optic Raman spectroscopy instrument was reported by (Clegg *et al.*, 2001). Two forms of TiO_2, anatase and rutile, are made during one step (calciner discharge) of the synthetic route. However, the amount of anatase must be controlled so that the final product retains good optical properties. Powder X-ray diffraction (XRD) had been used as an off-line measurement of quality; however, measurements were performed infrequently. More frequent quality measurements were hypothesized to enable a more efficient calciner discharge step, and Raman spectroscopy was chosen as the analytical tool. Raman spectra of anatase and rutile in the 150–800 cm^{-1} region have unique bands. Raman spectra of anatase/rutile mixtures show that the intensity ratio of 142 : 610 cm^{-1} bands correlated to ratios measured by XRD. Effects of temperature, crystal size, and window cleanliness on anatase measurement accuracy were also discussed.

24.4
Identification and Quantification of Organic Materials

24.4.1
Pharmaceutical Applications

Raman spectroscopy is a major component of process analytical technology (PAT) (Bakeev, 2005), the pharmaceutical industry's term for process control analytical chemistry and related topics. The most important PAT application of Raman spectroscopy is crystallization monitoring and control (Févotte, 2007; Yu *et al.*, 2004, 2007). The application is important because the polymorph determines such important properties as

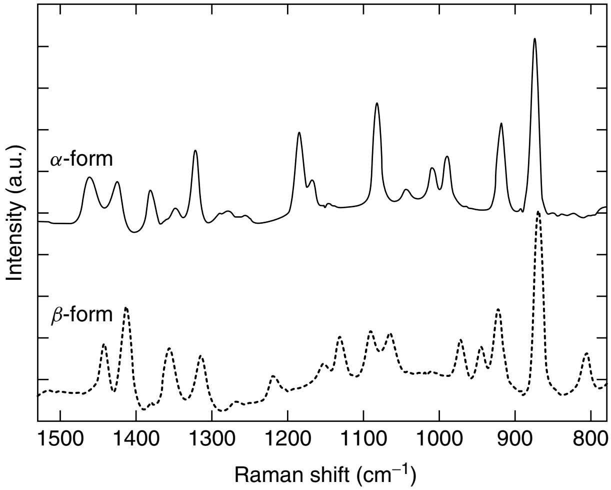

Fig. 24.6 Raman spectra of the metastable α-form and the stable β-form of L-glutamic acid. (Reprinted with permission from reference (Scholl *et al.*, 2006).)

solubility and rate of dissolution. Establishment of the theoretical and the experimental frameworks that define conditions under which the desired polymorph is the only or at least the dominant form are the major goals of researchers (Rodrìguez-Spong *et al.*, 2004; Llinàs and Goodman, 2008).

Crystallization monitoring depends on the differences in the Raman spectra of different polymorphs. L-Glutamic acid, which has two polymorphs, offers a dramatic example (Figure 24.6) (Scholl *et al.*, 2006). The metastable α-form is kinetically favored and is slowly converted to the thermodynamically more stable β-polymorph. In some cases, the differences in the spectra may be more subtle than those for L-glutamic acid, but they will be easily found by PCA, if not by visual inspection (Falcon and Berglund, 2004; Okumura and Otsuka, 2005). However, some authors consider that polymorph spectra differ sufficiently that univariate calibration is almost always adequate (Rantanen *et al.*, 2005).

Because of the ease of use and the ability to monitor changes online (O'Sullivan *et al.*, 2003), Raman spectroscopy has increasingly displaced powder X-ray diffraction in crystallization monitoring. There are also differences in the spectra of amorphous materials and crystalline forms, enabling on-line measurement of crystallinity (Nakano, Tokumura and Umakoshi, 2002). However, there are complications caused by presence of highly scattering materials, whose number and size are changing throughout the process. Sampling a large volume through use of a nonconfocal probe with large spot size, such as the Kaiser Optical Systems PhAT probe is an effective approach to this problem (Wikström, Lewis and Taylor, 2005). Another approach to improved quantification has been to combine Raman spectroscopy with image analysis using a conventional fiber probe and a small video camera simultaneously (Caillet *et al.*, 2007).

Other major pharmaceutical applications include monitoring of homogenization (De Beer *et al.*, 2006), inspection of incoming materials, and inspection of tablets for composition and uniformity. Transmission Raman spectroscopy may be nearly ideal for composition monitoring in formulated products, because it is rapid and provides accurate measures of average composition of a tablet (Matousek and Parker, 2007; Eliasson *et al.*, 2008).

24.4.2
Polymer Chemistry and Physics

Raman spectroscopy plays major roles in polymer processing and analysis. Even today, the technique remains a major tool in the characterization of entire classes of polymers (Billes and Mohammed-Ziegler, 2007). Most commercially important polymers do not themselves fluoresce under visible light, but many formulations contain additives or impurities that do. Excitation with deep red or near-infrared lasers is often needed to circumvent a fluorescence background. Many major applications are to measurement of physical properties such as crystallinity, porosity, stress, and film or fiber orientation. These are the properties that must be adjusted to obtain the desired application performance. Except in contamination studies, a known chemical composition is usually the starting point of the measurement.

It has long been known that the Raman spectra of crystalline and amorphous forms of most polymers are different (Stuart, 1996). The polymer conformation usually determines crystallinity, and markers can include intensity, position, and band width changes. Applications continue to appear (Rasha, 2006). Although most applications use single point spectroscopy only, high definition imaging has been used to map crystallinity in syndiotactic polystyrene (Zhang *et al.*, 1998).

Because polymer bands undergo small shifts when a polymer is stretched or bent, Raman spectroscopy can be used to probe the conformational changes associated with these deformations (Colomban, 2002; Young and Eichhorn, 2007). Polarized spectroscopy is generally used, because more detailed information is available (Sourisseau and Talaga, 2006). The technique has proven useful in measurement of orientation in films (Sourisseau, 2004; Reinecke *et al.*, 2001) as well as in fibers. The same techniques that have been developed for polymers and polymer blends can be applied to composites (Colomban, 2002; Tomba, Carella and Pastor, 2006).

24.4.3
Forensic and Homeland Security Applications

The Raman microprobe has long been used for the analysis of small particles, such as fibers, paint chips, and hairs (Adar, 1988). It is used primarily with samples for which the spatial resolution of an infrared microprobe is inadequate. Recently, there has been extensive application to forensic analysis, for example (Buzzini, Massonnet and Sermier, 2006; Massonnet *et al.*, 2003, 2005; Thomas *et al.*, 2003a,b). Analysis of paint chips from automobile accidents and from burglaries has been especially important. Buzzini and coworkers have presented case studies that illustrate the range of problems that are encountered in these two important areas (Buzzini, Massonnet and Sermier, 2006). Identification of illicit drugs (Hodges *et al.*, 1989; Huong, 1986) is a closely related example.

With increasing interest in detection of explosives, Raman spectroscopy is a candidate for rapid detection (Carter *et al.*, 2005; Cheng *et al.*, 1995; Hayward *et al.*, 1995; Lewis *et al.*, 1997). If low duty cycle pulsed lasers and gated intensified CCD detectors are used, stand-off systems that can operate in ambient light are feasible (Carter *et al.*, 2005). Recently developed fiber-optic spatial offset techniques that can retrieve spectra through translucent containers may provide a convenient means for the detection of concealed explosive materials or component materials for making explosives (Eliasson, Macleod and Matousek, 2007).

24.5
Biological Applications of Raman Spectroscopy

Raman spectroscopy has evolved as a versatile biochemical analysis tool with applications ranging from the analysis of subcellular components to the diagnosis of diseases and *in situ* evaluation of whole tissues. The positions and relative intensities of various Raman spectral bands can be used to quantitatively probe the structure and function of important biological molecules.

24.5.1
Subcellular Level

Raman band assignments, secondary structure signatures (Bandekar, 1992), and markers of side-chain environment (George, 2002) have been established for proteins. The Raman spectrum of a protein is largely dominated by bands associated with the peptide main chain, aromatic side chains, acidic residues, and sulfur-containing side chains. Amino acids that are important in primary structure are tyrosine with peaks at 830 and 850 cm^{-1}, tryptophan with peaks at 1014, 1338, 1361, and 1553 cm^{-1}, and phenylalanine with a peak at 1006 cm^{-1}. Amide I (C=O stretching) and amide III (C–H stretching and N–H in-plane bending) modes are usually used to characterize the secondary structure of the peptide backbone. The wavenumbers at which the amide I and amide III Raman bands occur for α-helical, β-sheets, and random-coiled structures are given in Table 24.2. Apart from the study of folded active proteins, Raman spectroscopy has the ability to provide a variety of probes into the structure of natively unfolded proteins (see Figure 24.7) (Maiti *et al.*, 2004). Protein-based enzymes have been studied in real time by Raman crystallography (Carey, 2006).

The characteristic Raman bands of phospholipids arise from the vibrations of the hydrocarbon chains. The hydrocarbon chains can exist with a high degree of ordering (trans form) or in relative disorder (gauche form)

Tab. 24.2 Raman wavenumbers (per centimeter) for amide I and amide III bands for various polypeptide conformations.

Protein secondary structure	Amide I	Amide III
α-Helix	1645–1660	1265–1300
β-Sheet	1665–1680	1230–1240
Random coil	1660–1670	1240–1260

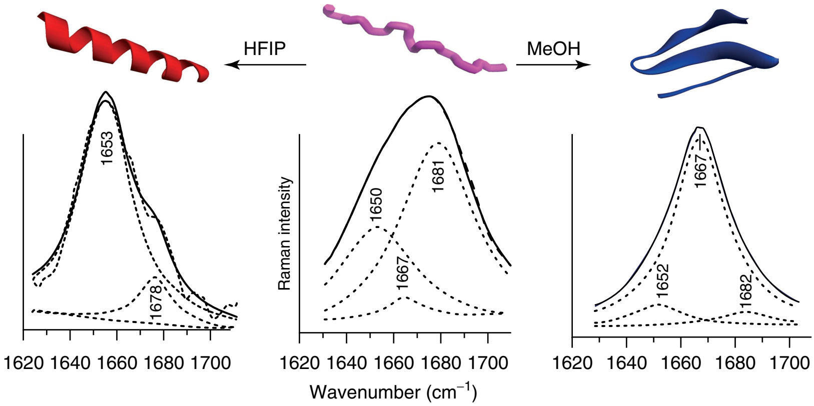

Fig. 24.7 Raman spectra of α-synuclein, a natively unfolded protein, in the presence of hexafluoro-2-propanol (HFIP) and methanol (MeOH). The secondary structure becomes largely α-helical in HFIP (1653 cm^{-1}) and predominantly β-sheet (1667 cm^{-1}) in 25% MeOH in water. (Reprinted with permission from reference (Maiti *et al.*, 2004), copyright American Chemical Society.)

(Mendelsohn and Moore, 1998). The phospholipids membrane conformation is temperature sensitive and can be probed with Raman spectroscopy. Sample Raman spectrums of cholesterol, a lipid, and lecithin, a phospholipid, are shown in Figure 24.8 (Tantipolphan *et al.*, 2006).

The Raman spectrum of a nucleic acid is dominated primarily by bands caused by vibrations localized either within the heterocyclic bases (500–800 cm^{-1}) or in backbone phosphate groups (800–1100 cm^{-1}). These Raman bands are employed as sensitive indicators of local structure, global conformation, intermolecular interaction, and molecular dynamics. Table 24.3 indicates the location of various Raman peaks in the spectra of different conformations of DNAs (Mahadevan-Jansen and Richards-Kortum, 1996). The Raman spectra of DNA–protein complexes yield information about the composition, secondary structure, and interactions of these molecules, including the chemical microenvironment of molecular subgroups.

24.5.2
Tissue Level

In recent years, Raman spectroscopy has seen a surge in applications to the study and diagnosis of diseases. The main aspect of Raman spectroscopy of cells and tissue is that it is capable of probing the subcellular milieu of intact cells. In this section, we describe the applications of Raman spectroscopy by tissue type. For a review on surface-enhanced Raman scattering and its biological applications, refer to these articles (Katrin *et al.*, 2002; Cotton, Kim and Chumanov, 1991).

24.5.2.1 Epithelial Tissue

The majority of the cancers originate in the epithelial tissue, such as esophagus, colon, larynx, bladder, prostate, cervix, breast, skin, lung, and lymph nodes. As these are readily accessible to fiber-optic probes in many cases,

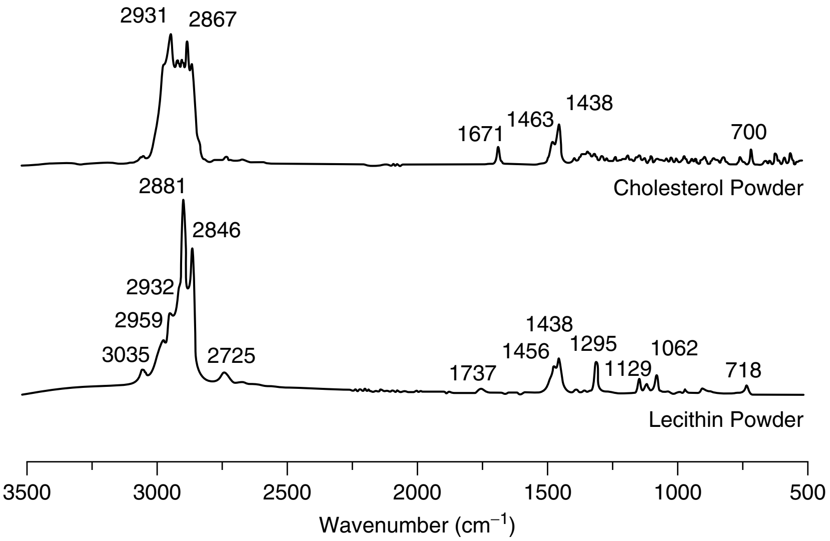

Fig. 24.8 Raman spectra of soybean lecithin and cholesterol powder. (Reprinted with permission from reference (Tantipolphan *et al.*, 2006), copyright Elsevier.)

Mahadevan-Jansen and Richards-Kortum (1996).

Raman spectroscopy has the potential to identify molecular and cellular changes associated with cancer cell proliferation (Short *et al.*, 2005). The use of multivariate spectral predictive models has enabled discrimination between benign and malignant tissue to a high degree of accuracy both *in vitro* and *in vivo*. In esophageal cancer, Raman spectroscopy has demonstrated higher levels of guanine, adenine, cytosine, uracil, O–P–O, β-sheet and disordered proteins and lower concentrations of glycogen, tryptophan, proline, and α-helix proteins in cancerous tissue as compared to benign tissue (Kendall *et al.*, 2003). In colon cancer, Raman spectroscopy has reported higher levels of guanine, adenine, cytosine, uracil, O−P−O, lipids, disordered proteins, phenylalanine, and lower levels of tyrosine and carotenoids than in benign tissue (Boustany *et al.*, 1999). In breast cancer, malignant tissue has shown greater concentrations of hydroxyproline and collagen and lower levels of glucose, lipid, and carotenoids than benign tissue (Redd *et al.*, 1993). Neoplastic prostate tissue has been demonstrated to have higher concentrations of guanine, adenine, cytosine, uracil, O−P−O, beta-sheet proteins, lipids, porphyrins, and lower levels of tryptophan, tyrosine, α-helix proteins, phenylalanine, and water compared to benign tissue (Crow *et al.*, 2003). In malignant lung tumor tissue, Raman spectroscopy has identified higher levels of nucleic acid, tryptophan and phenylalanine and lower levels of phospholipids, proline, and valine compared to normal tissue (Huang *et al.*, 2003). Raman spectroscopic studies on skin have looked at chemical enhancing agents for the percutaneous absorption of drugs (Williams *et al.*, 2006), the effect of UV-radiation protective agents in sunscreens for skin (Schallreuter and Wood, 2001) and the effect of aging on the water and protein structures in skin (Williams, Edwards and Barry, 1995).

24.5.2.2 **Muscular Tissue**

Raman spectroscopy has been applied to the study of contraction-induced conformational changes in muscle fibers and proteins of the skeletal muscles. Studies on the effect of Ca^{2+}, Mg^{2+}, and ATP on the contraction of muscle fibers showed that the contraction is characterized by a decrease in the intensity of Raman bands of protein side chains and an increase in the intensity of amide I and C−C stretch bonds (Caillé, Pigeon-Gosselin and Pézolet, 1983). A recent Raman spectroscopic study monitored changes in the relative levels of NADH and NAD in the bicep muscles of mice under oxidative stress (Sriramoju *et al.*, 2008). This approach could be useful in the study of age- and stress-induced changes in muscles and disorders such as muscular dystrophy and ischemia. Raman spectroscopy has been used to identify and classify different layers of tissue in bladder pathology and bronchial studies. Studies on bladder walls showed that the spectra of urothelium (lipids), lamina propria (collagen), and smooth muscle layer (myosin and actin) are easily distinguishable (de Jong *et al.*, 2002). Raman spectroscopy of bronchial tissue distinguishes between fibrocollagenous stroma tissue and smooth muscle, and could be used to diagnose histological changes in the lung tissue due to lung cancer (Koljenovic *et al.*, 2004).

24.5.2.3 **Nervous Tissue**

Raman spectroscopy has been used to study the human brain and some of the associated tumors. In normal brain tissue, the spectra of white matter show a greater contribution from lipids, proteins, and cholesterol, whereas the spectra of gray matter exhibit a large contribution from water (Mahadevan-Jansen and Richards-Kortum, 1996). In general, both gray and white matter spectra exhibit peaks from proteins and lipids (Mizuno *et al.*, 1994). Intracranial tumors such as meningeoma, glioma, and schwannoma, which originate from the meninges, glial cells, and Schwann cells, respectively, have been studied (Krafft *et al.*, 2005). Lipid concentration and composition in the brain have been observed to change indicative of brain tumors. Calcification of tissue has also been reported in the case of brain tumors (Mizuno *et al.*, 1994). A Raman map from a human brain tumor section is shown in Figure 24.9 (Krafft, 2004). Raman spectroscopy has been proposed as a water concentration monitoring tool for brain edema in addition to the intracranial pressure measurements using MRI and CT scans (Wolthuis *et al.*, 2001). Because protein misfolding underlies the pathology of several neurodegenerative conditions, Raman microscopy has been used to characterize the biochemistry of transmissible spongiform encephalopathies (Carmona *et al.*, 2004) and Alzheimer's disease (Sudworth *et al.*, 2006).

24.5.2.4 **Connective Tissue**

Raman spectroscopy has the ability not only to characterize tissue but also to offer quantitative information about tissue components. Quantitative measurements on analytes in blood serum (Rohleder, Kiefer and Petrich, 2004) and whole blood (Enejder *et al.*, 2002) have been made. Raman spectroscopy has also been used to identify microbial pathogens (Maquelin *et al.*, 2003) in blood. Further, it can accurately quantify the relative amounts of cholesterol, calcium salts, triglycerides, and phospholipids in homogenized arterial tissue (Brennan *et al.*, 1997) and hence, can be used to identify atherosclerotic plaque (van de Poll *et al.*, 2002).

Raman spectroscopy has the advantage of being sensitive to both the mineral and the organic components of mineralized tissue and is applicable to wet, thick solid specimens of bone. Raman spectroscopy has been used to study the composition (Penel *et al.*, 2005), chemical changes accompanying mechanical deformation (Morris *et al.*, 2004), aging (Freeman *et al.*, 2001; Ager *et al.*, 2005), and disorders (McCreadie *et al.*, 2006) of bone tissue and to characterize interactions between prosthetic implants and bone tissue (Bertoluzza *et al.*, 1994; Dippel *et al.*, 1998). Raman spectroscopy has also been used to study cartilage and its associated disorders (McCreadie *et al.*, 2006). Dental enamel has a similar composition as that of bone mineral. Polarized Raman spectroscopic studies have been performed to study the orientation of crystallites in dental enamel (Tsuda and Arends, 1994) and in dental caries (Ko *et al.*, 2006). Noninvasive Raman spectroscopy and imaging of biological specimens is a nascent, rapidly advancing field. Transcutaneous measurements on cadaveric and *ex vivo* bone specimens using spatially separated optical fibers were first reported in 2006 (Schulmerich *et al.*, 2006). In these measurements, depths of 3–4 mm below the skin were reached. Recently, diffusive Raman tomography has been demonstrated on canine bone tissue, also showing that Raman tomography can be integrated with CT and MRI (see Figure 24.10) (Schulmerich *et al.*, 2008).

24.5.3
Microorganisms

Raman spectroscopy has been developed as a simple and rapid identification and characterization tool for pathology. Single bacteria (Rösch *et al.*, 2005), yeast, (Rösch *et al.*, 2005) and cellular components of single spores (Esposito *et al.*, 2003) have been studied. Raman spectroscopy has been able to detect trace levels of microorganisms in the presence

of complex environmental backgrounds when used in combination with fluorescence spectroscopy and digital imaging (Kalasinsky *et al.*, 2007). The spatial distribution of different molecular species inside a living yeast cell has been probed (see Figure 24.11) (Huang *et al.*, 2005). In another interesting study, gram levels of anthrax spores in envelopes were detected on a mail sorting system using Raman spectroscopy (Farquharson *et al.*, 2004). Building Raman spectral reference libraries of all microorganisms of interest has great potential in the study

of surface contaminants, bioaerosols, water-borne, and food-borne pathogens.

Glossary

Epi-Fluorescence: A microscopy technique in which the same objective is used for the illumination of a specimen and collection of the excited fluorescence.

Exciton: A bound state of an excited electron and a hole in the lattice of a semiconductor or insulator. Excitons can move around the crystal lattice of the material in which it is formed.

Holographic Filter: An optical filter in which a three-dimensional diffraction pattern is formed in a photosensitive material. Depending on the pattern, the holographic filter can function as a wavelength sensitive mirror (also called a *notch filter*), diffraction grating or other type of filter.

Phonon: A vibrational mode of a crystal lattice.

Surface Plasmon: A surface electromagnetic wave that propagates parallel to the surface of a metal. Surface plasmons are excited at wavelengths that depend on the metal and the three-dimensional surface structure. Silver plasmons can be excited with visible radiation. Gold and copper plasmons can be excited with deep red and near-infrared radiation.

Tomography: A three-dimensional imaging technique in which the image is constructed from a series of sections obtained at different points in a solid material.

INTRODUCTION

An important advance in seismology during the past two decades has been the expansion and improvement of techniques for determining the attributes of an earthquake source from the information contained in the wave forms of the ground motion generated by that event. It is generally accepted that an earthquake is caused by the sudden slip of rocks along a geologic fault (see the original article). This mechanism can be characterized by a number of parameters: the orientation of the fault in space (dip and strike, which may vary along the fault); the geometry and dimensions of the rupture surface (length, width, area); the distribution of the slip vector specifying the motion of the rocks on one side of the fault relative to the other side (magnitude and direction, which may vary with position on the fault); the point of initiation of the rupture and the speed and direction of the subsequent rupture propagation; the orientation of the stresses driving the rupture; and some measure of the energy released.

With few exceptions, the volumes within which earthquakes occur are too deep within the Earth to be accessible to direct examination and instrumentation. The enhanced ability to derive the source parameters from seismograms has led to major advances in understanding the physics of the earthquake process and the relation of this physics to observable geological features, material properties, and Earth dynamics (Scholz, 1990). A succinct statement of the current status of source analysis from seismograms is offered by Tanioka and Ruff (1997).

In the original article, the classical method of determining basic characteristics of the focal mechanism (strike and dip of two planes, one of which is the fault; the direction of the slip vector on each of these planes; and the directions of the corresponding principal axes) is explained. The original method, still widely used, is an interpretation of the pattern of polarities of the first motion of the longitudinal (P) waves as recorded at a distribution of seismograph stations. This analysis assumes pure tangential slip on a planar surface (the fault–slip model of earthquakes) and gives the initial focal mechanism in cases where fault geometry changes during rupture. This method was supplemented by including the polarizations of the shear (S) waves (Stauder, 1960), which helped to settle an old debate about the correct body-force representation of an earthquake source.

In this era of broad-band, high–dynamic-range instrumentation (see SEISMOGRAPHS) the records of ground motion contain much more information than the arrival time and direction of vibration at the onset of the fundamental wave types. At the same time, the theory of seismic wave generation has advanced suffi-

ciently that much of this information can be extracted and analyzed in terms of the properties of the source.

A parameter that combines important properties of a simple point shear source is the *seismic moment*, the moment of one of a pair of equal but opposite orthogonal couples, i.e. there is zero net force couple (the *double couple source*; see the original article). In terms that relate this representation to the equivalent discontinuity in tangential displacement across a surface (shear dislocation), the seismic moment is given by $M_0 = \mu A D$, where μ is the shear modulus of the material in which the slip occurs. A is the area of the rupture surface, and D is the average displacement discontinuity across this surface. The seismic moment, expressed in newton-meters, is a useful way of stating the strength of an earthquake in terms of well-defined properties of the source. The introduction of the seismic moment as a measure of earthquake strength (Aki, 1966) was one step toward to utilization of a more complete description of the source, the *moment tensor*.

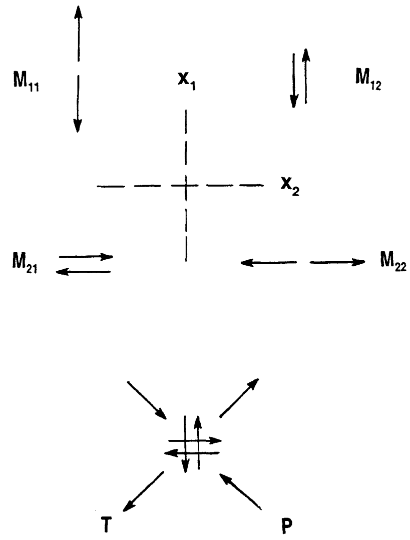

FIG. 1. (Top) Representative elements of the moment tensor, shown for the 1–2 plane only; X_3 is positive into the page. The tensor is symmetric, e.g., $M_{12} = M_{21}$, and so there is no net rotation about any axis; and the trace is usually assumed to be zero, so that there is no net volume change. (Bottom) The double couple equivalent to slip on a fault plane. If the fault plane is either the 1–3 plane or the 2–3 plane, the couples lie in the 1–2 plane. The eigenvectors of this tensor are the P and T axes of the focal-mechanism solution, the combination of dipoles without moment that generate the same movement of the surrounding medium.

1. THE SEISMIC MOMENT TENSOR

1.1 Body Force—Dislocation Equivalence

Much of the recent progress in source representation developed from papers published in the late 1950s and the 1960s (Honda, 1957; Kasahara, 1957, 1958; Steketee, 1958; Knopoff and Gilbert, 1960; Maruyama, 1963; Burridge and Knopoff, 1964). These contributions grew out of a classic work by Nakano (1923) on the forces giving rise to earthquake motion. One of the chief contributions of this era was understanding of the equivalence, for wave generation and the final static displacement and strain fields, of a jump in displacement across a surface in an elastic continuum (elastic dislocation theory; Love, 1944, pp. 221–228), and an appropriate distribution of body forces acting at the same point.

The double-couple model of fault slip is based on simplifying assumptions and represents the source as a pair of equal but opposite orthogonal couples about an axis, with no net moment. The general seismic source can be represented by body forces as a combination of double couples about three orthogonal axes (M_{ij} about the k axis) and dipoles without moment along these three axes, M_{kk}, Fig. 1 (Steketee, 1958; Aki and Richards, 1980, Chaps. 3 and 4). We further require that there is no net rotation produced at the source, so that $M_{ij} = M_{ji}$, and we usually assume no net volume change, so that $\sum M_{kk} = 0$. Debate continues as to whether there may be volume changes associated with the sources, in particular for deep (subcrustal) earthquakes.

The set of orthogonal axes may be chosen conveniently as either the set naturally associated with the fault (the normal **n** to the fault, the unit slip vector **d**, and the vector orthogonal to these), or geographic coordinates (vertical, north-south, east-west, the axes with respect to which three components of ground motion are usually measured at standard seismograph stations). The six elementary source elements are taken as the components of a symmetric tensor **M**, the *seismic moment* *tensor*. For a simple double-couple source, $\mathbf{M} = M_0(\mathbf{nd} + \mathbf{dn})$. The interchangeability of **n** and **d** in this expression shows that there are two orthogonal planes that are equivalent seismic sources, hence the inherent ambiguity of focal-mechanism solutions (see the original article).

In an arbitrary orthogonal coordinate system $\mathbf{e}_k$, $k = 1, 2, 3$, we have $\mathbf{M} = \sum\sum M_{ij}\mathbf{e}_i\mathbf{e}_j$, symmetric with zero trace. Because the moment tensor is symmetric, it can always be diagonalized, with orthogonal eigenvectors and real eigenvalues. Thus, the general source can always be represented by three orthogonal force dipoles. The directions of these dipoles give the orientations of the principal axes corresponding to the moment tensor, the so-called T (tension, minimum compression), P (pressure, maximum compression), and B (intermediate) axes. These axes can be related to the orientation of the stress field that produced the fracture by application of the theory of fracture appropriate for the medium, usually assumed in seismology to be brittle fracture, with slip governed by Coulomb friction (e.g., Jaeger, 1956, Chap. 22; also see Scholz, 1990).

1.2 Moment-Tensor Representations of Basic Fault Types

A pure double couple will be equivalent to two of these eigenvalues being equal in magnitude and opposite in sign, with the third one zero. The directions of the two dipoles (T and P axes) are at 45° to the forces forming the two couples (Fig. 1), or, equivalently, to the two planes, one of which is the fault plane. The intermediate axis (B axis) always lies in the fault plane. For a pure double-couple source in the p-q plane, $\mathbf{M} = M_{pq}\mathbf{e}_p\mathbf{e}_q - M_{pq}\mathbf{e}_q\mathbf{e}_p$ $(p \neq q)$. The seismic moment is M_{pq}. For real earthquake data, the eigenvalue with the smallest absolute value is usually much smaller than the other two, which are almost equal in magnitude (i.e., the double couple is often a good model), and the seismic moment is taken as the average of the absolute values of the larger two. Once the eigenvectors of the moment tensor are calculated, the strike, dip, and slip directions of the planes corresponding to the best double couple from the data are found by simple geometric relations (Aki and Richards, 1980, pp. 117–118).

The general moment tensor may be decomposed in a number of ways into tensors that can be interpreted in terms of the physical properties of the source (Lay and Wallace, 1995, Chap. 8). The moment tensor for faults of given orientation and mode of slipping may be calculated from the relations given in Aki and Richards (1980, p. 117). Thus, for a vertical, strike-slip fault, oriented north-south (dip = 90°, strike = 0°, slip direction = 0°)

$$\mathbf{M} = M_0 \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}$$

while for a reverse north-south striking fault (dip = 45°, strike = 0°, slip direction = 90°)

$$\mathbf{M} = M_0 \begin{bmatrix} 0 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

2. DERIVING THE MOMENT TENSOR FROM SEISMOGRAMS

2.1 Ground Motion in Terms of Moment-Tensor Components

The components of the moment tensor are derived from the recorded ground motion by treating the seismogram as the convolution of that tensor (assumes that all tensor components have the same time history) with linear filters that represent the action at the source (source spectrum, radiation pattern), the effects of propagation through the Earth to the station for the particular wave type, and the response characteristics of the seismograph (see SEISMOGRAPHS). In modern practice, the instruments are well calibrated, and so the third filter is known. The general structure of the Earth and the relevant material properties (elastic and inelastic) are adequately determined to permit the calculation of a satisfactory representation of the propagation effects. Thus, the radiation pattern for each wave type is known, and the propagation and instrumentation effects can be accounted for, leaving the source time function and the moment-tensor components to be recovered by inversion of the signal corrected for instrument response (Langston, 1981). If the source can be treated as a point (the wavelengths involved are sufficiently longer than the source dimensions), the displacement components (instrumental effects removed) are given by the convolution (Aki and Richards, 1980, p. 53)

$$u_n(\mathbf{x}, t) = \sum\sum M_{pq} G_{np,q}(\mathbf{x}, \mathrm{t}; \xi, \tau) \qquad (1)$$

where u_n is the n component of the displacement at position $\mathbf{x}$ and time t, and the second factor is the derivative with respect to ξ_q of G_{np}, the Green's function for the system, i.e., the n component of the displacement at $(\mathbf{x},t)$ due to a unit impulse in the p direction applied at position ξ at time τ. The Green's function is calculated from the known structure and material properties in the Earth along the propagation path. In studies on local or regional scales, empirical Green's functions, the recorded wave forms generated by earthquakes small enough to be taken as delta functions in space and time, are often used.

2.2 Inversion of Ground Motion for the Moment Tensor

Equation (1) may be used to calculate synthetic seismograms corresponding to a selected Earth model. Conversely, with u_n known from the seismograms and the Green's function calculated from known Earth structure, or through use of the empirical Green's functions, Eq. (1) can be inverted to yield the moment-tensor components. The seminal paper from which many contemporary computational schemes for this purpose have been developed is Dziewonski *et al.* (1981). The Harvard *Centroid Moment Tensor* analysis was developed directly from this paper and has produced source characteristics of many thousands of earthquakes as products of a routine procedure.

The general approach to inversion for source properties is to vary the source characteristics (moment-tensor components and source depth) systematically to obtain the best fit between calculated and observed portions of the wave train at a number of seismograph stations. Many computational schemes have been developed to implement the inversion process. Some algorithms use only the *P*-wave portion of the seismograms; others use the entire body-wave train up to the arrival of surface waves; still others incorporate surface waves as well.

The moment-tensor solutions for many earthquakes strong enough to produce good seismograms at a number of stations are now calculated routinely in almost-real time and are included as part of the information included in some earthquake bulletins and catalogs. Several centers offer world-wide distribution of their solutions by e-mail within hours of an event. Summaries of the methods used in their centers, with useful lists of references, are offered by Sipkin (1986, 1994) of the U.S. Geological Survey, and Kawakatsu (1995) of the Earthquake Research Institute, Tokyo.

3. COMPLEX SOURCES

The discussion of source analysis to here has been on the simplifying assumption of a point source of seismic energy release. It is obvious from observed fault lengths of a few kilometers for moderate earthquakes to hundreds of kilometers for great earthquakes, and from examination of the often complex early portion of seismograms, that, except for the very smallest, earthquakes are not well approximated by point sources. The slip is distributed, often in a patchy fashion, over a surface, and the source time function, essentially the rate function of the seismic moment release (Tanioka and Ruff, 1997), may be quite complicated. The complexity may be due to variations in fault strength and/or stresses along the rupture surface that lead to pauses and acceleration in the slip process.

Kikuchi and Kanamori (1982) and Kikuchi and Fukao (1985) describe in detail an analysis of the source time function and spatial distribution of moment release associated with complex body waves often observed from strong earthquakes. They show that the far-field source time function is the convolution of the velocity of the relative slip across the dislocation surface and the rate of change of the rupture area:

$$S(t) = \mu \int_0^\infty \dot{D}(t - t')\dot{A}(t')\,dt' \qquad (2)$$

where $S(t)$ is the far-field source time function, $D(\xi, t)$ is the relative displacement across the dislocation surface, $t'(\xi)$ is the arrival time of the rupture front at a point ξ of the surface, $A(t)$ is the area of the dislocation at time t, and the dot represents time differentiation. The integrand $\mu\dot{D}\,dA$ is the moment rate at the grid point. The fault is modeled by assigning a seismic moment value to point double couples distributed on a grid covering the fault surface. All of these point sources are assumed to have the same focal mechanism and time history. The sum of the moments at the grid points is the total seismic moment M_0 of the event. The orientation of the fault is taken from moment-tensor analysis. The dimensions of the fault may be taken form the aftershock distribution if there is no urgency about getting the result, or may be taken as big enough to accommodate a very large earthquake (Mendoza, 1996), so that the result will yield zero moment release over large areas of this assumed fault if it is bigger than the actual fault. The moments at the point sources are determined iteratively by application of the appropriate form of Eq. (1) together with least-squares adjustment. An example showing the moment release distribution on the fault, the source time function, and the focal mechanism corresponding to the best double couple is shown in Fig. 2.

A method based on the work of Hartzell and Helmberger (1983) for rapid inversion of P waves to derive the rupture history for large earthquakes is outlined in Mendoza (1996). An example of the slip distribution for a large earthquake is shown in Fig. 3. The displacements at each station are computed as described above, and the amount of slip at each grid point is varied to give the best fit of the calculated wave forms. The process may then be repeated with a new rupture velocity to search for the velocity that produces the smallest total difference between the observed and calculated wave forms. Hartzell and Heaton (1983) reached the encouraging conclusion that the inversion results using teleseismic data alone and combining teleseismic and local strong-motion data are very similar.

4. THE STRESS FIELD DRIVING THE RUPTURE

A prime purpose of seismic source studies is the acquisition of information about the regional or local stress field that drives the fault slip. This information provides the link between dynamic geological processes and the occurrence of earthquakes. As indicated previously, the eigenvectors of the moment tensor give the directions of the principal axes corresponding to moment tensor that describes the rupture. These directions can be related by fracture theory to the true ambient stress orientation only for fracture in an infinite medium that is intact, homogeneous, and isotropic with regard to strength, with known coefficient of Coulomb friction on the fracture surface, or for slip on a pre-existing fault for which the orientation of the fault plane and the ambient stress field have not changed since the fault was formed. In the real case, surfaces of weakness exist often within rock masses, mostly due to previous fractures, and the great majority of earthquakes occur on pre-existing faults. Planes of weakness may also be the result of the processes by which the rocks were emplaced. A new fault in homogeneous material will have the expected orientation with respect to the ambient stress field at the time of the initial fracture. Because of dynamic tectonic processes, the orientation of the stress field and/or the fault surface may change with time, so that later slip on that fault may not have a simple relation to the contemporary stress field.

Failure will occur preferentially along pre-existing surfaces of weakness. The focal-mechanism solution of subsequent earthquakes will reveal the mode of faulting (strike-slip, normal, reverse, or some combination) and the quadrant within which the axes of maximum and minimum compression lie. Gephardt and Forsyth (1984) developed a technique for searching for the most probable orientation of the axes of the ambient tectonic stress field in a region in which a large number of focal mechanisms of earthquakes have been determined.

In addition to the contemporary state of tectonic stresses in a region, the evolution of this stress state and the current rate of stress changes are of fundamental importance. Deng and Sykes (1997) have calculated the alteration of the stress field in southern California due to the occurrence of 36 earthquakes since the early 19th century and have related the post-seismic static stress patterns to the occurrence of subsequent moderate to micro earthquakes. The stress patterns of old, strong earthquakes

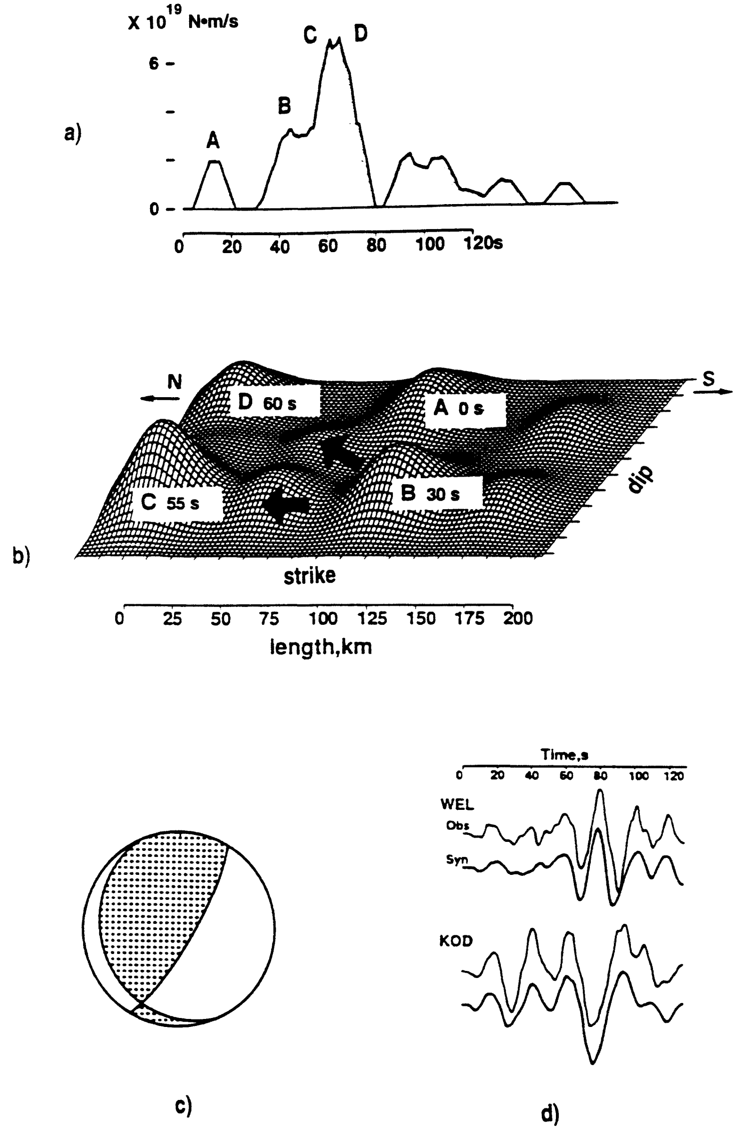

FIG. 2. Moment release in time and space for the great Tokachi-oki, Japan, earthquake of 16 May 1968. The moment magnitude was $M_w = 8.2$; total moment release as calculated by Kikuchi and Fukao (1987), 2.3×10^{21} N · m. (a) The source-time function (moment release rate) of this complex event. (b) The pattern of moment release over the fault plane. The largest subevents occurred 50 to 60 s after the origin time, and the moment release was essentially complete after 70 s. The fault plane strikes to the southeast at about 150°, and dips to the southwest at about 20°, as selected by those authors from the best double-couple solution, shown in (c). (d) Examples of the agreement between the observed wave forms and those synthesized from the final moment-tensor solution for two representative seismograph stations: Wellington, New Zealand, and Kodaikanal, India. persist, and the evidence suggests that they have a major influence on the locations of later events. Gross and Kisslinger (1997) have suggested a technique based on theory by Dieterich (1994) for estimating the state and rate of tectonic stresses from the temporal and spatial behavior of aftershocks of strong earthquakes. Both of these recent studies produced results

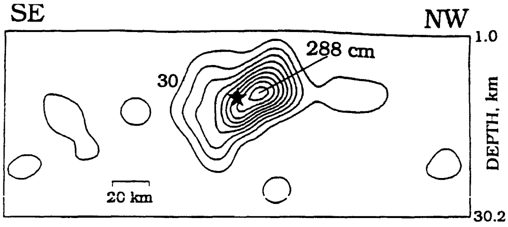

FIG. 3. The distribution of slip across the large assumed fault surface for the Guerrero, Mexico, earthquake of 14 September 1995, surface-wave magnitude 7.2, as calculated by Mendoza (1996) using his rapid finite-fault inversion procedure. The line of sight is perpendicular to the fault plane from above. Slip greater than 30 cm is contoured at 30-cm intervals. The star marks the hypocenter.

that can be compared with tectonic stress rates estimated from geodetic observations. Much research remains to be done in this emerging area of seismology.

In this Addendum, methods for recovering information about the kinematic properties of the earthquake source have been examined. The difficult problem of the dynamics of earthquake source processes is a subject of active investigation. While progress is being made, there are still major uncertainties about almost every aspect of this problem, including such fundamental questions as the appropriate constitutive relation for the fault plane. The energy budget of an earthquake is known only qualitatively, and the distribution of released elastic strain energy among processes like creation of new fracture surfaces, frictional heating of fault surfaces, and generation of propagating waves is still to be determined on a rigorous, quantitative basis.

GLOSSARY

Double-Couple Source: Body-force representation of shearing slip on a surface, consisting of two orthogonal force couples about an axis. The two couples have equal moments but opposite senses of rotation, so that the net moment is zero. This source is equivalent to two orthogonal dipoles without moment in the plane of the two couples, oriented at 45° to the forces constituting the couples, one dipole directed outward from the origin, the other inward.

Geologic Fault: Surface separating two blocks of rock, along which there has been tangential relative motion of the blocks.

Seismic Moment: A measure of earthquake strength, proportional to the area over which slip has occurred and the mean slip across that area.

Seismic Moment Tensor: A tensor, the components of which are the elementary dipoles (three without moment, six with moment) that together represent the general seismic source. The tensor is symmetric and usually assumed to have zero trace.

Source Time Function: The function expressing the rate of seismic moment release.

INTRODUCTION

In 1809, the Russian physicist Reuss performed the first recorded experiment of what would come to be known as electrophoresis (Reuss, 1809). Electrophoresis is defined as the migration, or movement, of electrically charged particles or dissolved species (solutes) in a conductive liquid or gel under the influence of an applied electric field. Reuss observed the electrophoretic migration of colloidal clay particles at an anode placed in a glass tube containing a bottom layer of wet clay, a second layer of wet sand, and a top layer of water. At the cathode, constructed in a similar fashion and ionically connected to the anode by a glass tube filled with water, the water remained clear and increased in volume, demonstrating the principle of electroosmotic flow (EOF). Also known as electroendosmotic flow or electroendosmosis, EOF is defined as the transport of neutral molecules or particles by a conducting solution under the influence of an electric field.

Numerous other experiments advanced the science of electrophoresis. Quincke (1861) showed that the migration rate of particles in an electric field is a linear function of potential gradient, while Hardy (1899) demonstrated the principle of the isoelectric point, which is defined as the *p*H at which a zwitterionic solute has zero electrophoretic mobility in an electric field. It was Michaelis (1909) who actually coined the phrase "electrophoresis" to describe the migration of ionic species in electric fields, and determined the isoelectric points of some enzymes in a U-shaped electrophoresis cell by measurements of electrophoretic mobilities at various *p*H values. Tiselius (1937) performed free-solution electrophoresis for protein separations and was the first to show that serum is composed of albumin and α-, β-, and γ-globulins, for which he won the Nobel prize in 1948. In Tiselius's experiment, the arms of a U-tube cell were filled with a *p*H buffer and a small amount of the protein under study, and then connected to nonpolarizable electrodes. The motion of the protein–buffer boundaries

was observed under the influence of a known potential gradient using a schlieren optical detection method to observe the boundaries between proteins.

Despite some significant instrumental improvements in electrophoresis experiments conducted with U-tube cells or on rectangular-shaped gel slabs, electrophoresis techniques were cumbersome and time-consuming, and produced separations with somewhat poor resolution among the separated components. Dramatic improvements were on the horizon, beginning in 1967 with the construction of the first experimental capillary electrophoresis (CE) system by Hjerten (1967), who then used the instrument to achieve high-efficiency separations of proteins, nucleic acids, and inorganic ions. In CE, the glass tubes or gel slabs used previously to separate solutes based on their electrophoretic mobilities were replaced by narrow-bore capillaries as the separation device. In 1979, Mikkers *et al.* (1979) performed electrophoresis in 200-µm inside diameter (i.d.) capillaries, and Jorgenson and Lukacs began electrophoresis experiments in 75-µm i.d. glass capillaries that resulted in seminal papers (Jorgenson and Lukacs, 1981, 1983) that showed the full potential of the technique for high-resolution separations. An intense period of research and development on CE science, separation methods, and instrumentation ensued, culminating in the introduction of the first commercial instrument in 1988. The first international scientific symposium devoted to CE was held in 1989, and the field has experienced exponential growth to the present day.

Today, capillary electrophoresis is one of the fastest growing techniques in analytical chemistry. Approximately 1500 scientific papers are published each year on CE, covering not only advances in instrumentation and methodology, but also applications to important problems in a variety of scientific disciplines. Among the important applications of CE are high-resolution separations in life science [DNA, polymerase chain reaction (PCR) products, oligonucleotides, purines, proteins, polypeptides, amino acids, carbohydrates, catecholamines, vitamins, chiral isomers, pharmaceuticals], environmental science (polyaromatic hydrocarbons, pesticides, pollutants), analytical chemistry (polymers, inorganic and organic ions, organic acids and bases, dyes and their precursors) and forensic and anti-terrorist science (illicit drugs, gunshot residues, DNA, explosive residues). Clearly, it is not possible to do justice to all areas of such a large field in a short article such as this. Therefore, in the sections that follow, the emphasis is on the most important theoretical, chemical, and procedural aspects of capillary electrophoresis.

The outline of the remainder of the article is as follows. The first section is devoted to a description of basic concepts that apply to all embodiments of capillary electrophoresis. Next, the instrumentation section describes the five essential components of a CE instrument, also known as a capillary electropherograph: the sample introduction system, the capillary (where the separation of complex mixtures into individual components occurs), the buffer system, the high-voltage power supply, and the detector. In the section entitled "Modes of Separation", a discussion of separation principles (*i.e.*, the physical and chemical mechanisms for resolving a mixture into its individual components) is combined with a description of diverse applications from the current scientific literature to illustrate the usefulness and limitations of the different CE separation techniques.

1. BASIC CONCEPTS

1.1 Electrophoresis

The objective in an electrophoresis experiment is to move individual solutes in a mixture through a separation medium at different velocities so that they exit from the medium at different times or, alternatively, reach different locations on the medium at a given time. In one popular embodiment of conventional electrophoresis, the medium is a gel slab either in the form of a free-standing membrane or as a gel supported on a planar stationary support, *e.g.*, a rectangular glass plate. Typical gels used in this application are two-phase colloidal systems (paper, starch, cellulose acetate, agarose) in an aqueous solvent or polymeric materials such as polyacrylamide. The slab is immersed in a buffer solution in an electrophoresis chamber and an electrical potential is applied across the length of the gel to set up an electric field (*i.e.*, a gradient of electrical potential). At the end of the experiment, the individual components will have migrated to different points along the direction of the gradient by processes that are described in Sec. 3. The locations of the components on the slab can be determined by a number of methods, including staining (followed by optical detection), radiography (for radioactive or radioisotopically tagged solutes), or detection with immunoreagents. This electrophoresis method is slow, labor intensive, not amenable to full automation, and prone to relatively poor reproducibility. The last results from a number of factors, including difficult-to-control solute adsorption effects on the gel and thermal contributions to solute migration (due to poor dissipation of Joule heat) that vary across the slab and result in broadening of the zones of the separated components. Improvements in the separation of mixtures are achieved by two-dimensional techniques, where successive electrophoresis experiments are performed on the same gel slab in perpendicular directions *via* two different separation modes.

Despite the problems described above, gel slab electrophoresis is an extremely useful and versatile method that is widely used today, principally in the separation and identification of complex mixtures of biological macromolecules. However, these problems have been addressed by capillary electrophoresis, and dramatic improvements in separations have been achieved. CE grew out of a remarkable convergence of scientific and technological advances in analytical chemistry. The principal advance came in the recognition that performing electrophoretic separations in small i.d., open-tubular capillaries, such as those used in gas chromatography (GC; see CHROMATOGRAPHY), reduces the problems associated with adsorption on gel media and thermally induced convective dispersion (Mikkers *et al.*, 1979). Separations in small i.d. capillaries also increases the degree of interaction between solutes and the capillary surface, which we will see has a large effect on separation efficiency. Further, detectors developed for chromatography instrumentation (principally liquid chromatography, LC) could be adapted, with certain modifications, to automatic detection of components eluting from the electrophoresis capillary. With these advances, it became possible to develop extremely fast, high-resolution separations for small quantities of materials. Capillary electrophoresis complements chromatography because separation selectivities are based on different chemical and physical principles and because it provides high-resolution separations of materials that are not amenable to chromatographic separations (*e.g.*, some large biological macromolecules). In fact, one approach for certain difficult samples takes advantage of their complementary nature by coupling CE to LC in a serial fashion to get two-dimensional separations with resolutions that exceed the capabilities of either method alone.

CE has a number of dramatic advantages compared with LC. These include faster analyses, higher efficiencies (defined in Sec. 1.3), smaller sample size requirements ($\leq \approx 10\,\mathrm{nL}$ *versus* $\approx 10\,\mu\mathrm{L}$), greater mass sensitivity (attomole *versus* picomole), lower flow rates ($\approx 100\,\mathrm{nL\,min^{-1}}$ *versus* $\approx 1\,\mathrm{mL\,min^{-1}}$), which reduce reagent consumption, and fewer column inventory requirements (one CE capillary suits a variety of samples so that different columns for different sample types are not required as in LC). These are among the key factors that account for the increasing popularity of CE for separations in liquid media.

1.1.1 Electrophoretic Mobility Electromigration is defined as the movement of a charged species under the influence of an electric field. In electrophoresis, however, it is more generally used to describe the movement of all solutes, whether they be neutral or charged. In this article, the term migration is used for brevity. In the case of a charged solute, a major contributor to migration results from its electrophoretic mobility, μ_{EP}, defined as

$$\mu_{\mathrm{EP}} = q/6\pi\eta r, \tag{1}$$

where q is the solute's electrical charge, η is the viscosity of the medium through which the solute is migrating, and r is the solute radius. Electrophoretic mobility is essentially a measure of the velocity of a charged species in an electric field of unit strength, in units of $\mathrm{cm^2\,V^{-1}\,s^{-1}}$. The linear dependence of μ_{EP} on the charge/size ratio is exploited in many modes of CE separations. Further, η is a strong function of such experimental parameters as *p*H, temperature, and ionic strength (a quantity related to the sum of the products of concentration and squared charge for all the ionic species in solution, expressed in terms of concentration units, *e.g.*, molarity). This provides additional experimental control of μ_{EP} in capillary electrophoresis. The effect of some parameters can be predicted *a priori*, *e.g.*, the dependence of the electrophoretic mobility of a solute with a known acid dissociation constant (K_a) as a function of *p*H. In the case of a weak acid, for example, the equilibrium concentration of the charged (unprotonated) and neutral (protonated) forms of the solute as a function of *p*H will control its mobility.

1.1.2 Electroosmotic Flow As described earlier, electroosmotic flow (EOF) is the transport of neutral molecules by a conducting solution under the influence of an electric field. In capillary electrophoresis, EOF results directly from the physical and chemical properties of the materials and chemicals used in the experiment. In the most common CE configuration, a fused-silica capillary is used with an aqueous buffer at *p*H >3 (see Secs. 2.2 and 2.3). In this case, the surface of the capillary is composed of ionized silanoate groups ($\mathrm{SiO^-}$). In the buffer, the layer closest to the capillary wall contains specifically adsorbed (tightly held) buffer cations, while a second layer consists of nonspecifically adsorbed (loosely held), hydrated buffer cations. This arrangement is known as an electrical double layer, and the electrical potential difference across the shear plane between these layers is termed the zeta potential (ζ). Under the influence of an applied electric field, the loosely held cations migrate toward the negatively charged cathode and drag other buffer constituents (water, cations, anions, solutes) along with them. This is known as EOF, and it results in the transport of neutral molecules and cations in the direction of the cathode. In addition, even though anions have a migration component in the direction of the anode due to their electrophoretic mobilities, they too will be transported toward to the cathode if the electroosmotic mobility (defined below) is greater than their electrophoretic mobility. This is typically the case at alkaline *p*H for most solutes of interest.

The electroosmotic mobility μ_{EOF} is defined as

$$\mu_{\mathrm{EOF}} = \varepsilon\zeta/4\pi\eta, \qquad (2)$$

where ε is the dielectric constant of the buffer and ζ is the zeta potential. Electroosmotic mobility is essentially a measure of the velocity of a neutral species in an electric field of unit strength, in units of $\mathrm{cm^2\,V^{-1}\,s^{-1}}$.

There are CE applications where it is desirable to eliminate EOF or reverse its direction. Coating the capillary with a hydrophobic material that prevents access of the buffer to the surface silanoate groups would eliminate the electrical double layer described above that is a requirement for EOF. In this ideal case, there is no EOF, and only charged species in the capillary will migrate in the electric field, and they will do so according to their electrophoretic mobilities. The simplest way to reverse EOF is to reverse the polarity of the two electrodes; however, this does not reverse the relative directions of EOF and the electrophoretic mobility of a given solute. To accomplish this type of EOF reversal, a flow modifier such as cetyltrimethylammonium bromide (CTAB) or cetyltrimethylammonium chloride (CTAC) is added to the buffer at concentrations above a threshold required to effect flow reversal. These molecules attach to the silanoates on the capillary in a manner that creates a modified capillary surface with a net positive charge. The electrical double layer is then composed of anions and hydrated anions from the buffer, in contrast to the example described earlier, and EOF will be in the direction of the anode. In general, the magnitude of μ_{EOF} is dependent on experimental parameters such as *p*H, temperature, ionic strength, and viscosity. In special cases (*e.g.*, ampholytic flow modifiers, see Sec. 3.2), μ_{EOF} magnitude and EOF direction are both strong functions of *p*H.

1.1.3 Separation in Capillary Electrophoresis In a capillary electrophoresis separation, the net mobility of a solute being analyzed (an analyte) is the sum of its electrophoretic and electroosmotic mobilities. The velocity of the analyte (in $\mathrm{cm\,s^{-1}}$) through the capillary is simply the product of the mobility and the electric field strength. Therefore,

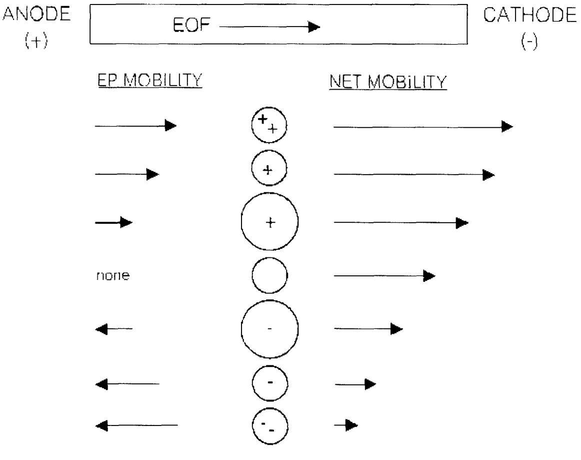

FIG. 1. Schematic representation of the electrophoretic migration of a mixture of anions (−), cations (+), and neutral molecules in capillary electrophoresis. The sizes of the molecules are represented by the sizes of the circles. The magnitude of the ionic charge is represented by the number of + and − symbols in the circles. In this example, the mixture was introduced at the anode end of the capillary and the direction of EOF is towards the cathode. The net mobility of a species is the sum of its electrophoretic and electroosmotic mobilities, and the magnitude and direction of each of these are indicated by the length and direction of the arrows, respectively.

the fastest separations can be performed with the highest field strengths. In practice, however, separations are performed at moderate field strengths to reduce Joule heating of the buffer, thereby preventing such undesirable consequences as vaporization of the buffer and thermal degradation of temperature-sensitive samples.

In the absence of specific analyte interactions with the capillary (*e.g.*, adsorption on silanoate groups), with materials added to the capillary (*e.g.*, a gel or a chromatographic stationary phase), or with a buffer modifier, a mixture of analytes will exit from the capillary (elute) at the cathode in the order of their net mobility. As an example, consider the electrophoretic separation of a mixture of anions and cations (of a variety of sizes and charges) and neutral molecules in an uncoated capillary. The analytes will elute at the cathode in the following order (see Fig. 1):

1. small, multiply charged cations;
2. small, singly charged cations;
3. large, singly charged cations;
4. neutral molecules (unresolved, *i.e.*, all elute at the same time);
5. large, singly charged anions;
6. small, singly charged anions;
7. small, multiply charged anions.

If the mixture being analyzed contains only anions, the direction of EOF can be reversed so that EOF and anion electrophoretic mobility are in the same direction. This causes the anions to migrate through the capillary more quickly and results in a faster separation. In this case, small, multiply charged anions would elute prior to large, singly charged anions.

In Sec. 3, a variety of CE separation modes that include special capillary and buffer arrangements (designed to promote specific analyte interactions with the capillary or the buffer modifier) are described. It will be seen that additional levels of selectivity in CE separations can be added to electrophoretic mobility and electroosmotic flow.

1.2 Resolution

The objective in a capillary electrophoresis experiment is to move individual analytes in a mixture through the capillary at different velocities so that they elute at different times. The analytes then move into an on-line detector that provides a real-time plot of detector response as a function of migration time. This plot is known as an electropherogram, and is a direct analog of the chromatogram (see CHROMATOGRAPHY).

The statistical treatment of electropherograms and that of chromatograms to determine important qualities of separations (efficiency, resolution, separation factor, and capacity factor) are fairly similar. The statistical methods for modes of CE that involve partitioning of the analyte between the aqueous phase and another phase (gel, micelle, chromatographic stationary phase, *etc.*) are strictly analogous to those used for chromato-

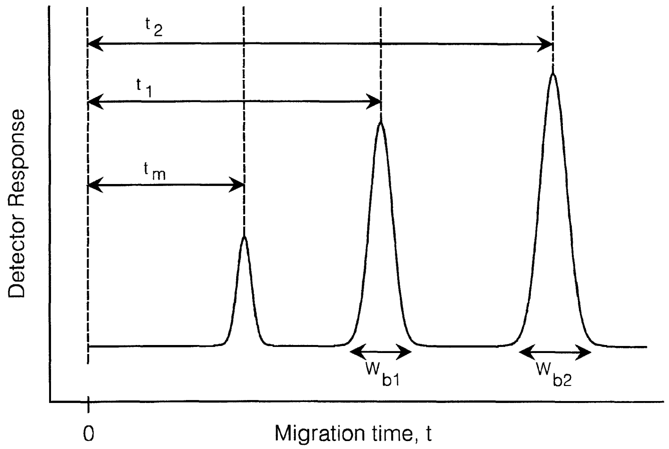

FIG. 2. Hypothetical electropherogram showing the response of a detector as a function of migration time t. The migration times for analyte 1, analyte 2, and a neutral marker are t_1, t_2, and t_m, respectively. Electrophoretic peak with is W_b.

graphic data (see CHROMATOGRAPHY), and are not included in this article. However, the treatment for modes of CE based on electrophoretic and electroosmotic mobilities is briefly discussed here.

The hypothetical electropherogram shown in Fig. 2 displays the response of a detector as a function of migration time t. The sample (composed of analytes 1 and 2) is introduced into the capillary at time zero as a narrow zone. The molecules of analytes 1 and 2 migrate through the capillary and elute at their characteristic migration times t_1 and t_2. As a way to normalize the time axis of the electropherogram, the elution time t_m of a "neutral marker", a molecule that is transported only by EOF, is used. While the components in the sample are being separated and eluted, the once-narrow zones broaden. This is primarily the result of diffusion under the influence of both temperature and concentration gradients. As a result of this zone spreading, the components elute as Gaussian-like peaks rather than as sharp bands. The degree of spreading is indicated by the magnitude of the peak width W_b. A fundamental chromatographic parameter that encompasses migration time and band spreading is the number of theoretical plates N:

$$N = 16(t_l/W_{bl})^2. \tag{3}$$

In terms of electrophoretic variables, N is expressed as

$$N = (\mu_{\mathrm{EPl}} + \mu_{\mathrm{EOF}})V/2D_l, \tag{4}$$

where V is the applied electrical potential (commonly referred to as the applied voltage) and D_l is the diffusion coefficient of the analyte. Theoretical plates were first used to describe separation mechanisms in distillation processes, and were later adapted to chromatographic and electrophoretic separations. Briefly, a theoretical plate is an imaginary unit in the capillary wherein one complete mechanistic separation process step occurs. For example, in micellar electrokinetic capillary chromatography (MECC, Sec. 3.4), this would be a single equilibrium partitioning of the analyte between the micellar phase and the aqueous phase. In the entire column, there are N of these imaginary units. CE practitioners routinely calculate N values from electropherograms because it is a good indication of separation quality and the ability of a method to provide narrow peaks (high values of N being more desirable). This measure of CE efficiency is frequently normalized to the capillary length L to give the height equivalent of a theoretical plate,

$$H = L/N. \tag{5}$$

In the CZE of large biomolecules, wall adsorption can adversely affect separation efficiency, and models have been developed to predict its effects on plate height (Minarik *et al.*, 1995).

Other fundamental parameters are used as measures of the quality of a separation scheme. The separation factor α is a measure of the ability of a particular separation scheme to separate two components, and is defined in terms of electrophoretic variables as follows (Karger and Foret, 1993):

$$\alpha = \mu_{\mathrm{EP1}}/\mu_{\mathrm{EP2}}. \tag{6}$$

Therefore, the separation of two analytes depends on their relative electrophoretic mobilities. The extent of separation depends on the difference in migration times and the sharpness of the peaks, and is commonly described in terms of the resolution R:

$$R = 2(t_2 - t_1)/(W_{\mathrm{b1}} + W_{\mathrm{b2}}). \tag{7}$$

Narrow peaks with very different migration times are said to be separated with high resolution. A well-resolved peak arising from a pure substance is very desirable from both an analytical and a preparative viewpoint. The resolution can also be expressed in terms of electrophoretic variables (Jorgenson and Lukacs, 1983):

$$R = 0.177(\mu_{\mathrm{EP2}} - \mu_{\mathrm{EP1}})\{\mathrm{V}/[(\mu_{\mathrm{EP}} + \mu_{\mathrm{EOF}})\mathrm{D}]\}^{1/2}, \tag{8}$$

where μ_{EP} is the average electrophoretic mobility and D the average diffusion coefficient of the two analytes. It can be seen that resolution increases as $\mu_{\mathrm{EP}} + \mu_{\mathrm{EOF}}$ approaches zero, but this requires increasingly longer separation times. For example, if μ_{EP} equaled $-\mu_{\mathrm{EOF}}$, resolution would be infinite; however, the solutes would be moving at equal but opposite velocity to the EOF and therefore would never elute. Therefore, a compromise between resolution and analysis time is usually required.

CE separations are typically faster and more efficient than LC separations. This advantage arises in great part from the characteristics of EOF and the fast migration times. Capillary EOF is characterized by a flat flow profile across the cross-sectional diameter of the capillary, with smaller flow rates at locations only in extremely close proximity to the capillary wall. This flat flow profile results in a narrow electrophoretic zone for a given solute, and gives narrow, well-resolved peaks. In contrast, pumped flow in LC is characterized by the parabolic profile of laminar flow, with the flow velocity at the column walls much smaller than the flow at the center of the column. This results in a broadening of the chromatographic zone for a given solute, and gives rise to broader peaks with lower resolution compared with CE.

CE separations with $N = 400\,000$–$2\,700\,000$ have been reported on 80–100-cm-long capillaries for separations that require only a few minutes. This is approximately 100 times better than the efficiencies of LC separations (as defined by the number of theoretical plates, N), which typically take about 10 times as long. For comparison, CE efficiencies are also approximately 2–10 times better than that of capillary GC separations. CE has the advantage that, with minimized injection and detection volumes and properly dissipated Joule heat, the largest contributor to band broadening is longitudinal diffusion of the analyte. The effects of longitudinal diffusion are reduced by keeping analysis times short.

A fundamental knowledge of the physical and chemical processes occurring in the capillary is critical to the successful design and implementation of a separation. The experimental variables that control N, α, and R are different for the various modes of CE, and are discussed in Sec. 3.

1.3 Qualitative and Quantitative Analysis

Qualitative analysis is the identification of a component responsible for a peak in the electropherogram. It is not possible to predict migration times exactly on the basis solely of the characteristics of the sample and the CE separation scheme. Several empirical expressions have been developed to calculate effective mobilities better on the basis of operational parameters. One such expression allows the effective mobilities of singly and multiply charged ions to be predicted over a wide range of buffer ionic strength (Friedl *et al.*, 1995). However, from an operational standpoint, the ability to predict migration times is generally not required. Correct peak assignments for an unknown analyte can be made by comparison with a literature electropherogram run under identical conditions, but this is not a very reliable approach. More reliable peak assignments are made by comparison with an electropherogram from injection of a known standard, by the use of an internal standard, or by identification using an on-line or off-line analytical method. Identification of unknown materials can sometimes be done on line with detectors based on ultraviolet–visible absorbance, fluorescence, mass spectroscopy, or electrochemistry (Sec. 2.5). Alternatively, it can be done by collection of effluent fractions (corresponding to individual components) followed by off-line spectroscopic, chemical, or biochemical analysis.

Quantitative analysis of analyte concentration is usually based on measurement of the height or area of the electrophoretic peak and comparison with peaks resulting from CE of a known standard. Modern CE instrumentation has data-acquisition and -processing equipment (*e.g.*, computers with integration and calibration software) for this purpose. However, CE peak areas are a function not only of analyte concentration, but also of analyte migration time. Since the analyte zone velocity in CE is a function of both μ_{EP} and μ_{EOF}, the separated components do not all migrate to the detector at the same velocity. The peak areas for two components of equal concentration and detector response will therefore not be equal, as the later eluting component travels more slowly through the detector. In contrast, for high-performance liquid chromatography (HPLC) the later eluting peak would be shorter and broader, but the two peak areas would be the same (see CHROMATOGRAPHY). This velocity effect in CE must be factored into the calibration calculations if the goal is the determination of analyte concentrations based on peak areas. High accuracy and precision in quantitative analysis by CE requires precise control of many factors, including EOF, capillary surface chemistry, temperature, buffer composition (*p*H, ionic strength, concentration of modifiers), and sample introduction volumes.

2. INSTRUMENTATION

Modern CE instrumentation (see schematic diagram in Fig. 3) has reached a very sophisticated state of development. It is highly automated, with computer control of the sample introduction, separation, and detection parameters and of the data acquisition and analysis. Special software for issues specific to CE separations, such as shifting migration times, correction of peak areas for analyte velocities, and estimation of analyte isoelectric points and molecular weights is also commercially available. At present, there are more than ten suppliers of capillary electropherographs in the U.S.

2.1 Sample Introduction

There are several sample introduction methods commonly used in capillary electrophoresis. The specific method used depends upon parameters such as separation mode and sample matrix. In each method, however, the inlet end of the capillary is physically moved from the buffer inlet vial to a sample vial for sample introduction, then returned to the inlet vial for electrophoresis. The length of the sample plug is usually more important than the actual volume, and only picoliters or nanoliters of sample solution are actually injected or consumed. Such a small volume requires care in handing, and it is typically contained in microliter or milliliter sample vials. The sample is often dissolved in the same buffer solution used during CE separation (Sec. 2.3). The sample concentration should be significantly lower than the buffer concentration, since concentrated samples may distort the electric field within the capillary, reducing separation efficiency and resolution. Sample introduction methods can be divided into three types: hydrodynamic, electrokinetic, and sample concentration.

Hydrodynamic sample introduction methods use flow generated by pressure, vacuum, or gravity to transport the sample solution into the capillary. In all cases, important factors for reproducible injections include buffer viscosity, sample viscosity, capillary radius, capillary length, and injection time. Sample temperature is also important because it affects buffer and sample viscosities. When these factors are reproducibly controlled, the volume of sample introduced is reproducible even if solution composition or *p*H is not well controlled.

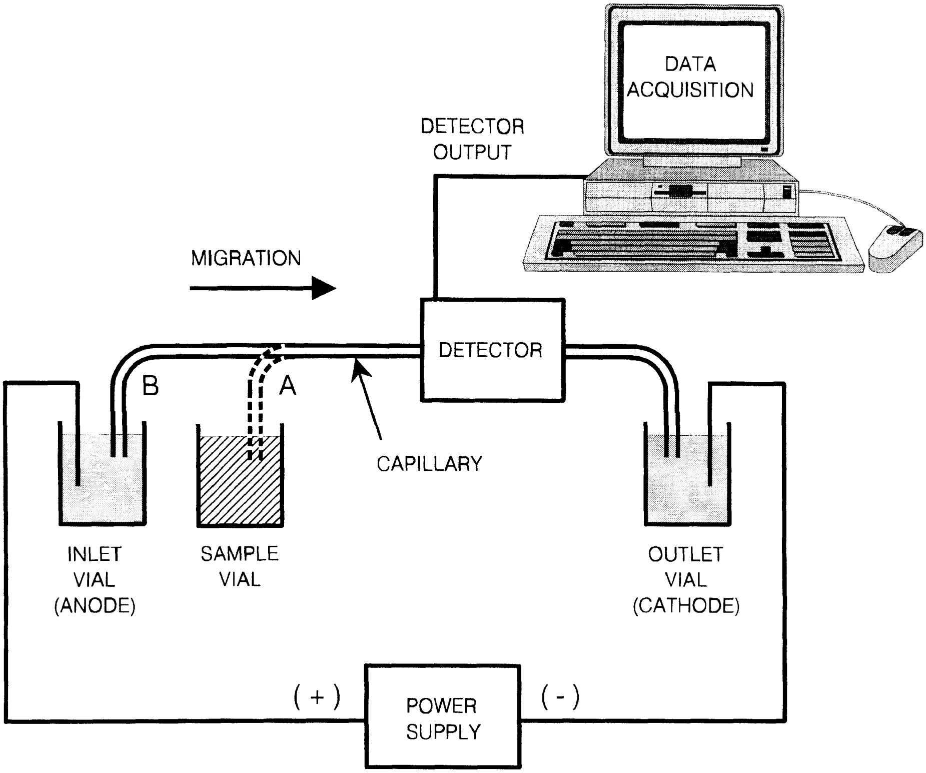

FIG. 3. Schematic diagram of capillary electrophoresis instrument, also known as a capillary electropherograph. During sample introduction (A), the capillary is immersed in the sample vial. During electrophoresis (B), the capillary is immersed in the inlet vial. This schematic diagram shows the use of an on-column detector (see Sec. 2.5).

Hydrodynamic methods require more instrumentation than electrokinetic methods and do not work well with packed capillaries (*e.g.*, capillary gel electrophoresis, CGE), yet have the advantages that sampling bias is not created and matrix effects are minimal. For aqueous sample solutions, the sample plug volume or length can be easily calculated from the experimental parameters. Pressure-based hydrodynamic injection requires that pressure be applied to the sample vial or, alternatively, a vacuum applied at the detector side of the capillary. Pressure leaks affect reproducibility, and the time period that pressure is applied must be carefully controlled. This type of sample introduction works particularly well with capillary isoelectric focusing (CIEF, Sec. 3.2), since the entire capillary can be filled in a short time. Gravity-based hydrodynamic injection, also known as siphoning injection, is performed by inserting the inlet end of the capillary into the sample vial and then raising this vial above the capillary outlet vial. The height and time required are on the order of millimeters and seconds, both of which must be carefully controlled, yet this type of sample introduction remains instrumentally simpler than pressure-based methods. Electrophoresis is initiated after the sample has been introduced and the capillary is returned to the inlet vial. It is important to keep the inlet and outlet vials at the same level to prevent siphoning during electrophoresis, which would induce laminar flow in the capillary and resultant degradation of separation efficiency and resolution.

Electrokinetic (or electromigration) sample introduction uses an electric field to transport analytes into the capillary. The amount of analyte injected depends upon the applied voltage, capillary radius, μ_{EOF}, analyte concentration, analyte μ_{EP}, viscosity, and injection time. Sample solution temperature, buffer temperature, conductivity, and *p*H will affect μ_{EOF} and μ_{EP} and therefore injection reproducibility. In some cases, it is necessary to adjust the ionic strength of the sample to obtain good injection precision. Electrokinetic introduction is instrumentally simpler than pressure-based methods, as the high-voltage supplies and controls are already in place on the instrument. The main disadvantage of electrokinetic introduction is that because analyte transport onto the column is based upon both μ_{EP} and μ_{EOF}, a sample loading bias is created (*i.e.*, a higher analyte μ_{EP} results in greater loading). However, this bias can be corrected for mathematically and can actually be used for an additional level of selectivity. For example, a capillary treated to eliminate electroosmotic flow injects cations or anions exclusively, and neutrals will not be injected.

Sample concentration methods for sample introduction include techniques known as sample stacking and field-amplified sample injection. These methods are similar to electrokinetic sample introduction and also concentrate the analyte in the capillary, often leading to signal enhancements of 100–1000-fold. Sample stacking utilizes a sample solvent (*e.g.*, water) with lower conductivity than the electrophoretic buffer. This results in higher electric fields when the capillary is placed in the sample vial and voltage is applied. Under the higher electric field, analytes migrate to the boundary between the low-conductivity sample plug and the high-conductivity buffer. At this interface the migration is slowed on account of the (relatively) lower electric field. This serves to focus or decrease the width of the analyte plug; however, it must be noted that neutrals are not focused. During sample introduction, cations are stacked at the front of the lower-conductivity plug, whereas anions are at the back. Laminar flow and Joule heat can degrade performance, however, and so typical voltages are lower than those used during CE separations. Field-amplified sample injection utilizes similar principles to focus the analytes; however, a small plug of very low-conductivity solution that does not contain analyte is injected first. This results in even higher electric fields than generated in sample stacking and smaller injected sample volumes.

Modern CE instrumentation includes autosampling accessories for automatic sample introduction by the techniques just described. Automatic sample introduction typically increases the precision of CE analyses, and also increases the efficiency of laboratory analyses since it does not require the constant attention of an operator.

2.2 Capillaries

The capillaries used in CE are made of fused silica, Teflon, or Pyrex, with fused silica being used for the vast majority of separations. They range in length from 3 to 100 cm (with most separations performed using 30–100-cm-long capillaries), in i.d. from 25 to 200 µm (with 50- and 75-µm i.d. capillaries being fairly typical) and in outside diameter (o.d.) from 200 to 375 µm (with 350–375 µm being typical). The fused-silica capillaries have a 10–20-µm-thick external polyimide cladding to impart strength and flexibility.

Fused-silica capillaries are commonly available in untreated, surface-modified (coated), and gel-filled forms. Capillary choice is affected by the CE separation mode used, compatibility with the buffer or reagent choices, and cost. Careful control of the surface of untreated capillaries is important for reproducible control of electrophoretic and electroosmotic mobilities and can be easily achieved by selection of a buffer *p*H that sets the silanol/silanoate equilibrium chemistry at the desired point. The capillary surface can also be modified to reduce or eliminate EOF and to reduce analyte adsorption or interaction with the column. This was first demonstrated by Hjerten (1985). Analyte–column interactions can cause significant problems such as band broadening, irreproducibility, and irreversible analyte binding, especially in the analysis of large biopolymers such as peptides, proteins and DNA. Modifiers include covalently bonded molecules, polymers, and groups with either anionic or cationic functionality. Non-covalently bonded modifiers can also be added to the buffer system for temporary, removable surface modification. Modifier characteristics to consider include stability with the buffer during long-term use and inertness to analytes and buffers. Commonly used modifiers include bonded alkyl chains, polymers such as polyacrylamide (PA) or poly(vinyl alcohol) (PVA), and zwitterionic buffer additives. PA is the most common polymer used in this application and is also frequently used as the packing material in gel-filled capillaries for CGE. These CGE capillaries are prepared by performing the polymerization directly in the capillary to produce a cross-linked polymeric gel with a porous network having narrow, well-defined pore size distributions. Finally, surface-modified capillaries ordinarily used in gas chromatography and cyclodextrin-modified capillaries (for chiral separations) have also found limited use.

Precise control of capillary temperature is essential for reproducible CE, since migration time, electrophoretic and electroosmotic mobilities, injection volume, and separation efficiency and resolution are all functions of temperature. In addition, temperature control helps dissipate the Joule heat generated by the electrical power applied to the capillary, thereby preventing such undesirable consequences as vaporization of the buffer and thermal degradation of temperature-sensitive samples. Temperature control of the capillary (at temperatures near ambient, to approximately ±0.1 °C) is achieved by a variety of methods, including forced-air cooling, thermostatted liquid cooling, and the use of Peltier cooling devices. Finally, pressurization of the capillary at the inlet and outlet is sometimes required to prevent solvent outgassing (especially in capillary electrochromatography, CEC), which can perturb the flat flow profile required for high-resolution CE separations.

In capillary zone electrophoresis (CZE) and MECC, uncoated capillaries are used; in CZE, capillary ion electrophoresis (CIE), CIEF, and dynamic sieving capillary electrophoresis (DSCE) applications, coated capillaries are used; and in CGE and CEC, capillaries packed with sieving gels and LC stationary phases, respectively, are used. More details on these separation modes are presented in Sec. 3.

2.3 Buffers and Other Reagents

CE separations can be performed over a wide *p*H range (approximately 2–10.5). A variety of buffer systems are used in CE, including phosphate, tetraborate, carbonate, phthalate (for indirect detection methods, discussed below), and tris(hydroxymethyl) aminomethane–boric acid ("Tris–borate buffer"). Buffers are used individually and in combination, at typical concentrations of 0.01–0.1 *M*. Precise control of the buffer composition in the inlet vial, outlet vial, and capillary is essential for reproducible CE. In practice the buffer solution is replaced after a few experiments to prevent ionic depletion, which causes irreproducibility. The primary purposes of the buffer are to provide a conducting medium for electrophoretic and electroosmotic movement of analytes, to control the surface chemistry of fused silica capillaries, and to control the ionization and partitioning equilibria of analytes. These are key factors in adjusting the resolution of a CE separation and can be achieved by controlling the *p*H or by the use of buffer modifiers.

Increasing buffer *p*H will increase μ_{EOF}, since the zeta potential (with silica capillaries) increases with increasing *p*H. In contrast, increasing the ionic strength of the buffer will decrease μ_{EOF}, since the zeta potential decreases with increasing ionic strength. It is also important to know the isoelectric point (*p*I) or the acid dissociation constant K_a (typically expressed as $pK_a = -\log K_a$) of the analytes being separated, since they play important roles in determining their electrophoretic migration properties. Many CE separations are designed around the fact that at high *p*H, most biological molecules are anionically charged and are repelled from the negatively charged walls (in the case of an uncoated capillary); this reduces sample–wall interactions and sample losses due to adsorption on the wall. This approach allows uncoated capillaries to be used in the separation of proteins, as first shown by Lauer and McManigill (1986).

A variety of additives can be added to the buffer to modify the resolution of CE separations. For example, organic solvents are added to improve the solubility of analytes with limited solubility in water. In some cases, even 100% nonaqueous buffers have been successfully used in CE separations. Other materials (*e.g.*, potassium sulfate, ammonium sulfate) are added to prevent analyte adsorption on the capillary. Cyclodextrins, which are donut-shaped, water-soluble oligosaccharides with hydrophobic cavities and hydrophilic exteriors, can be added as additional partitioning phases to help separate analytes on the basis of their relative sizes and hydrophobic/hydrophilic characteristics. Another important cyclodextrin application is in the separation of stereochemical isomers, or enantiomers (see Sec. 3.1). In MECC (Sec. 3.4), detergents (*e.g.*, sodium dodecyl sulfate, SDS) are added as micellar partitioning phases. Soluble ion exchangers and charged colloidal particles have also been used in partition-assisted CE separations.

Additives can also be used to measure important CE parameters or to improve detector sensitivity. A small molecule, soluble and neutral at the *p*H used for analysis, can be added as a neutral marker to provide a measure of EOF velocity, since it has zero electrophoretic mobility. In ultraviolet–visible absorbance detection (Sec. 2.5.1), highly absorbing modifiers can be added to the buffer to perform indirect detection, where the decrease in measured absorbance due to the elution of a nonabsorbing analyte is detected as a negative peak. A similar approach can also be used in fluorescence (Sec. 2.5.2) and electrochemical (Sec. 2.5.4) detection.

In CZE, MECC, and CGE, the same buffer is used in the inlet and outlet vials; in CIEF, different solutions are used in the inlet and outlet vials, while an ampholyte is used in the capillary; and in capillary isotachophoresis (CITP), leading and trailing buffers are used to segregate the analytes into discrete zones. More details on these separation modes are presented in Sec. 3.

2.4 High-Voltage Power Supplies

High electric fields are required to generate the electrophoretic and electroosmotic velocities needed for high-resolution CE separations. Electric field strengths of 100–700 V cm^{-1} are generated across capillaries using high-voltage power supplies rated for use between 10 and 70 kV, with a typical experiment being performed at 30 kV. The current requirements on the power supply are fairly low, typically $<300\,\mu$A, and so the power ratings for these supplies are on the order of 10 W. The voltage and current outputs should be very stable for reproducible separations. Capillary electropherographs have interlocks to prevent electrical shocks to operators *via* accidental exposure to high voltages. Most CE modes are performed with constant-voltage power supplies, with the exception of CITP (Sec. 3.5), which is done in a constant-current mode.

Additional levels of efficiency and sensitivity in CE separations can be obtained with programmable power supplies. ac voltages, dc voltage pulses, and voltage ramps ("gradients") have all been used to modify analyte velocities in the capillaries in ways that improve resolution. The use of voltage gradients, where the applied voltage is changed linearly with time during the electrophoresis experiment, has been particularly successful in high-resolution separations of DNA fragments by CGE. Reversible-polarity options can allow the direction of migration to be reversed for applications where this is desired. Improved sensitivity in radiometric detection (Sec. 2.5.5) can be realized by increasing analyte residence time in the detector by voltage control of the analyte migration velocity. Finally, the use of a second power supply to apply a radial voltage to the capillary has been used to change the zeta potential and, therefore, change μ_{EOF} [Eq. (2)].

2.5 Detectors

A wide variety of detectors are available for use with CE. Many of these are common to LC (see CHROMATOGRAPHY) and have been modified to accommodate the unique constraints of CE. Requirements common to all CE detectors include issues related to connection to the capillary, compatibility with the buffer chemicals, low flow rates, high electrical fields at the capillary outlet, and sensitivities for the small amounts of analytes used in CE ($\leq 10^{-15}$ mol). Real-time, on-line detection is the preferred approach because of the problems inherent in handling small amounts of analytes for post-CE detection by an off-line analysis method.

The choice of a suitable detector from among the many available types is based on the requirements of the separation problem as well as detector availability and cost. General principles and CE applications of the most common detectors are discussed briefly in the rest of this section. Nondestructive detectors do not chemically or physically destroy the sample and are well suited to preparative applications where it is desirable to collect pure fractions of an individual component eluting from the capillary. Preparative CE is often performed to collect a pure sample of an analyte for subsequent off-line chemical, biochemical, or spectrometric analysis. In addition, nondestructive detectors can be used as the first detector in a tandem detector arrangement to improve the selectivity of on-line analyte detection.

In the sections that follow, detection limits (the minimum amount of detectable material) are given for each detector, although it must be emphasized that these are approximate values that depend on many variables, particularly the chemical and physical properties of the material being detected. The detection limits are given in terms of moles of analyte in the injected sample.

2.5.1 Ultraviolet–Visible Absorbance Ultraviolet–visible (UV–vis) absorbance detectors simply measure the absorption of light (in a particular wavelength range) by the analytes, and are the most widely used detectors in CE. This is primarily a result of two factors. First, optical absorbance detectors are amenable to integration with optically transparent fused-silica capillaries. Second, most compounds of interest absorb 190–800-nm radiation, while many other compounds that do not absorb can be chemically complexed or derivatized (*e.g.*, in a post-capillary column reactor) to form highly absorbing species. An example of this is the absorbance detection at 520 nm of the complexes formed between 4-(2-pyridylazo)resorcinol (PAR) and transition-metal ions such as Fe^{II}, Fe^{III}, Cu^{II}, Ni^{II}, Zn^{II}, Co^{II}, and Pb^{II}. If a nonabsorbing analyte is not amenable to complexation, CE can be performed in a buffer containing a highly absorbing modifier or in a light-absorbing buffer (*e.g.*, phthalate), and the analyte can be detected as a negative peak in a high-absorbance background (Small and Miller, 1982). This is sometimes referred to as indirect UV–vis absorbance detection. Monochromator-based scanning spectrometers and photodiode array detectors can provide an added level of identification, as the UV–vis absorbance spectrum can sometimes be used to confirm the identity of an analyte giving rise to a CE peak. The current generation of fast-scanning monochromator detectors typically have better signal-to-noise ratios than photodiode array detectors, and are preferred for applications requiring greatest sensitivity.

The capillary itself is typically used as the flow-through absorbance cell ("on-column" detection). Here, a section of the external polyimide cladding is removed from the capillary, and the UV–vis radiation is directed through the capillary. The absorbance A of an analyte is given by Beer's law:

$$A = \varepsilon b C, \tag{9}$$

where ε is the analyte molar absorption coefficient, b is the optical path length, and C is the analyte concentration. The small path lengths offered by the capillary i.d. have been largely offset by operation at low wavelengths (190–220 nm) where absorption coefficients are typically greatest, by sample-concentration injection methods (Sec. 2.1), which increase analyte concentrations in the capillaries by 100–1000-fold, and by the use of extended–path-length absorbance cells. An extended–path-length capillary known as a bubble cell is formed by a proprietary process that increases capillary i.d. (and therefore optical path length) in the detector by 3–5-fold. A second type of extended–path-length cell ("Z-cell") is formed by making two right-angle bends in the capillary and then directing the sample beam down the length of the middle leg of the "Z" instead of through the cross-sectional diameter of the capillary. This results in approximately a 20-fold improvement in sensitivity. Finally, optical detector designs are very efficient at reducing the amount of scattered light that reaches the photodiode, which also helps sensitivity.

UV–vis absorbance detectors are nondestructive, and for strongly absorbing analytes the detection limit is about 10^{-13}–10^{-16} mol. Further details on UV–vis absorbance can be found in OPTICAL SPECTROMETERS and MOLECULAR SPECTROSCOPY.

2.5.2 Fluorescence Fluorescence detectors measure the light emitted by the analyte after optical excitation by either a lamp (deuterium, quartz–tungsten–halogen, xenon, mercury) or a laser (laser-induced fluorescence, LIF). When a broad-band radiation source such as a lamp is used, the excitation of the analyte is limited to a narrow wavelength range by use of a monochromator. Detection of the fluorescent emission is performed with a photodiode or a photomultiplier tube located at a right angle from the excitation source. As in UV–vis absorbance detection, the capillary itself can be used as a flow-through detection cell, but improvements in sensitivity have been achieved by coupling the capillary to a cell with planar quartz windows, which reduces the amount of light scattering (Chen and Dovichi, 1994).

Fluorescence detectors are more selective than UV–vis absorbance detectors because not all compounds that absorb light subsequently fluoresce. Since only a small percentage of compounds natively fluoresce, analytes are usually derivatized with fluorescent tags. Derivatization can be performed either prior to the separation, in the capillary using a fluorescent tag added as a buffer modifier, or after elution from the capillary in a post-column reactor. Novel, analyte-specific fluorescent tags form an intense area of research, and have resulted in tremendous improvements in sensitivity for important analytes. For example, the fluorogenic reagent 3-(4-carboxybenzoyl)-2-quinoline-carboxaldehyde produces highly fluorescent isoindole derivatives with amino acids and peptides (Liu *et al.*, 1991). Nonfluorescing analytes can also be detected by indirect detection, whereby the CE separation is performed in a buffer containing a highly fluorescing modifier and the analyte is detected as a negative peak in a high-fluorescence background.

LIF is used when low detection limits are required, since the intensity of the emitted fluorescence is proportional to the number of excited molecules, which in turn is proportional to the intensity of the excitation radiation. LIF has been particularly useful for DNA analyses with intercalating dyes, which has eliminated the need for derivatization of the DNA. The increasing number and types of semiconductor and solid-state laser sources has increased the popularity of fluorescence detection and made it applicable to a wider range of analytes. Fluorescence detectors can be nondestructive (*e.g.*, if the analyte is not derivatized) and they have a detection limit of about 10^{-14}–10^{-21} mol. Further details on molecular fluorescence can be found in OPTICAL SPECTROMETERS and MOLECULAR SPECTROSCOPY.

2.5.3 Mass-Spectrometric Mass-spectrometric detectors measure the abundance and mass-to-charge (m/z) ratio of ions produced from analytes eluting from the capillary. For this measurement, the molecules are ionized (singly or multiply) after they elute and then introduced into the vacuum chamber of a mass analyzer. Ionization and subsequent mass measurement are accomplished with a variety of instrumentation. In order to do on-line coupling of CE with mass spectrometry (MS), the mass spectrometer must accommodate conditions unique to CE, including high–salt-content buffer systems, high electrical fields on the capillary outlet (which is interfaced to the inlet of the MS), and low flow rates. Although the low flow rates characteristic of CE make coupling to MS easier than is the case for LC, the other conditions constrain the ionization methods and mass analyzers that are used in CE.

Ionization methods coupled on-line with CE include electrospray ionization, ion-spray ionization, atmospheric-pressure ionization, and inductively coupled plasma ionization. Matrix-assisted laser desorption ionization (MALDI) has been used successfully off line in CE analyses. Electrospray ionization interfaces were first developed by Smith *et al.* (1988) and are the most popular devices for coupling capillaries to mass spectrometers. Typically, electrospray ionization uses buffer flow through a steel needle (on the end of the capillary) held at a high electrical potential to ionize analytes that are amenable to either negative or positive ionization modes. For optimum ionization efficiency, and therefore optimum detection limits, the design of the interface between the capillary outlet and the electrospray needle is critical. Combinations of sheath flow liquids (Wahl and Smith, 1994) with capillary outlet tip modifications have been used to enhance detection sensitivity.

Mass analysis brings an additional level of information to CE analysis. The mass spectrum of a detected peak, which is a plot of ion intensity versus m/z, contains molecular-weight, formula, and structural information. Mass analyzers utilized include quadrupole ion trap, quadrupole filter, time-of-flight, and ion-cyclotron-resonance (ICR) mass spectrometers. Each of these can also be used to perform tandem experiments ("MS–MS") if the analyzers are properly equipped. MS–MS experiments provide detailed structural information about an analyte and have been applied to polypeptide sequence determination. Time-of-flight analyzers are useful for the measurement of very high-mass analytes ($>3\,000$ atomic mass units, u) and for rapid CE (in which eluted peaks may be only a few seconds wide), while ICR instruments are used in applications requiring the highest mass resolution. Mass analyzers can be operated either as universal detectors (by monitoring the intensity of all m/z regions of the mass spectrum) or as selective detectors (by monitoring selected m/z regions). Mass-spectrometric detectors are destructive and have typical detection limits of about 10^{-15}–10^{-18} mol. Further details on mass spectrometers can be found elsewhere in this Encyclopedia (see MASS SPECTROMETERS).

2.5.4 Electrochemical Electrochemical detectors measure changes in current or conductivity between a set of electrodes in a detection cell. It must be noted that these are not the same electrodes that are used to generate the high electric fields needed for electrophoretic migration. Electrochemical detectors are seeing increasing use in biochemical analyses because many biochemical compounds are electroactive since they are easily oxidized. Also, several novel detector designs have been reported that are free from electrophoretic voltage interference, making this a reliable detection method.

Amperometric detectors measure the current produced by a controlled-potential electrolysis of the analyte in the buffer. The analytes from the column elute past a working electrode (one of three electrodes in the detector cell) set at a specific potential with respect to a reference electrode. If an analyte can be oxidized or reduced at this potential, the transfer of electrons at the electrode–buffer interface serves as the amperometric detection signal. Some recent designs use on-column detection with 5–25-μm-diameter working electrode wires either placed over the capillary outlet (Zhong and Lunte, 1996) or inserted directly into the end of the capillary (Swanek *et al.*, 1996). An additional level of information can be obtained with voltammetric detectors, wherein the potential of the working electrode is changed with respect to time as the analyte passes through the cell. Voltammetric detectors provide additional measures of the thermodynamic and kinetic properties of the electron-transfer reactions of the analytes, which can be used to aid in the identification of unknown analytes. As with UV–vis and fluorescence detectors, indirect methods of detection are possible with amperometric detectors, whereby a nonelectroactive analyte is detected as a negative peak when the CE separation is performed in a buffer containing a high concentration of an electroactive modifier.

In conductivity detectors, the electrical conductivity of the eluting buffer is measured by applying an alternating voltage between two electrodes and measuring the resulting current. Conductivity is related to the current/voltage ratio and represents the contribution of the individual equivalent conductivities of all ions in solution, including the analyte ions. Measuring the small conductivity due to an eluting ion in the presence of the high background conductivity of the buffer is difficult. Suppression of the conductivity of the buffer (Small *et al.*, 1975) dramatically improves the sensitivity. For example, consider the case where a sodium carbonate buffer is used in anionic separation by CE. As the buffer exits from the capillary, it passes through a cation exchanger (suppressor) loaded with hydrogen ions. Sodium ions from the buffer displace hydrogen ions from the ion-exchange sites on the suppressor, with two beneficial results. First, carbonic acid is formed by the ion-exchange reaction, so that detection is carried out with a background characterized by the low conductivity of carbonic acid, as opposed to the higher conductivity of sodium carbonate. Second, the analyte anions are paired with hydrogen ions instead of sodium ions, so that detector sensitivity is increased because the equivalent conductivity of the hydrogen ion is approximately seven times as large as that of the sodium ion. Several on-column conductivity-cell designs have been developed that incorporate the electrodes and the suppressor directly on the end of the capillary. Conductivity detection is usually described as suppressed or nonsuppressed to indicate whether ion exchangers are incorporated.

Amperometric detectors are destructive and have typical detection limits of about 10^{-18}–10^{-19} mol. Conductivity detectors are destructive if a suppressor is used, and have typical detection limits of about 10^{-15}–10^{-16} mol. Further details on electrochemistry can be found in ELECTROCHEMISTRY.

2.5.5 Other Detectors Other detectors use optical, radioactive, or other analyte properties as the basis of detection, but are not as widely used as those already discussed. Detectors based upon analyte optical properties (or on the properties of the products of post-separation reactions involving the analyte) include refractive-index, thermooptical, and chemiluminescence detectors. Radiometric detectors detect radioactive decay from commonly used isotopes of phosphorus, sulfur, or hydrogen that have been incorporated into the analyte. Detectors based on other analyte characteristics (*e.g.*, nuclear magnetic resonance spectrum, Raman spectrum, proton-induced x-ray emission, particle light scattering) and capillary characteristics (laser-induced capillary vibration) have found special applications as on-line detectors in capillary electrophoresis.

2.6 Integrated Capillary Electrophoresis Microdevices

An exciting development in capillary electrophoresis is the fabrication of miniaturized capillary electropherographs on planar substrates such as silicon, quartz and glass. These CE instruments were first introduced in 1991 (Fan and Harrison) with CE separation channels (the planar analog to conventional capillaries) built on the surface of silicon substrates. These channels were fabricated by use of a combination of masking, photolithographic, and etching techniques that had been primarily developed for the fabrication of silicon-based integrated circuits and microelectromechanical structures (MEMS). Since then, sample-introduction, separation-channel, and detector components have been fabricated on glass and quartz by modifications of silicon micromachining methods. While some detectors, such as electrochemical detectors, have been integrated into these devices (Ewing and Gavin, 1996), other detection schemes, such as laser-induced fluorescence, are being performed with some integrated components (*e.g.*, post-column reactors) and some external components (*e.g.*, the laser and photodiode) not integrated onto the substrate (Fluri *et al.*, 1996). On account of the extremely small size of the separation channels, which are typically $5 \times 50\,\mu m^2$ in cross-section, the efficiency of these separations is excellent, with 70 000–160 000 theoretical plate separations reported on 5–50-mm-long channels with 0.1-nL sample volumes and 10–20-s migration times (Manz *et al.*, 1993). In addition, these devices can perform multichannel separations of a single sample by multiple, complementary modes of separation. This is achieved by voltage control of the direction and speed of sample electrophoretic migration in a grid array of perpendicular channels, each of which can be tailored to provide a particular mode of separation (Sec. 3).

3. MODES OF SEPARATION

A wide range of separation selectivity can be obtained by separating analytes not only on the basis of differences in their electrophoretic mobilities, but also on differences in their isoelectric point, molecular size, hydrophobic and hydrophilic nature, molecular structure, polarity, and stereochemistry. In this section, CE modes of separation are discussed that exploit these analyte properties. In addition, applications from the current scientific literature are used to illustrate the usefulness and limitations of the different CE separation techniques. It will be seen that CIEF, CGE, and CITP are capillary analogs of slab gel electrophoresis, while CZE, CIE, MECC, and CEC are uniquely capillary techniques.

3.1 Capillary Zone Electrophoresis (CZE)

Capillary zone electrophoresis (CZE), also known as free-solution capillary electrophoresis (FSCE), separates analytes primarily on the basis of differences in their electrophoretic migration rates. When CZE is performed in untreated capillaries, migration is related to the sum of the electrophoretic and electroosmotic mobilities. In treated (*i.e.*, wall-coated) capillaries, migration is due solely to the electrophoretic mobility of the analytes. The capillaries are not packed with a gel or a sta-

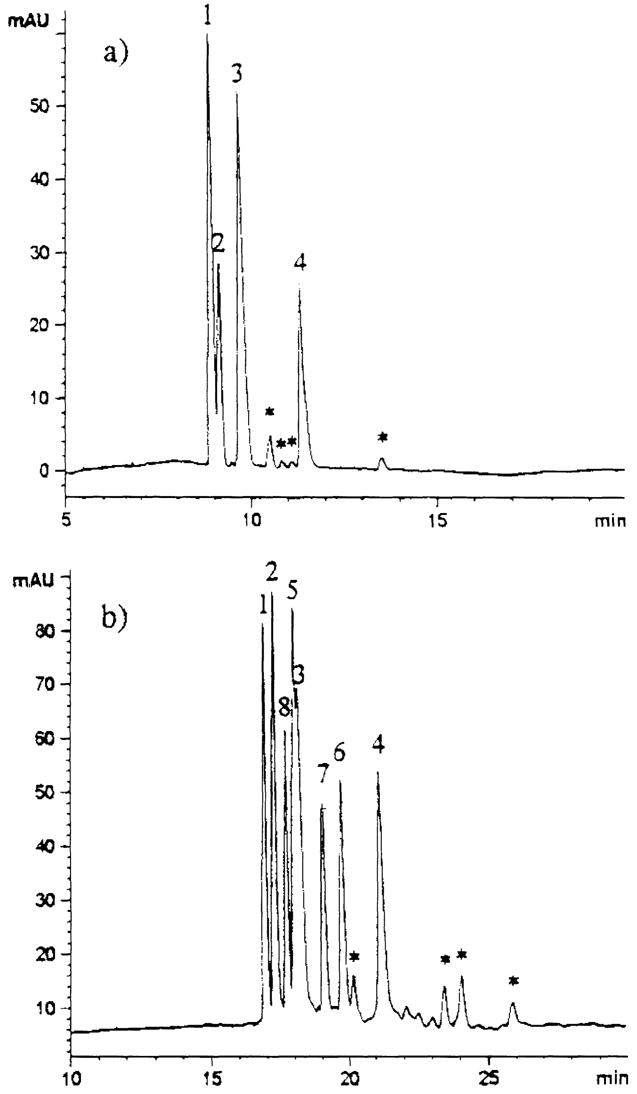

FIG. 4. CZE separation of all eight stereoisomers of Tyr-Lys-Trp (a) without and (b) with 18-crown-6 tetracarboxylic acid added to the buffer as a chiral selector. Sample introduction: hydrodynamic (pressure) injection, 50 mBar, 2 s. Capillary: fused silica, untreated, 50 cm long × 75 μm i.d., 30 °C, 30 kV applied voltage. Buffer: *p*H 2 Tris-borate buffer, with or without 0.01 *M* chiral selector. Detection: UV–vis absorbance at 210 nm. Elution order of analytes in (a): 1, LLL/DDD; 2, LDL/DLD; 3, LLD/DDL; 4, DLL/LDD. Elution order of analytes in (b): 1, LLL; 2, LLD; 3, LDL; 4, DLL; 5, DDL; 6, DLD; 7, LDD; 8, DDD. Asterisks indicate peaks due to side products of the crude peptides. tionary phase material, and the same buffer is used in the capillary and the inlet, outlet, and sample vials. This mode of CE has found particularly good applications in the determination of amino acids, peptides, proteins, nucleosides, nucleotides, and vitamins.

Chiral compounds can be separated by addition of an appropriate modifier (*e.g.*, cyclodextrin) to the buffer. These compounds are molecules that are not superimposable with their mirror images; *e.g.*, in organic chemistry, they are molecules that contain a carbon atom that is covalently bonded to four different functional groups. They are also known as stereoisomers, optical isomers, optically active isomers, diastereomers, and enantiometers. In many pharmaceutical, agrochemical, and biological applications, where optical purity can influence effectiveness, stereoisomers can be difficult to separate in HPLC. The ability of CZE to separate stereoisomers is demonstrated in Fig. 4, showing separation of the eight stereoisomers produced in the solid-phase synthesis of the (target) tripeptide D-Tyr-L-Lys-L-Trp (Riester *et al.*, 1996). The prefixes D and L refer to the relative configuration of the atoms on the enantiomeric forms of each peptide group. In solid-phase peptide synthesis the polypeptide is produced stepwise from individual amino acids in an automated reactor. Side reactions, deletion errors due to an incomplete coupling cycle, and isomerization can all lead to undesired stereoisomers. The eight different tripeptide stereoisomers are separated into four pairs that each elute together in the absence of a chiral selector [Fig. 4(a)], but are completely resolved when a chiral selector is added as a buffer modifier [Fig. 4(b)]. This CZE method was used to investigate the rate of racemization (a reaction whereby a pure L or D form of a stereoisomer is converted into a mixture of equal parts of L and D forms). This work demonstrated the ability of CZE to measure the optical purity of the derivatized amino acid starting materials used in solid-phase peptide synthesis and was the first separation of all stereoisomers of a three–chiral-center tripeptide by CZE.

Figure 5 shows the electropherogram for the separation of 5-(dimethylamino)naphthalene-1-sulfonic acid (Dns-OH) and four L-amino acids using a capillary electropherograph microfabricated on quartz and Pyrex glass substrates (Fluri *et al.*, 1996). The analytes were derivatized with *o*-phthaldialdehyde in a microfabricated post-column reactor prior to fluorescence detection. The remarkable speed and efficiency of separations performed on integrated CE microdevices is demonstrated by the fact that all five analytes elute within 20 s, with N ranging between 23 000 and 94 000 theoretical plates based on analysis of the peaks (Sec. 1.2).

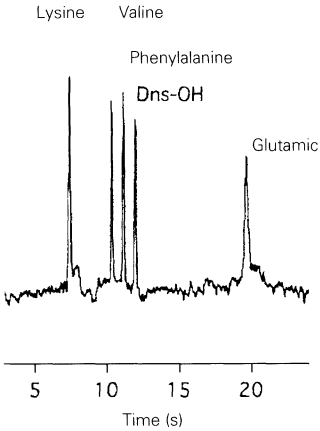

FIG. 5. CZE separation of a mixture of of 5-(dimethylamino)naphthalene-1-sulfonic acid (Dns-OH) and four L-amino acids using a capillary electropherograph microfabricated on quartz and Pyrex glass substrates. Sample introduction: electrokinetic injection, −1.8 kV, 5 s. Separation channel: Pyrex glass, 4.5 cm long × 45 μm wide × 15 μm deep, −11 kV. Buffer: 0.027 *M* sodium hydrogen carbonate and 0.012 *M* sodium carbonate, adjusted to *p*H 9.7. Detection: LIF following post-column reaction with 0.004 *M* *o*-phthaldialdehyde, He/Cd excitation (9.3 mW, 325 nm), photomultiplier tube detection. Reprinted (in part) from Fluri *et al.* (1996). Copyright (1996) American Chemical Society.

The speed and efficiency of CZE illustrated in the determination of small polypeptides and amino acids has also been applied in the determination of proteins. For large molecules such as proteins, the secondary and tertiary structures of the molecule have an effect on the net charge and its size or hydrodynamic radius. The effect of these parameters on the electrophoretic mobility of some proteins has been studied (Ma *et al.*, 1995). Protein modifications such as degradation, glycosylation, deamidation, or sequence changes will result in altered CZE migration times. These effects have allowed CZE to be successfully applied to confirmation of protein identities and detection of purity, heterogeneity and post-translational modifications in both native and synthetic proteins (see Sec. 3.2). Alternatively, protein sequence can be determined by peptide mapping, as reviewed for recombinant proteins by Ganzler *et al.* (1995). Peptide mapping involves enzymatically breaking a protein into smaller polypeptides. Analysis by CZE provides a map or fingerprint of the constituent polypeptides. Different enzymes are used to produce a variety of maps, and each map can be used for comparison or as a quality check for recombinant methods. Further, using a mass spectrometric detector, molecular weight can be measured and in many cases the sequence of each individual polypeptide can be determined.

Capillary ion electrophoresis (CIE), also sometimes referred to as capillary ion analysis (CIA), is a special name given to CZE separations that are optimized for the separation of small ionic species. UV–vis absorbance (Sec. 2.5.1) is the most common detection mode used in CIE; however, since many of these ions do not absorb UV–vis radiation, indirect de-

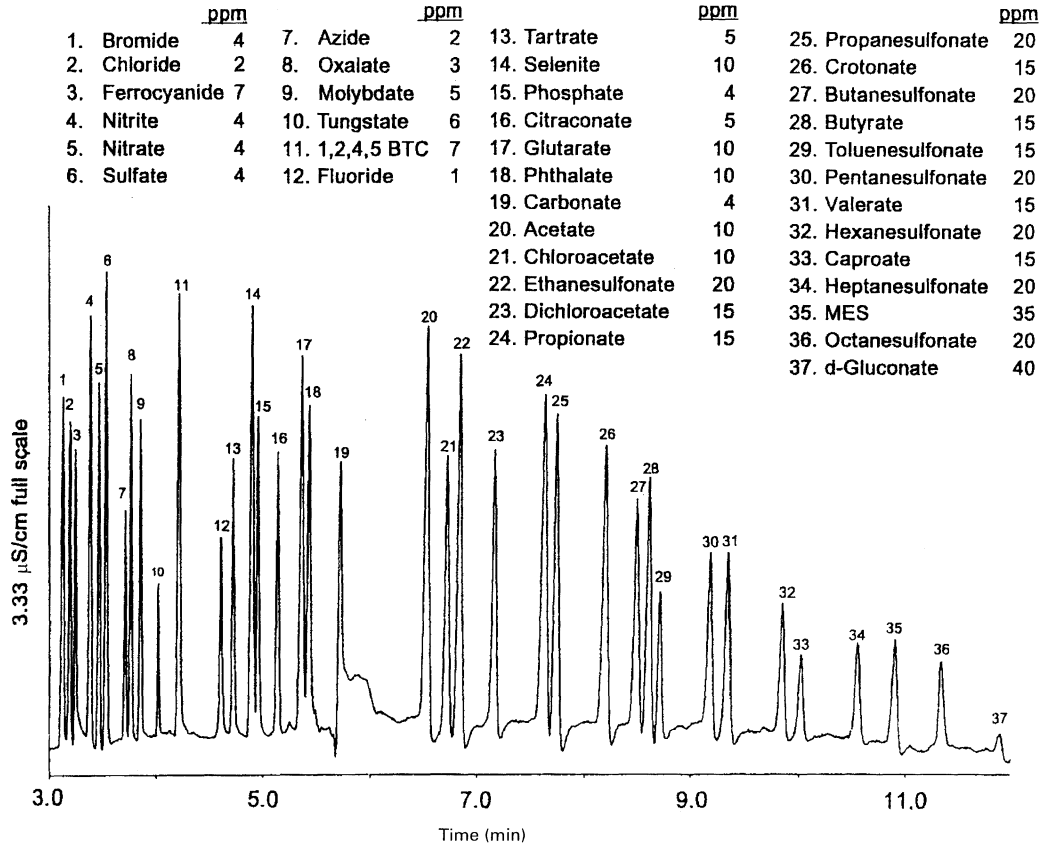

FIG. 6. CIE separation of 37 anions. Sample introduction: hydrodynamic (pressure) injection, 25 mbar, 12 s. Capillary: fused silica, 60 cm long × 50 μm i.d., room temperature, 30 kV applied voltage. Buffer: 0.05 *M* 2-{*N*-cyclohexylamino}-ethanesulfonic acid, 0.02 *M* lithium hydroxide, 0.03% Triton® X-100 surfactant (Rohm & Haas, Philadelphia, PA, U.S.A.). Detection: nonsuppressed conductivity, with detector response shown as 33 μS cm^{-1}. Cetyltrimethylammonium bromide (CTAB), 0.001 *M*, was flushed through the capillary prior to analysis. Peak assignments for the 37 anions are shown along with the concentrations of the individual anions in the mixture in parts per million (ppm). MES represents 2-[*N*-morpholino]ethanesulfonic acid. Reprinted (in part) from Jones *et al.* (1996) with permission from *American Laboratory*. Copyright (1996) International Scientific Communications, Inc.

tection schemes are typically used. Conductivity detectors, both suppressed and nonsuppressed, are also finding increasing use in CIE. When cations and anions are both present in the sample mixture, untreated fused-silica capillaries are used. However, when the sample contains only anions, wall-coated capillaries can be used to decrease the migration time for the analyte anions.

In Fig. 6, the CIE separation of 37 anions is shown (Jones *et al.*, 1996). To decrease the electrophoretic migration time of the anions, the direction of electroosmotic flow was reversed by treating the fused-silica capillary with CTAB prior to analysis. The elution order is determined by the electrophoretic mobility and, therefore, the charge/size ratio of the anions. As an example, consider the order of elution for the Group VIIA anions in the sample (bromide, chloride and fluoride). These anions are singly charged and their hydrated ionic radii increase in the order bromide < chloride < fluoride. Therefore, bromide elutes first, followed in order by chloride and fluoride. The excellent speed and resolution of capillary electrophoresis is also demonstrated by this example, as nearly all of the peaks are separated with baseline resolution in a separation that takes less than 12 min and uses only 12 nL of sample solution.

3.2 Capillary Isoelectric Focusing (CIEF)

In capillary isoelectric focusing (CIEF), analytes are separated on the basis of differences in their isoelectric points. As opposed to the other CE zonal modes of separation, CIEF is, as the name implies, a focusing technique. Further discussion of CIEF requires some definitions of terms. An ampholyte (or amphotere) is a compound that can exist as either a cation or an anion depending on the buffer *p*H. Ampholytes can take many forms, but the type most commonly used in CIEF comprises organic compounds with both amino (basic) and carboxylic acid functional groups. In its basic form, an ampholyte is an anion, while in its acidic form, it exists as a cation. The buffer *p*H at which the ampholyte is neutral is the isoelectric point, *p*I.

CIEF is performed by a three-step process on capillaries that have been treated to eliminate EOF. First, the sample is injected into the capillary along with a mixture of ampholytes. This is typically done by hydrodynamic injection of relatively large sample volumes, since the sample can fill the entire capillary. Second, a focusing step is performed with high electric fields (typically 400–700 $\mathrm{V\,cm^{-1}}$) across the length of the capillary. The inlet (anode) vial contains a dilute, acidic anolyte (*e.g.*, phosphoric acid), and the outlet (cathode) vial contains a dilute, basic catholyte (*e.g.*, sodium hydroxide). Focusing is performed until the current drops to a steady value, and usually takes 3–5 min. During this step, a *p*H gradient is established along the length of the capillary, and sample analytes migrate to their individual isoelectric points in the capillary and are focused into sharp zones. These zones are the narrowest when there are a large number of ampholytes with evenly spaced isoelectric points introduced during the first step. In the third and final step, the analyte zones are mobilized so that they move to the CE detector. Mobilization can be achieved by an electrophoretic process, whereby the high voltage is first turned off, the compositions of the anolyte and/or the catholyte are changed (*e.g.*, by addition of a salt), and the voltage is then turned back on. When the voltage is turned on, a gradual shift in the *p*H gradient in the capillary occurs, the analytes acquire electric charges, and the analytes then move towards the detector as a result of electrophoresis. Adding a salt containing a cation other than the hydrogen ion to the anolyte will produce mobilization towards the anode. Conversely, adding a salt containing an anion other than the hydroxyl ion to the catholyte will produce mobilization to the cathode. Mobilization can also be performed by hydrodynamic means. Here, hydrostatic pressure caused by pressurization of the catholyte or anolyte vial, or by changing the level of either the catholyte or anolyte vial, causes buffer flow through the capillary.

CIEF is used for a variety of separation problems, such as proteins, monoclonal antibodies, and hemoglobins. In Fig. 7, the CIEF separation of recombinant human growth hormone (rhGH) variants is shown (Shimura and Karger, 1994). The analytes are detected as a complex formed by post-column reaction with a reagent (TR-Fab') synthesized by the reaction of a purified mouse monoclonal antibody with tetramethylrhodamine-5-iodoacetamide. CIEF was a particularly good mode of separation for this analysis on account of the fairly large sample volume that could be loaded into the capillary. In CIEF, the order of elution is related to the *p*I's of the individual analytes. With appropriate *p*I standards, a calibration curve of *p*I versus mobilization time can be used to determine the *p*I of an unknown analyte with an absolute accuracy of 0.05 pI units.

3.3 Capillary Gel Electrophoresis (CGE)

In capillary gel electrophoresis (CGE), separation is enhanced by size exclusion (*i.e.*, sieving) in polymeric gels containing a network of pores with narrow, well-defined size distributions. Small analytes permeate through the pores in the polymer and appear early in the electropherogram. Large analytes are slowed down by the gel; therefore, they have longer migration times and appear later in the electropherogram. This elution order is the

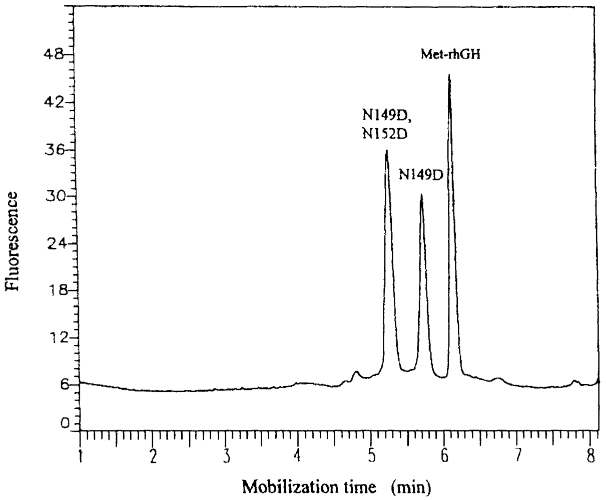

FIG. 7. CIEF separation of a mixture of recombinant human growth hormone (rhGH) variants. Mixture contains met-rhGH, the monodeamidated variant (N149D), and the dideamidated variant (N149D, N152D), each at a concentration of 10 $\mu g\,L^{-1}$. Sample introduction: hydrodynamic (vacuum) injection, 10 μL syringe. Capillary: polyacrylamide-coated fused silica, 15 cm long × 75 μm i.d. Ampholyte: 6% Pharmalyte 3–10 (Pharmacia LKB Biotechnology, Piscataway, NJ, U.S.A.). Catholyte: 0.02 *M* sodium hydroxide. Anolyte: 0.01 *M* phosphoric acid. Focusing: 1 min at 200 $V\,cm^{-1}$ and 4 min at 400 $V\,cm^{-1}$. Mobilization: change anolyte to 0.01 *M* phosphoric acid containing 0.1 *M* sodium chloride, 400 $V\,cm^{-1}$. Detection: LIF at 580 nm following post-column reaction with TR-Fab' complexing reagent, Ar^+ excitation (2 mW, 488 nm). Reprinted (in part) from Shimura and Karger (1994). Copyright (1994) American Chemical Society.

opposite of that in size-exclusion chromatography (SEC; see CHROMATOGRAPHY), where molecules that are too large to permeate the pores in the stationary-phase particles flow around the particles and appear first in the chromatogram, while small molecules that permeate the pores travel a long and tortuous path through the particles and elute last. In CGE, capillary walls are typically treated to enhance gel adhesion and stability. EOF is therefore eliminated and the analytes migrate through the gel as a result of their electrophoretic mobilities, which can add a second degree of separation selectivity to that based on size exclusion.

Typical gels in CGE include polyacrylamide (PA), agarose, and poly (ethyleneoxide), with PA being the most common. CGE with PA gels is frequently referred to as capillary polyacrylamide gel electrophoresis (C-PAGE). The gel is usually either a rigid, cross-linked polymer that is attached to the capillary wall or a linear polymer solution that is not cross-linked and is not fixed to the capillary. CGE capillaries with cross-linked gels occasionally have problems with gel stability (which can limit their usefulness to 100–200 analyses) and with bubble formation during electrophoresis (which can be addressed by careful control of experimental parameters). Also, electrokinetic injection is typically used with these types of gels because hydrodynamic injection is not usually capable of introducing the sample into the gel-filled capillary. In contrast, when the gel is a polymer solution composed of non-cross-linked polymers (*e.g.*, a linear polyacrylamide gel), either hydrodynamic or electrokinetic injection can be used. Also, capillary lifetimes are much longer than for capillaries with cross-linked polymers, as it is possible to introduce a new polymer solution into a capillary by a simple pressure loading technique prior to a given set of CGE experiments. With this mode of CGE, sometimes referred to as dynamic sieving capillary electrophoresis (DSCE), the capillary wall is treated to prevent EOF transport of the sieving gel out of the capillary. The polymer type, chain length, and concentration are all selected to give the desired size-exclusion properties for the separation problem at hand.

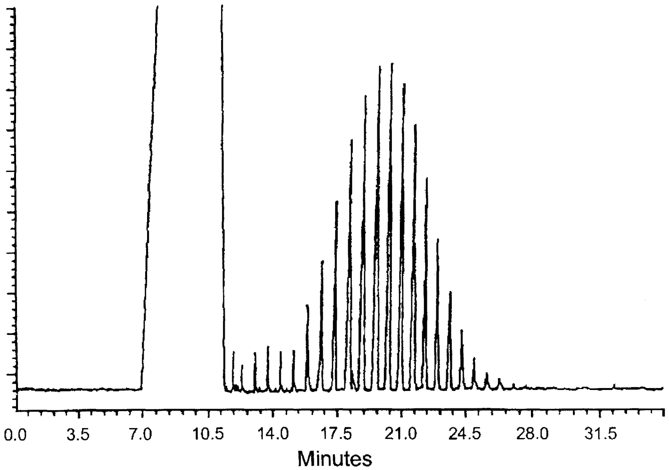

FIG. 8. CGE separation of phthalate-derivatized poly (ethylene glycol) oligomers. Sample introduction: electrokinetic injection, −10 kV, 60 s, sample concentration 1300 mg L^{-1}. Capillary: fused silica, 45 cm long× 75 μm i.d., filled with cross-linked polyacrylamide gel, −10.9 kV applied voltage. Buffer: Tris–borate, pH 8.3. Detection: UV–vis absorbance at 275 nm. Reprinted (in part) from Wallingford (1996). Copyright (1996) American Chemical Society.

In the CGE electropherogram shown in Fig. 8, the separation of phthalate-derivatized poly(ethylene glycol) oligomers is shown (Wallingford, 1996). An oligomeric set is a collection of polymers, each composed of one more monomer unit than the previous polymer. It is important to analyze these because the distribution of polymers within the set and the average molecular weight of the set determine key physical properties of the polymer. The oligomers elute in order of increasing size, and a smooth curve drawn so as to connect the individual oligomeric peak maxima can be related to the molecular-weight distribution (polydispersity) of the oligomers. With appropriate molecular-weight standards, a calibration curve of log(molecular weight) *versus* migration time can be used to estimate the molecular weight of an unknown polymer by CGE analysis. The benefits of CGE in the example shown in Fig. 8 were higher-accuracy measurements relative to gel permeation chromatography (GPC) and higher separation efficiencies (100 000–300 000 theoretical plates) than is possible with HPLC. Differences in the average weight and polydispersity between two vendors of the "same" polymer were also observed by the author.

Gel-filled capillaries were introduced by Cohen and Karger (1987), who first used them for the separation of polynucleotides by CGE. Today, CGE is widely used for many important separations in biochemistry, including nucleic acids, oligonucleotides, PCR products, DNA molecules (with as many as 5000 base pairs), DNA sequencing reaction products, and proteins. Native proteins can be separated by CGE as uncomplexed species, but molecular size determination becomes difficult because of mixed electrophoretic and size-exclusion contributions to the net mobilities of the proteins. In one very popular CGE method, proteins are treated with sodium dodecyl sulfate (SDS). The SDS denatures and interacts with each protein to produce adducts with virtually the same charge/size ratio, yet the size differences are retained. Similarly, some oligonucleotides and DNA fragments differ from one another in size but not in their charge/size ratios. None of these samples can be resolved by CZE (since they all have the same charge/size ratio), but the size discrimination properties of CGE allow separation with high resolution. CGE can also therefore be used to determine molecular weights.

The application of CGE to DNA sequencing analyses, first demonstrated by Swerdlow and Gesteland (1990), has provided significant advances in terms of speed and resolution compared with traditional slab gel electrophoresis. Standard DNA sequencing methodologies are used to produce single strands of DNA that terminate after each nucleotide type (deoxyadenosine, deoxycytidine, deoxyguanosine, and deoxythymidine, or A, C, G, T). For a DNA strand that contains G at base

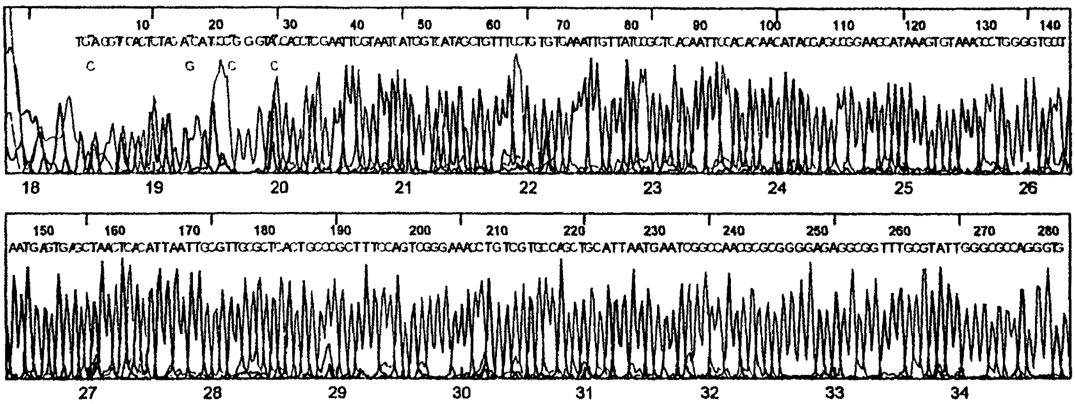

FIG. 9. Capillary gel electrophoresis of DNA sequencing products: partial electropherograph (fluorescence intensity *versus* time) showing separation of products of length 1 through 282 bases. Upper numbers show length (in bases), letters indicate terminal base. Sample introduction: electrokinetic injection, $-200\,\mathrm{V\,cm^{-1}}$, 5 s. Capillary: fused silica, poly (vinyl alcohol) coated, filled with 2% *T* (*T* = total monomer concentration) linear polyacrylamide, 30 cm long × 75 μm i.d., $-150\,\mathrm{V\,cm^{-1}}$ applied voltage. Buffer: 100 m*M* Tris-50 m*M* TAPS-2 m*M* EDTA-7 *M* urea. Detection: LIF, argon-ion laser (5 m*W*, 514 nm) excitation, photodiode array detection. Reprinted (in part) from Carrilho *et al.* (1996). Copyright (1996) American Chemical Society.

number 54 and 87, for example, two individual strands (sequencing products) of lengths 54 and 87 are produced with a terminal G. Ordinarily, the four groups of sequencing products would be labeled with radioactive isotopes and determined individually in a single slab gel experiment, with the analysis alone taking many hours. With CGE, however, each group of sequencing products is labeled with a different fluorescent tag and the groups are combined and analyzed by CGE with a significantly shorter analysis time.

An example of this type of analysis, using a replaceable linear polyacrylamide, low voltages, and laser-induced fluorescence detection, is shown in Fig. 9 (Carrilho *et al.*, 1996). By identifying the terminal base on each sequenced product, the sequence of the entire polynucleotide was determined. The experiment shown in Fig. 9 was used to sequence a polynucleotide (ssM13mp18 template) with greater than 1000 bases (only a portion is shown) in less than 90 min, whereas comparable gel-slab analysis would take from 8 to 18 h. The ability to sequence large polynucleotides by CE provides significant improvements relative to slab gel electrophoresis. CE is faster, uses smaller reagent and sample quantities, generates less waste, and is easier to automate.

3.4 Micellar Electrokinetic Capillary Chromatography (MECC)

As the name implies, micellar electrokinetic capillary chromatography (MECC) takes advantage of both electrophoretic and chromatographic separation mechanisms. The detector output is therefore called an electrokinetic chromatogram. MECC can separate charged and neutral analytes, but its most important application is for separation of neutral species, which cannot be separated by CZE. MECC is performed in untreated capillaries and analytes are partially solubilized by micelles added to the buffer, *i.e.*, they partition between the micellar and buffer phases. The degree to which each analyte partitions between the micelles and the buffer is the basis for separation. Electroosmotic mobility and micellar electrophoretic mobility are typically controlled so that the time an analyte spends in the micelle phase is directly related to its migration time. The micelles are analogous to the stationary phase in reversed-phase LC (see CHROMATOGRAPHY) and are referred to as a "pseudophase" because they migrate through the capillary. The use of a micellar phase to enhance electrophoretic separation was first demonstrated by Terabe *et al.* (1984). Drugs, vitamins, and

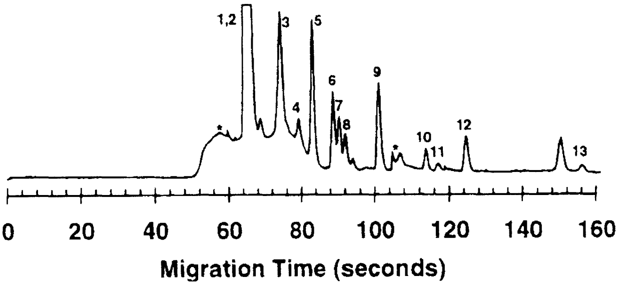

FIG. 10. MECC analysis of fifteen amino acids, allowing quantitation of ten. Sample introduction: electrokinetic injection, −100 V, 2 s. Capillary: fused silica, untreated, 10 cm long × 25 µm i.d., −12 kV applied voltage. Buffer: 0.175 *M* 2-(*N*-cyclohexylamino) ethanesulfonic acid adjusted to pH 9; containing 0.10 *M* sodium dodecyl sulfate (SDS) as the micellar additive. Detection: LIF following pre-column on-line reaction with 0.110 *M* *o*-phthaldialdehyde and 0.220 *M* β-mercaptoethanol in 0.025 *M* borate buffer at pH 9.5, He/Cd excitation (2 mW, 354 nm), photomultiplier tube detection. Elution order of analytes: 1 and 2, glutamine and serine and threonine; 3, alanine and glycine; 4, tyrosine; 5, taurine; 6, valine; 7, glutamate; 8, methionine; 9, aspartate; 10, leucine; 11, phenylalanine; 12, isoleucine; 13, lysine. Asterisks indicate peaks due to impurities and/or reagents. Reprinted (in part) from Lada and Kennedy (1996). Copyright (1996) American Chemical Society.

large peptides are among the compounds commonly determined by MECC.

Micelles are created in the buffer solution by the addition of surfactant molecules. These straight-chain molecules have a hydrophilic end and a hydrophobic end, and, above a critical micelle concentration (typically 10^{-3} *M*), they aggregate to form a micelle. The number of molecules that form a micelle is called the aggregation number and can vary from 2 to over 100. Different surfactants will have different critical concentrations and aggregation numbers. Surfactant molecules can be nonionic, anionic, cationic, or zwitterionic (*e.g.*, having both cationic and anionic functional groups). SDS, the most common surfactant used in MECC, is an anionic molecule that forms micelles with an aggregation number of 162, an average charge of −63, and an average molecular weight of 18 000. In aqueous buffers, SDS molecules orient their hydrophobic ends inward and hydrophilic ends outward. Surfactant concentration and structure determine the degree of partitioning for each analyte and therefore affect resolution and migration time. The charge/size ratio determines micelle electrophoretic mobility, and buffer *p*H control is used to keep the surfactant molecules in the correct ionic state. Hydrophilic analytes that remain in the buffer will elute first, while hydrophobic analytes remaining in the micelle will elute last. Surfactant molecules are chosen for their hydrophilic/hydrophobic balance, solubility, purity, and cost. The buffer is then chosen so that the electrophoretic mobility of the micelles is opposite to, and of lower magnitude than, the electroosmotic flow. In this manner the micelles are attracted to the inlet vial (based on electrophoretic mobility) but ultimately migrate to the detector. Finally, it should be noted that separation of chiral compounds can be achieved by the use of a chiral surfactant (such as deoxycholate or taurodeoxycholate).

Separations can be enhanced in MECC by the use of buffer modifiers. Molecules added to the buffer can change the charge of the micelle, change the solubility of the analytes in the buffer, or act as a secondary pseudophase into which the analytes partition. These can all affect analyte solubility in the micelle and therefore MECC separation characteristics. Common modifiers include organics such as methanol and isopropanol, and metal ions, which attach to the surface of the micelle. Cyclodextrins are also used as modifiers, and analytes can partition into cyclodextrin molecules on the basis of the relative sizes of the analyte and the cyclodextrin cavity and on hydrophobic/hydrophilic interactions.

Figure 10 shows an electrokinetic chromatogram of a mixture of amino acids detected in a microdialysis fluid (Lada and Kennedy, 1996). Continuous dialysate flow was mixed on line with a derivatization reagent and introduced into a flowing buffer solution (orthogonal to the capillary inlet). The buffer flow was paused periodically to allow electrokinetic injection into the capillary. Most of the derivatized analytes were unresolved under CZE conditions. In contrast, MECC using SDS micelles allowed the separation and quantitation of ten amino acids, including leucine and isoleucine. The rapid analysis time allowed for greater temporal resolution during *in vivo* monitoring. Compounds were identified by matching migration times to known standards, while unidentified peaks and the broad peak early in the electropherogram were products of side reactions or minor products detected as a result of *in vivo* conditions. The rapid analysis and high number of theoretical plates for the MECC method permitted a fast sampling rate and simultaneous quantitative monitoring of ten analytes.

3.5 Capillary Isotachophoresis (CITP)

Capillary isotachophoresis (CITP) can be used either as a separation method or as a sample preconcentration method prior to another separation mode. In CITP, the sample solution is sandwiched between two buffers, a leading buffer and a trailing (or terminating) buffer. The leading buffer contains an ion with a higher electrophoretic mobility than any analyte ions in the sample. Similarly, the trailing buffer contains an ion with a lower mobility than all those in the sample. A constant current is passed through the capillary from the high-voltage power supply, and the analyte ions segregate into individual, discrete zones. Analyte ions having the highest mobilities form a zone at the boundary near the leading buffer, whereas those with the lowest mobilities form a zone nearest the trailing buffer. In this way the analytes are "stacked" according to their mobilities, with the length of each zone determined by the total amount of each analyte present. An analyte present in a large amount in the sample, for example, will form a wide zone, while a trace component will form a narrow zone. In addition, the concentration of each analyte in its particular zone is proportional (based upon mobility factor) to the concentration of the leading buffer. Thus, CITP can be used to calibrate many analytes with only a single component concentration standard to determine the relationship between zone length and the amount of analyte.

Once the analyte zones come to equilibrium, both buffers and all analyte zones begin to migrate together to the detector, and they do so at the migration velocity of the leading buffer. The zones do not separate as in other CE modes, but remain adjacent to one another. The result is that a CITP electropherogram has an unusual step-function appearance (each step a different analyte zone) rather than the series of Gaussian-like peaks observed in the electropherograms for other CE modes. CITP is usually carried out in coated capillaries to eliminate electroosmotic flow; thus, CITP is typically used to determine anions and cations. Migration time cannot be used for analyte identification in CITP because it is a function of the number of analyte ions in the sample.

The ability of CITP to focus a trace component into a narrow, concentrated zone at a concentration level near that of the leading buffer makes it an ideal candidate for analysis of dilute samples, since they are, in effect, preconcentrated by this method. Once the analytes have been focused, additional leading buffer is loaded behind the terminating buffer to enable electrophoretic migration and analyte separation to occur. The time at which electrophoresis is initiated is important because the analytes begin to migrate after focusing occurs, and enough capillary length must remain for adequate separation. This method of focusing followed by normal electrophoresis is termed transient CITP. Focusing the analytes in this way allows very large sample volumes (>100-fold larger than other methods, filling 20–50% of the capillary volume) to be injected without loss of electrophoretic performance.

The use of transient CITP to focus and separate analytes is illustrated in Fig. 11, where the separation of various length oligomers of poly(deoxyadenylic acid) is demonstrated under varying CITP focusing conditions (Auriola *et al.*, 1996). The decrease in migration time and resolution observed in Fig. 11(d) occurred because the focusing voltage was applied beyond the point in time at which the analytes were focused. As a result, the focused analytes migrated through the capillary prior to sepa-

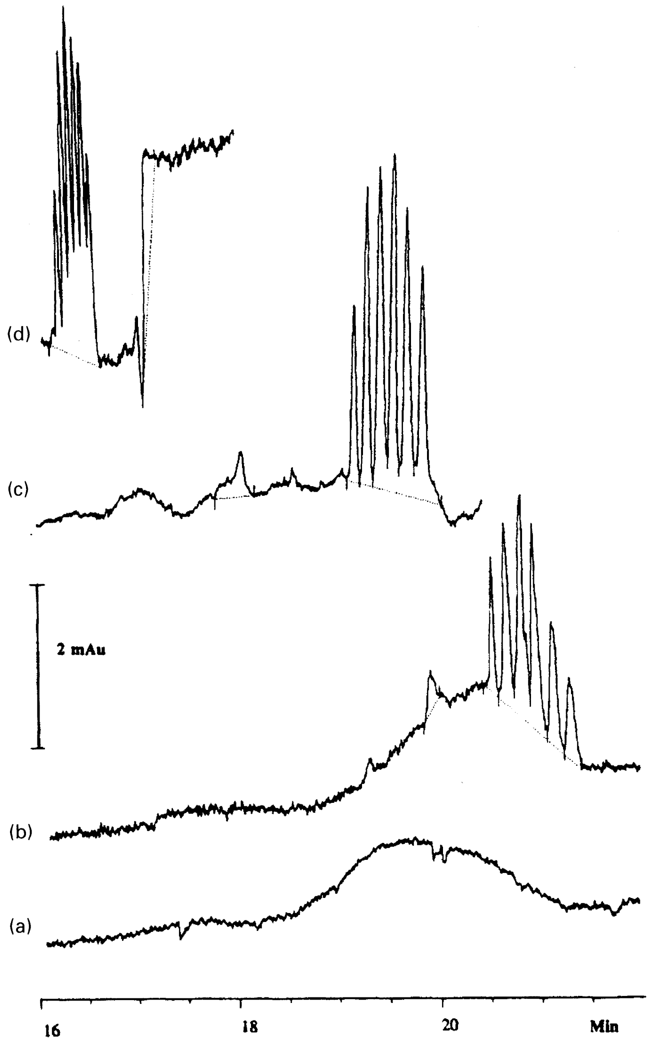

FIG. 11. Separation of poly(deoxyadenylic acid) pd(A)$_{19-24}$ oligomers with lengths of 19 through 24 units, using transient CITP. The effects of the following focusing times and voltages are shown: (a), no focusing; (b), 0.25 min; −15 kV; (c), 0.5 min, −30 kV; (d), 1.5 min, −30 kV. Sample introduction: hydrodynamic (pressure) injection, 48 s (10% of column length). Capillary: fused silica, untreated, 60 cm long ×50 μm i.d., 23 °C, −30 kV applied voltage for electrophoresis. Buffer: leading buffer 0.100 *M* ammonium formate, *p*H 4.5, containing 12% polyethylene glycol (average molecular weight 20 000) as a molecular sieving agent and to reduce EOF; terminating buffer 2-(*N*-morpholino)ethanesulfonic acid (MES) adjusted to *p*H 4.5. Detection: UV–vis absorbance at 254 nm. Elution order of analytes: pd(A)$_{19}$ through pd(A)$_{24}$ in order of increasing molecular weight. Reprinted (in part) from Auriola *et al.* (1996). Copyright (1996) American Chemical Society.

ration. This reduced the effective electrophoretic capillary length, adversely affecting electrophoretic efficiency.

3.6 Capillary Electrochromatography (CEC)

Capillary electrochromatography (CEC) is another separation method that utilizes both electrophoretic and chromatographic separation mechanisms. Similar to LC, separation in CEC is provided by the partitioning of analyte molecules between a mobile phase and a stationary phase, and it is well suited to neutral compounds. CEC uses electroosmotic flow rather than pressure to drive the mobile phase through the column. This results in better resolution than LC because it eliminates zone broadening due to parabolic flow profiles. Further, the small stationary-phase particles (1.5 μm diameter) required in LC to achieve resolutions approaching those obtained in CE require extraordinarily high pumping pressures, which are difficult to obtain in practice. Currently, CEC is only slightly (5–10 times) superior to traditional pumped-flow LC in terms of separation efficiency (N), and the expected narrow peaks are not observed on a routine basis. This has been theorized (Wan, 1997) to result from the effects of overlapping electrical double layers (on neighboring silica particles), which disturb the EOF profile. The magnitude of this perturbation decreases with increasing interparticle porosity, increasing particle diameter, and increasing buffer concentration.

In CEC, stationary phases consist of untreated or surface-modified silica particles that are typically 1.5 µm (or greater) in diameter. Untreated silica particles can contain ionizable surface groups that contribute to generation of EOF, while surface-modified particles reduce EOF in interparticle regions. The most common stationary phases are those based on siloxanes (see Chromatography), including particles that have been treated with long-chain–hydrocarbon functional groups to form $Si{-}O{-}Si(CH_3)_2{-}(CH_2)_{17}{-}CH_3$. These octadecylsilica particles, also known as C_{18} particles, are the most common stationary phase in CEC, although other particles where the C_{18} hydrocarbon group has been replaced with a more polar functional group (*e.g.*, phenyl, cyano, amino) can be used in the separation of more polar molecules. Particles can be loaded into the capillary as a dry powder or as a slurry, using either high-pressure liquid, high-pressure gas, electroosmosis, or electrophoresis. The stationary phases are retained in the capillaries by column-end frits of various designs. Common problems encountered with frits include bubble formation and zone broadening. Some research has been directed toward creating packing material by *in situ* polymerization, and such stationary phases do not require column-end frits. Pressurization of the capillary at the inlet and outlet is sometimes required to prevent solvent outgassing in CEC, which can perturb the EOF flow profile. Finally, electrokinetic injection is typically used in CEC because hydrodynamic injection is not usually capable of introducing the sample into the packed capillary.

Mobile phases commonly used in CEC are similar to those used in reversed-phase LC (see Chromatography), such as acetonitrile–water mixtures; however, a buffer salt is added to support electroosmosis and electrophoresis. Solvent gradients can be created by pressure programming, or by using a T-shaped inlet capillary in combination with two programmable power supplies to combine two different mobile phases dynamically (Yan *et al.*, 1996).

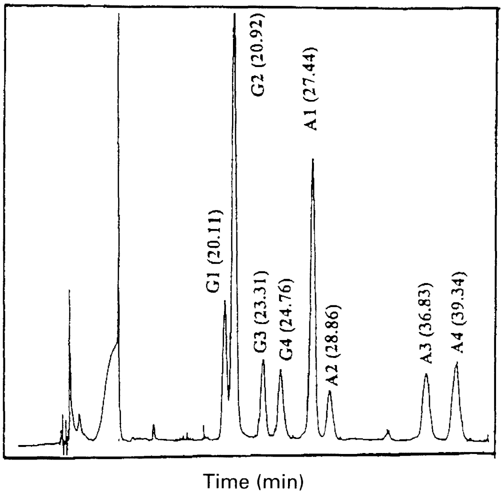

FIG. 12. CEC separation of eight diastereoisomeric deoxyguanosine and deoxyadenosine adducts of *anti*-benzo[g]chrysene. Sample introduction: electrokinetic injection. Capillary: fused silica, untreated, 40 cm long × 75 µm i.d., packed with 5 µm octadecylsilica particles, 15 kV applied voltage. Buffer: sample buffer 0.005 *M* ammonium acetate; chromatographic buffer 0.0085 *M* ammonium acetate in 29:71 acetonitrile:water. Detection: UV absorbance at 261 nm. Elution order of analytes: deoxyguanosine adduct diastereomers G1–G4 followed by deoxyadenosine adduct diastereomers A1–A4. Numbers in parentheses next to analyte peak labels are migration times in minutes. Reprinted (in part) from Ding and Vouros (1997). Copyright (1997) American Chemical Society.

CEC is often used to separate analytes that are difficult to resolve by LC, for neutral analytes not resolved by CZE, and for hydrophobic analytes not separated well by MECC. Here, CEC separations performed without surfactants (as are needed in MECC) make interfacing the capillary to some detectors, such as a mass spectrometer, less troublesome. Figure 12 shows the application of CEC to the separation of enantiomeric adducts of deoxynucleosides and anti-dihydrodiol epoxides of benzo[g]chrysene (Ding and Vouros, 1997). The relative amounts of the stereoisomers produced in the reaction between the deoxynucleoside and the epoxide provides information useful for mutagenic analysis. In this example, CEC separation results in nearly baseline resolution of all eight possible stereoisomers in the standard mixture.

GLOSSARY

Ampholyte, Amphotere: A compound that can exist as either a cation or an anion depending on buffer *p*H. In its basic form, an ampholyte is an anion, while in its acidic form, it exists as a cation.

Analyte: In capillary electrophoresis, the solute being determined.

Anode: In capillary electrophoresis, a positively biased electrode used in applying high electrical potentials across capillaries; typically immersed in the inlet buffer vial of a capillary elelctropherograph.

Anolyte: In capillary isoelectric focusing, buffer solution in the inlet (anode) vial of a capillary electropherograph.

Buffer: A solution whose composition is selected to minimize changes in *p*H that would otherwise occur as a result of chemical reactions. The *p*H is controlled by the relative concentrations of acidic and basic forms of ionizable solutes.

Capillary, Capillary Column: In capillary electrophoresis, the narrow-bore column of fused silica, Pyrex, or Teflon in which separation occurs.

Capillary Electrochromatography (CEC): Capillary electrophoresis mode whereby analytes are separated on the basis of differences in both electrophoretic migration rates and partitioning between the buffer and a chromatographic stationary phase.

Capillary Electropherograph: Instrumentation used in capillary electrophoresis.

Capillary Electrophoresis (CE): Technique for high-resolution separations of complex mixtures based on electrophoresis within small-bore capillaries.

Capillary Gel Electrophoresis (CGE): Capillary electrophoresis mode whereby analytes are separated on the basis of differences in both electrophoretic migration rates and molecular size.

Capillary Ion Analysis (CIA), Capillary Ion Electrophoresis (CIE): Capillary zone electrophoresis mode that is optimized for the analysis of small ionic species.

Capillary Isotachophoresis (CITP): Capillary electrophoresis mode used to separate analytes in dilute solutions on the basis of differences in their electrophoretic migration rates.

Capillary Isoelectric Focusing (CIEF): Capillary electrophoresis mode used to separate analytes on the basis of differences in isoelectric points.

Capillary Zone Electrophoresis (CZE): Capillary electrophoresis mode performed in open-tubular, uncoated capillaries whereby analytes are separated on the basis of differences in electrophoretic migration rates.

Cathode: A negatively biased electrode used in applying high electrical potentials across capillaries; typically immersed in the outlet buffer vial of a capillary electropherograph.

Catholyte: In capillary isoelectric focusing, the buffer solution in the outlet (cathode) vial of a capillary electropherograph.

Chromatography: Chemical separation and analysis technique based on differences in partitioning of an analyte between a solid or liquid stationary phase and a gas, liquid, or supercritical fluid mobile phase.

Dynamic Sieving Capillary Electrophoresis (DSCE): Capillary electrophoresis mode whereby analytes are separated on the basis of differences in both electrophoretic migration rates and molecular size.

Electroendosmosis, Electroendosmotic Flow, Electroosmotic Flow (EOF): Transport of neutral molecules or particles by a conducting solution under the influence of an electric field.

Electromigration: Movement of a charged species under the influence of an electric field. In electrophoresis, however, more generally used to describe the movement of all solutes, whether they be neutral or charged.

Electroosmotic Mobility: A measure of the velocity of a neutral species in an electric field of unit strength.

Electropherogram: In capillary electrophoresis, a plot of detector response as a function of migration time.

Electrophoresis: Migration, or movement, of electrically charged particles or solutes in a conductive liquid or gel under the influence of an applied electric field.

Electrophoretic Migration: See **Migration**.

Electrophoretic Mobility: A measure of the velocity of a charged species in an electric field of unit strength.

Elution: In capillary electrophoresis and chromatography, a term used to describe the process whereby the analyte exits from the separation column in a flowing medium.

Free-solution Capillary Electrophoresis (FSCE): See **Capillary Zone Electrophoresis**.

Gas Chromatography (GC): Chromatography with a gaseous mobile phase.

Gel: In slab gel electrophoresis, a two-phase colloidal system or a polymer used as a partitioning media. In capillary electrophoresis, a polymer containing a network of pores with a narrow, well-defined size distribution that is incorporated into the capillary either as a fixed, cross-linked polymer or as a non-cross-linked polymer solution.

Gel Electrophoresis: Separation and analysis technique, performed on gel slabs, where analytes are separated on the basis of differences in electrophoretic migration rates and then determined as separated zones on the slab.

Height Equivalent of a Theoretical Plate: In capillary electrophoresis and chromatography, a quantity used to describe the efficiency of a separation.

Ionic Strength: A term equal to one-half the sum of the products of concentration and squared charge for all the ionic species in solution. Denoted by the symbol I and expressed in terms of concentration units, *e.g.*, molarity.

Isoelectric Point: The *p*H of a solution in which an ampholyte or some other ionizable species is neutral and has zero electrophoretic mobility in an electric field. Denoted by the symbol *p*I.

Liquid Chromatography (LC): Chromatography with a liquid mobile phase. Also referred to as high-performance liquid chromatography.

Micellar Electrokinetic Capillary Chromatography (MECC): Capillary electrophoresis technique in which the analytes are partially solubilized by micelles added to the buffer, *i.e.*, they partition between the micellar and buffer phases. The degree to which each analyte partitions between the micelles and the buffer is the basis for separation.

Micelle: Aggregation of straight-chain molecules, each of which has both a hydrophilic end and a hydrophobic end. The aggregation occurs above a certain concentration, called the critical micelle concentration. Used in micellar electrokinetic capillary chromatography to add separation selectivity based on the degree of analyte partitioning between the buffer and micellar phases.

Migration: In electrophoresis, an abbreviated version of the term electromigration, used to describe the movement of both neutral and charged species under the influence of an electric field. Also referred to as electrophoretic migration.

Migration Time: In capillary electrophoresis, the length of time it takes an analyte to travel through the capillary.

Neutral Marker: In capillary electrophoresis, a molecule that is transported only by electroosmotic flow and can therefore be used to measure EOF mobility.

Number of Theoretical Plates: In capillary electrophoresis and chromatography, a measure of the efficiency of a particular separation scheme.

Resolution: In capillary electrophoresis and chromatography, a measure of the extent of separation achieved between two analytes.

Separation Factor: In capillary electrophoresis, the ratio of the electrophoretic mobilities of the two analytes. In chromatography, the ratio of the capacity factors (or partition coefficients) of the two analytes.

Size Exclusion Chromatography (SEC): Liquid chromatography technique that separates chemical compounds on the basis of their physical size.

Slab Gel Electrophoresis: See **Gel Electrophoresis**.

Solute: A species dissolved in a liquid.

Theoretical Plate: In capillary electrophoresis and chromatography, an imaginary unit in the capillary or column wherein one complete mechanistic separation process step occurs. For example, in micellar electrokinetic capillary chromatography, this would be a single equilibrium partitioning of the analyte between the micellar phase and the buffer phase.

Zeta Potential: In capillary electrophoresis, the potential difference across the shear plane between the layers of the electrical double layer formed at the capillary/buffer interface.

Zone: In capillary electrophoresis, a term used to describe the width and profile of an analyte band as it migrates through the capillary.

Zwitterion: A molecule containing both cationic and anionic functional groups.

INTRODUCTION

The ability to assign a time to an object's formation or to an event on historic, prehistoric, or geologic timescales relies on a set of techniques that are commonly termed dating. In practice, this can mean a variety of things depending on the field of investigation, but it usually refers to the chronological date before the present. The most widely used dating tool is the transformation of elements via radioactive decay. Depending on the choice of radioactive nuclides, times from a few days or years to the age of the solar system can be explored. Techniques based on chemical tracers and atomic transformations have also proven important as dating tools in specific applications.

The science of dating techniques is central to a broad range of disciplines, including geomorphology, geochemistry, tectonics, cosmology, art history and archaeology, paleontology, hydrology, oceanography, environmental

science, and even criminology. The field has expanded rapidly in recent years with advances in the ability to quantify very small amounts of even the rarest of nuclides. This article attempts to give a broad overview of the field as it is currently practiced, with specific references to some of the more recent work.

The first section contains brief discussions of the basic principles of radioactive decay, sources of radionuclides, and the techniques of mass spectrometry, thermoluminescence, and electron-spin resonance. The subsequent sections describe specific applications in a variety of fields. Section 2 is devoted to the uses of the primordial radionuclides. The text briefly presents each nuclide or system of nuclides with regard to its origin, uses, and limitations. Section 3 focuses on the applications of cosmogenic and anthropogenic nuclides and is aligned according to application, since a number of nuclides can be applied to a given problem. Each section has been augmented with suggested reading to provide more in-depth treatments in specific areas. Summary tables are provided to correlate nuclides with various areas of research. The interested reader is encouraged to explore the titles in the Further Reading list for discussions on the wide variety of applications.

1. BASIC PRINCIPLES

1.1 Radioactive Decay

The general term radioactive decay is applied to any process by which one nuclide transforms into another via the emission of an α particle or a β particle (positive or negative), fission, electron capture, and even, in rare cases, emission of a proton (see RADIOACTIVITY). This transformation follows a first-order rate law, with the rate of change of the number of radionuclide atoms N given by

$$\frac{\mathrm{d}N}{\mathrm{d}t} = \lambda N, \tag{1}$$

where the decay constant λ is ln2 divided by the nuclide half-life, $t_{1/2}$. In Eq. (1), $\mathrm{d}N/\mathrm{d}t$ is termed the activity and expressed in disintegrations per unit time. Integrating Eq. (1) with respect to time gives the relationship between the number of initial atoms N_0 and the number remaining after time t,

$$N = N_0 \mathrm{e}^{-\lambda t}. \tag{2}$$

Knowing the number of atoms N and with an estimate of the initial N_0, the time t over which the system has been decaying can be calculated. For example, after a time $t = t_{1/2}$, N will be equal to $\frac{1}{2}N_0$.

Alternatively, if the daughter nuclide is stable, the number of daughter atoms present at time t, D_t, is given by the number of parent atoms which have decayed in time t, $P_0 - P_t$, plus any initial daughter atoms D_0 present at time $t = 0$:

$$D_t = D_0 + (P_0 - P_t) = D_0 + P_t(e^{\lambda t} - 1). \tag{3}$$

The time t can then be obtained as

$$t = \frac{1}{\lambda}\ln\left(1 + \frac{D_t - D_0}{P_t}\right). \tag{4}$$

Equations (3) and (4) are valid only for closed systems (with no loss of parent or daughter or intermediate nuclides.)

Sometimes the parent is connected to the stable daughter through a series of shorter-lived radionuclides, such as in the ^{238}U–^{206}Pb series shown in Fig. 1. Here the parent ^{238}U decays to ^{234}Th via the emission of an α particle. The ^{234}Th goes on to decay to ^{234}Pa via β^- emission, and so on until the stable end product ^{206}Pb is reached. This chain involves a total of eight α-particle and six β^- decays. Provided the decay time of the parent is long compared with those of the intermediate products, Eqs. (3) and (4) can still be used to connect the initial parent and final stable daughter nuclides.

In the case where the measured daughter is itself decaying, the parent–daughter relationship becomes

$$D_t = D_0 \mathrm{e}^{-\lambda_2 t} + \frac{\lambda_1}{\lambda_2 - \lambda_1} P_0(e^{-\lambda_1 t} - e^{-\lambda_2 t}), \tag{5}$$

with λ_1 and λ_2 being the parent and daughter decay constants, respectively. If the parent half-life is longer than the daughter half-life, an equilibrium situation is reached after a

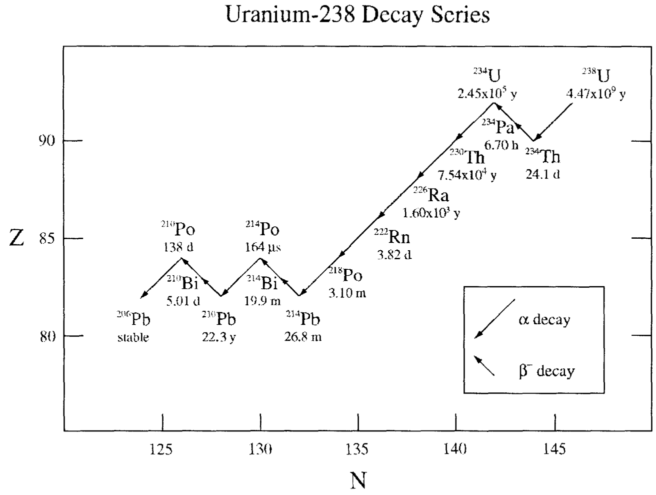

FIG. 1. Schematic diagram of the the ^{238}U decay series, displayed on a grid of proton number Z *versus* neutron number N.

few daughter half-lives, where the activity ($A = \lambda N$) ratio of the parent to the daughter, A_1/A_2, is given by $(\lambda_2 - \lambda_1)/\lambda_2$. In the case of a very long-lived parent (such as ^{238}U compared with ^{234}U in Fig. 1), $\lambda_2 \gg \lambda_1$ and $A_1 = A_2$. This is called secular equilibrium and can be extended to the activity of any nuclide in the chain, $A_1 = A_2 = A_3 \ldots.$

1.2 Sources of Radionulides

1.2.1 Primordial Radionuclides At the condensation of the solar system from the solar nebula there were a large number of unstable isotopes of the elements that are present on earth today, and even a few higher-Z elements no longer present. Most of these have since decayed to the stable nuclides that make up our natural isotopic abundances. The few exceptions are those with half-lives on the order of, or greater than, the age of the Earth (about 4.5×10^9 y). These long-lived radionuclides form the group called the primordial or primary radionuclides, because they have been around since the beginning of the solar system. Those commonly used for dating are given in Table 1, along with their half-lives.

1.2.2 Cosmogenic Radonuclides Cosmogenic nuclides are constantly being formed through nuclear reactions between the cosmic-ray flux and various constituent atoms of the Earth's atmosphere, hydrosphere, and lithosphere. Cosmic rays consist mostly of high-energy protons, about 10% α particles and 1% heavier nuclides. They originate from the Sun and from outside our solar system. The portion from the Sun shows a definite modulation, which has been correlated with sunspot activity. The Earth's magnetic field tends to focus the cosmic rays at the poles, giving a latitudinal variation in intensity. The energy distribution of the incident or primary cosmic rays is very broad and peaks around 300 MeV. This is sufficient energy to produce numerous secondary products from a single primary collision, in what is commonly termed a shower. These secondaries also include neutrons, which can interact even at very low energies via capture reactions. Lal and Peters (1967) contains an in-depth characterization of the cosmic-ray flux, its spatial distribution in height and latitude, and the resulting reactions.

The atmosphere is quite efficient at reacting with cosmic rays, with about $\frac{2}{3}$ of the atmospheric cosmogenic nuclides produced in the stratosphere and $\frac{1}{3}$ in the troposphere. Those produced in the stratosphere must first make it to the troposphere before they are removed via both wet and dry deposition.

The cosmic-ray flux that reaches the Earth's surface is greatly reduced in intensity by interactions with the atmosphere. Nevertheless, significant cosmogenic nuclides are produced by interactions of cosmic-ray components with target nuclei in the oceans, and in

Table 1. Primordial radionuclides: parent–stable daughter systems.

Parent–daughter	Parent half-life[a] (y)	Parent natural abundance (%)[a]	Applications
^{40}K–$^{40}Ar(10.72\%)$–$^{40}Ca(89.28\%)$	1.277×10^9	0.0117	Micas, volcanic rocks, glauconite

surface soils and rocks. Since cosmic rays are strongly absorbed in the surface, these *in situ* produced nuclides provide important means of studying erosion rates and exposure histories for a variety of geomorphic surfaces (Cerling and Craig, 1994; Bierman *et al.*, 1995). Figure 2 shows a representative depth profile for the neutron flux generated by cosmic-ray interactions in concrete (Liu *et al.*, 1994). Note that the flux peaks slightly below the surface. Only reactions induced by muons are important at significant depths.

1.2.3 Noncosmogenic *In Situ* Production A low flux of slow neutrons can also be generated by the reaction of α particles from U and Th with light elements such as Ca and K in the Earth via (α, n) reactions. These neutrons can be captured by ^{35}Cl to produce ^{36}Cl or by ^{235}U to induce fission. These are *in situ* processes that are not cosmogenic in origin, and are important in U- and Th-bearing deposits.

1.2.4 Anthropogenic Radionuclides The advent of the nuclear age has provided a new source of radionuclides. The atmospheric nuclear tests of the late 1950s and early 1960s spread neutron-activation and fission products around the globe that are now serving as tracers for processes on the order of 30–40 y. Examples include tritium (^3H), ^{36}Cl, and ^{129}I. This source is termed the bomb pulse and produced concentrations of tritium and ^{36}Cl in rainwater and ice cores several orders of magnitude above the prebomb background. This effect is clearly shown in Fig. 3. Man's continued activities with nuclear power reactors and nuclear fuel reprocessing have significantly elevated the global inventory of ^{129}I, producing point sources for tracing modern groundwaters and ocean circulation patterns (Rucklidge, 1995; Raisbeck *et al.*, 1994). There is also evidence for local elevated concentrations of ^{36}Cl in surface and shallow ground water from nuclear fuel reprocessing plants and reactor emissions.

1.3 Detection Techniques

1.3.1 Traditional Decay Counting The ability to determine the number of parent and daughter nuclides at a given time, or the activity due to their decay, is a necessary requirement of most nuclear dating methods. This can be achieved by measuring the nuclide directly by mass spectrometric methods or by counting the number of β or α particles emitted (or the associated γ-ray emission) in the decay and using Eq. (1) to obtain the activity. Activity can then be converted back to the number

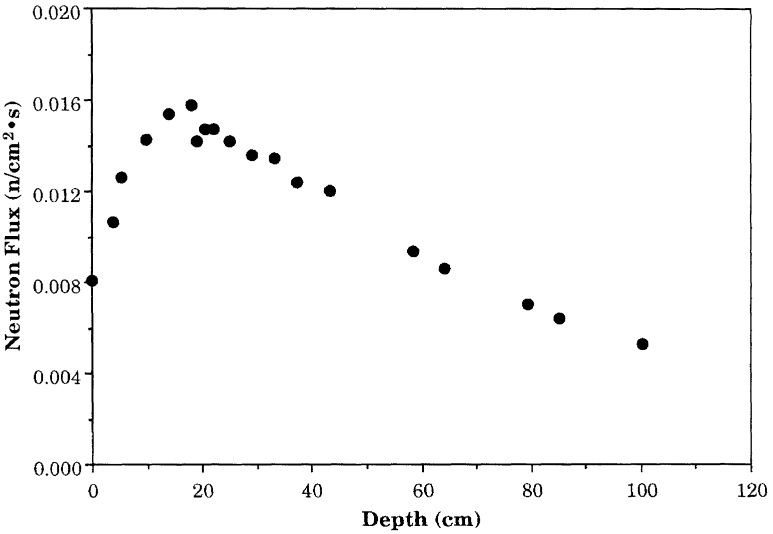

FIG. 2. Measured depth profile of neutrons produced in concrete (data from Lui *et al.*, 1994).

of atoms N or, in some cases, used directly. For example, the widely used radionuclide ^{14}C ($t_{1/2} = 5730\,y$) is traditionally quantitated by counting its β^- decays. This is possible because the average activity of "modern" prebomb carbon in the biosphere is about 13.6 decays per minute per gram carbon; counting rates above background are obtained when sufficient carbon is available. If the nuclide is very long-lived, but has a measurable abundance, then the activity is also measurable by virtue of the much greater N. This is the case with many of the nuclides in the uranium and thorium decay series. However, decay counting becomes less feasible, if not impossible, for much rarer nuclides with longer half-lives. Reviews of nu-

clear detection techniques can be found in this Encyclopedia and in Knoll (1979).

1.3.2 Traditional Mass Spectrometry Modern mass spectrometry has revolutionized the field of nuclear dating. While the ability to measure time comes from the radioactive decay clock, it is no longer necessary to count these decays to obtain an accurate estimate of the number N in Eq. (2). Only a brief overview of the technique is given here. For a more complete discussion of traditional mass spectrometric techniques the reader is referred to MASS SPECTROMETRY.

The basic principle of a mass spectrometer is the fact that accelerated ions in a uniform magnetic field will bend with radii of curvature squared, r^2, proportional to their mass to charge ratio m/q. If a sample of an element is ionized to a single charge state, then the individual isotopes of that element will appear at different positions in the focal plane of the magnet and can be individually identified. Dickin (1995) discussed the requirements as applied to measurements of geological samples, including chemical separations necessary prior to analysis and preferred means of ionization and detection. Thermal-ionization mass spectrometry (TIMS) is the most widely used means of ionization today.

The analytical quantification of the individual isotope concentration is usually achieved through isotope dilution. In this technique the sample is measured with a spike of enriched isotope of known concentration. Comparison of the results for the pure sample, the pure spike and mixtures of the two allows the initial isotope concentration to be determined. This has the advantage that any matrix effects cancel because two isotopes of the same element are compared directly.

1.3.3 Accelerator Mass Spectrometry The technique of accelerator mass spectrometry (AMS) follows the basic principles of mass spectrometry, except that in AMS the ions are accelerated to much higher energies, as high as tens of MeV. This is most often carried out in the two stages of a tandem accelerator, similar to that depicted in Fig. 4. In the first stage

negative ions from the ion source are electrically and magnetically selected for the desired mass (for example, 14 for ^{14}C determination). In some applications the negative-ion injection has an advantage in that interfering isobars (nuclides with the same mass but different nuclear charge Z) may not make negative ions (as is the case for ^{14}N in the ^{14}C determination) However, this restriction can also prove problematic for the determination of very electropositive species, such as ^{41}Ca, or noble gases such as Ar.

The negative ions are accelerated through a potential gradient to energies of 3–10 MeV (depending on the terminal voltage) at the central terminal of the accelerator. At this point the ions are passed through a stripper foil or gas and transformed into positive ions. The result is a distribution of positive charge states, which is a function of the initial ion identity and ion velocity. At this stage any residual molecular species which may have survived the initial ionization process are destroyed. The positive ions are then further accelerated back to ground potential at the exit of the accelerator.

The resultant ions exiting the accelerator have a spread in energies due to multiple charge states produced in the central stripper. These are separated in an electrostatic analyzer and/or velocity filter. An additional magnetic analyzer further reduces the background, selecting only those ions of a given mass (which now ideally have the same charge state.) This set is not necessarily unique and may still have a mix of isobars. The next major advantage of AMS is the detection of the product ions using nuclear detection techniques. These techniques are capable of counting individual atoms and separating them by their elemental Z. For example, modern AMS systems can separate ^{36}Cl from the much more common ^{36}S and measure 1 atom of ^{36}Cl in the presence of 10^{15} atoms of stable chlorine atoms (^{35}Cl and ^{37}Cl). A more thorough discussion of the technique of AMS can be found in Elmore and Phillips (1987) and Tuniz *et al.* (1998).

Accelerator mass spectrometry has opened up the area of cosmogenic nuclides to a broad range of applications, making possible studies with isotopes which are too rare or in concentrations too low to have been measured by decay counting. In the case of the widely used ^{14}C, AMS now allows measurements of much smaller samples and extends the technique to much older dates. The main disadvantage of AMS is the cost involved. Historically developed on machines built for basic nuclear physics research, the field has now come into its own with many laboratories acquiring much smaller accelerators that have been optimized for the purpose of AMS. One such facility is the National Oceans Science AMS facility (NOSAMS) at Woods Hole Oceanographic Institute, Massachusetts, U.S.A., dedicated to the measurement of ^{14}C. There are currently over 30 facilities worldwide with AMS capabilities.

1.4 Thermoluminescence and Electron-Spin Resonance

Nuclear radiation is typically called ionizing radiation because it is of sufficient energy to eject bound electrons from substances, producing free electrons and positive ions. The techniques of thermoluminescence (TL) and electron-spin resonance (ESR) rely on the trapping of these electrons by defects in the crystal structures of nonconducting solids. These defects can be vacancies, displacements (sometimes caused by the ionizing radiation itself), or impurities in the lattice, which provide sites for free electrons. The electrons usually remain trapped until dislodged by thermal vibrations (heating) or photoexcitation by ultraviolet light (as in solar bleaching). Once dislodged the electrons can diffuse through the crystal until they either become retrapped in a stable (deeper) site or recombine with a positive ion. If the recombination is radiative, light is emitted whose wavelength is characteristic of the type of luminescence center or crystal impurity. This process is called thermoluminescence (TL).

Potassium-, uranium-, and thorium-bearing minerals in the surrounding soils, or in the sample itself, provide a relatively constant flux of ionizing radiation. Therefore, the object to be dated has been accumulating dose over the period of time since it was last heated to a temperature (or exposed to the Sun's UV radiation) that released the electrons from any trapping sites and reset the TL clock. If we assume that the TL light obtained is propor-

Table 2. Primordial radionuclides: disequilibrium systems.

Nuclides	Half-lives[a]	Applications
^{238}U–^{234}U–^{230}Th	4.468×10^9 y–2.455×10^5 y–7.538×10^4 y	Carbonates: corals, shells; sediments; ferromanganese nodules/crusts

tional to the accumulated paleodose dose D_P, the time t since the last resetting of the TL clock can be calculated by

$$t = D_P/D_R. \tag{6}$$

The annual dose rate D_R is a sum of the doses due to the α, β, and γ radiations from the nuclear decays. If the sample has been near the surface for any length of time, there will also be a background flux from cosmic-ray reactions. The specific contributions of each component in a sample depend on a number of factors, including burial history and soil and sample water content (which attenuates the radiation.) When possible the γ flux is measured at the excavation site.

In practice, a material to be TL dated is sequentially heated. Different types of traps release their electrons at different temperatures, termed glow peaks, those with the highest temperatures being the most stable. By measuring the number of photons of each type emitted as a function of temperature, the total radiation dose D_P can be determined if the trapping efficiencies are known. This is usually calibrated by making TL measurements with γ-ray sources at known doses.

Since TL requires heating the sample to high temperatures, it is unsuitable for a number of materials which decompose upon heating. An alternative is the method of electron-spin resonance (ESR), which measures the microwave absorption by unpaired electrons in the material when it is placed in a varying magnetic field. Although not as sensitive as TL, ESR has the advantage of measuring the trapped electrons in their trapping centers, and thus does not require luminescence centers or annealing the material. This means that the same sample can be measured numerous times and used to calibrate the dose by adding additional radiation through exposure to γ sources. Applications include tooth enamel, bone, and calcite (Aitken, 1990). The reader is referred to PHYSICS IN ARCHAEOLOGY for additional discussions of TL and ESR.

2. TECHNIQUES BASED ON PRIMORDIAL RADIONUCLIDES

This section contains an overview of the major applications of primordial radionuclides in use today. The parent–daughter systems are summarized in Tables 1 and 2. Many of these utilize what is called the isochron method for age determination. This method is presented in Sec. 2.1.1 in relation to the Rb–Sr system. Since it is not possible to discuss each system in great depth, the reader is referred to Faure (1986), Titayeva (1994), and Dickin (1995) for details on applications of interest.

2.1 Equilibrium Techniques

2.1.1 Rb–Sr and the Isochron Method The element rubidium has two naturally occurring isotopes, ^{85}Rb and ^{87}Rb, with abundances of 74.17 and 27.83%, respectively. The dating capabilities come from the radioactive ^{87}Rb, which decays with a half-life of 4.75×10^{10} y by β^- emission to ^{87}Sr (natural abundance 7.00%). While rubidium has no minerals of its own, the ionic radius of the Rb^+ ion is close to that for the K^+ ion. Since both are alkali metals, Rb^+ replaces K^+ in all potassium-bearing minerals. The product Sr isomorphously replaces Ca in some minerals, but differs in coordination number in others.

This results in considerable variation in the Rb/Sr ratio between formations with different histories and even between different minerals in the same formation. The differentiation of Rb and Sr in magmatic melts produces Rb/Sr ratios which vary from 0.06 in basalts to 0.53 in granite, with an average value of 0.23 for the Earth's crust (Titayeva, 1994).

In principle, the time since the formation of a rock or mineral can be found by Eq. (3). In the Rb–Sr case, D_t = number of ^{87}Sr atoms in the sample, D_0 = number of initial ^{87}Sr atoms and P_t = number of ^{87}Rb atoms in the sample. However, measuring absolute abundances is very difficult. A way around this problem is to normalize everything to a nearby isotope with the same approximate abundance, and measure all three by mass spectrometry. In this case, ^{86}Sr (natural abundance of 9.86%) is chosen as the normalizing isotope, and Eq. (3) becomes

$$\left(\frac{^{87}\mathrm{Sr}}{^{86}\mathrm{Sr}}\right)_{\mathrm{sample}} = \left(\frac{^{87}\mathrm{Sr}}{^{86}\mathrm{Sr}}\right)_{\mathrm{initial}} + \frac{^{87}\mathrm{Rb}}{^{86}\mathrm{Sr}}(e^{\lambda t} - 1) \quad (7)$$

The use of Eq. (7) requires knowledge of the initial $^{87}\mathrm{Sr}/^{86}\mathrm{Sr}$ ratio. This is difficult to estimate on its own, and today determination through the construction of isochrons is the method of choice. Inspection of Eq. (7) shows that it has the form of a straight line. If a number of samples with the same age but different Rb/Sr ratios are plotted on a graph of $^{87}\mathrm{Sr}/^{86}\mathrm{Sr}$ versus $^{87}\mathrm{Rb}/^{86}\mathrm{Sr}$, the slope $e^{-\lambda t} - 1$ will give the age and the intercept gives the initial $^{87}\mathrm{Sr}/^{86}\mathrm{Sr}$ ratio of the sample, a quantity of geological interest in itself. In this case the resulting line is a true isochron. Because of the large natural abundance of the decay product ^{87}Sr and the long half-life of the parent ^{87}Rb, this technique works best when applied to samples with high Rb/Sr ratios.

Just because the data plot on a line does not necessarily mean that they are derived from samples which are the same age. One test of a true isochron is to calculate the mean square weighted deviates (described in Dickin, 1995). The MSWD, as it is commonly referred to, gives a measure of the scatter of the data points about the straight line. If the scatter is larger than predicted by the analytical uncertainties of the measurements, then the MSWD > 1. The larger the MSWD, the less likely it is that the line formed is a true isochron. This pitfall is demonstrated in Fig. 5 from Innocent *et al.* (1997), showing Rb/Sr isochrons from the dating of celadonites, green clays close to glauconite. The data in Fig. 5(a) are derived from a group of whole minerals, giving an effective age for the group of 96 ± 1 million years. However, the large MSWD of 44 suggests that there are large variations in the individual ages of the minerals, even though the group defines a single line. An alternative method is to construct an internal isochron, derived from the leachates and residues of a single mineral. Figure 5(b) is an example where the ratios for two leachates (enriched in ^{86}Sr) and the residue (depleted in ^{86}Sr, but enriched in radiogenic ^{87}Sr) are plotted along with the whole-mineral ratios. The

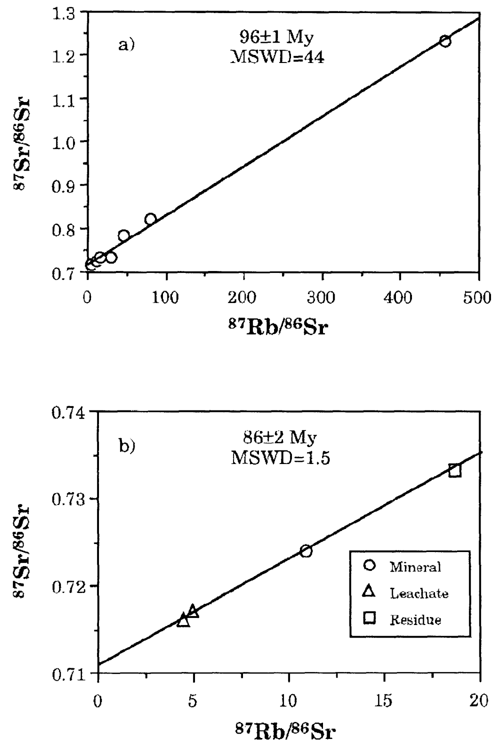

FIG. 5. Rb/Sr isochrons for (a) whole-mineral samples and (b) leachates, whole mineral, and residues for a single sample (data from Innocent *et al.*, 1997).

data clearly define a line with an extracted age of 86 ± 2 millions years for the sample (with a corresponding MSWD of only 1.5).

2.1.2 Sm–Nd There are seven naturally occurring isotopes of samarium, three of which are radioactive (see Table 1). The shortest-lived ^{147}Sm is the only one useful for dating, with a half-life of 1.06×10^{11} y and a natural abundance of 15.0%. It decays by α-particle emission to ^{143}Nb (abundance 12.18%). The isotope of choice for normalization in an equation analogous to Eq. (7) is ^{144}Nd, with a natural abundance of 23.80%. (Although ^{144}Nd is itself radioactive, its half-life is so long that is can be considered stable in this context.) Since both the parent and daughter are lanthanides, they have very similar chemistries and are not differentiated by secondary processes. This gives much more uniform natural Sm/Nd ratios in samples than is seen in Rb–Sr dating, and isochrons tend to cover a very small range in ^{143}Nd/^{144}Nd ratio. The Sm–Nd technique is particularly well suited to dating the origin of very old rocks and sediments and meteorites.

2.1.3 Lu–Hf Lutetium exists in nature as two isotopes, the stable ^{175}Lu (natural abundance 97.41%) and ^{176}Lu (natural abundance 2.59%), which has a half-life of 3.78×10^{10} y and decays by β^- emission to ^{176}Hf (natural abundance 5.206%). Standard isochron analysis can be performed using 18.606% abundant ^{177}Hf as the normalizing isotope.

One of the principal applications is in dating zircon. Since hafnium is a chemical analogue of zirconium, it is enriched in zircons and the chemical resistance of zircon to weathering makes it a good candidate for dating ancient sediments. However, ^{176}Lu/^{177}Hf is strongly fractionated in sedimentary systems. This may actually prove useful in differentiating between sediment reservoirs and recycling of basalts to the mantle.

2.1.4 Re–Os Rhenium-187 has a natural abundance of 62.60%. It decays with a half-life of 4.35×10^{11} y via β^- emission to stable ^{187}Os (natural abundance 1.6%). The two elements are strongly fractionated between mantle and crustal material, the Re being partitioned into magmatic liquids and the Os staying with the mantle material. This has the potential for studying such processes as ore formation (Freydier *et al.*, 1997), magma genesis, and mantle evolution (Esperanca *et al.*, 1997). The Re–Os system is also well suited to the study of iron meteorites, which contain relatively high concentrations of Re and Os and have large variations in the Re/Os ratios, making it easy to construct isochrons with high precision (Smoliar *et al.*, 1996). The normalizing isotope of choice is ^{188}Os, with a natural abundance of 13.3%.

The potential of Re–Os dating has only begun to be realized through advances in ionization techniques in mass spectrometry, most notably negative thermal ionization mass spectrometry (NTIMS) (Creaser *et al.*, 1991). Rhenium–osmium isochrons in iron meteorites have also been measured with AMS by Ding *et al.* (1997). The two methods compare favorably, with AMS having the advantage of being able to make measurements on single grains with no chemical preparation of the sample.

2.1.5 K–Ar, Ar–Ar The element potassium has three naturally occurring isotopes: ^{39}K, ^{40}K, and ^{41}K. The radioactive ^{40}K has a natural abundance of only 0.0117% and a half-life of 1.227×10^9 y. However, since potassium is prevalent in minerals, there is sufficient ^{40}K in the Earth's crust to be a useful dating tool. The decay of ^{40}K has two branches; β^- decay produces ^{40}Ca in 89.33% of the decays and electron capture (EC) leads to ^{40}Ar in the other 10.67%. The product ^{40}Ca is of limited use because it comprises 96.94% of natural calcium, which is very abundant in most rocks. This makes identifying the small radiogenic component essentially impossible. Argon, on the other hand, is a noble gas and rarely found naturally in rock formations. The main contaminant is atmospheric Ar, which is 99.60% radiogenic ^{40}Ar. This is overcome by using the 0.337% abundant, non-radiogenic ^{36}Ar as an indicator of atmospheric contamination, since purely radiogenic ^{40}Ar in rocks should be free of ^{36}Ar. Isochrons can also be constructed for the K–Ar system, in this case adding a separate term for the atmospheric contribution and accounting for the branching ratio for the EC decay:

$$\left(\frac{^{40}\mathrm{Ar}}{^{36}\mathrm{Ar}}\right)_{\mathrm{sample}} = \left(\frac{^{40}\mathrm{Ar}}{^{36}\mathrm{Ar}}\right)_{\mathrm{atm}} + \left(\frac{^{40}\mathrm{Ar}}{^{36}\mathrm{Ar}}\right)_{\mathrm{initial}} + \frac{^{40}\mathrm{K}}{^{36}\mathrm{Ar}}\frac{\lambda_{\mathrm{EC}}}{\lambda_{\mathrm{tot}}}(e^{\lambda_{\mathrm{tot}}t} - 1). \qquad (8)$$

The analytical techniques commonly used to obtain the individual concentrations of Ar and K are discussed in Dickin (1995). The potassium content of the sample can be found by a number of means, including x-ray fluorescence, atomic absorption, and isotope dilution mass spectrometry. The argon is determined by isotope dilution mass spectrometry using $^{38}\mathrm{Ar}$ as the known spike.

A variation on the K–Ar dating technique is Ar–Ar dating (sometimes referred to as $^{40}\mathrm{Ar}/^{39}\mathrm{Ar}$ dating). In this application the sample is placed in a fast-neutron flux and $^{39}\mathrm{K}$ (natural abundance 93.258%) is converted into $^{39}\mathrm{Ar}$ via the (n, p) reaction. The amount of potassium in a sample can then be determined by mass spectrometry of $^{39}\mathrm{Ar}$, at the same time as the other Ar determinations are being made. Since the number of $^{39}\mathrm{Ar}$ atoms formed is a function of the reactor flux Φ and the energy distribution of the neutrons, standards of known age are used as flux monitors and irradiated along with the sample. One problem with this technique is the possibility of other nuclear reactions occurring during irradiation that also produce argon isotopes, the principal ones being $^{40}\mathrm{K(n, p)}^{40}\mathrm{Ar}$, $^{40}\mathrm{Ca(n, n\alpha)}^{36}\mathrm{Ar}$ and $^{40}\mathrm{Ca(n, \alpha)}^{39}\mathrm{Ar}$. Loss of $^{39}\mathrm{Ar}$ from mineral grains due to recoil during the irradiation is also a concern.

The assumption of a closed system is often difficult to fulfill when the species is a trapped noble gas. The Ar–Ar method allows the sample to be heated incrementally and the ages determined from the argon released in each step. This is an important test of alteration in the ages due to loss of argon, with the first ages often younger than those obtained later in the heating process (Ortega-Rivera *et al.*, 1997).

Another advance in Ar–Ar dating is the application of laser microprobe ablation. This allows single grains to be analyzed and selection of specific inclusions can then be made. A portion of the September 1997 issue of *Geochimica et Cosmochimica Acta* (Vol. 61, No. 18) is devoted to papers on Innovative Applications of $^{40}\mathrm{Ar}/^{39}\mathrm{Ar}$ Microanalytical Research.

2.1.6 U–Pb, Th–Pb, Pb–Pb Lead has four naturally occurring isotopes: $^{204}\mathrm{Pb}$, $^{206}\mathrm{Pb}$, $^{207}\mathrm{Pb}$, and $^{208}\mathrm{Pb}$. Only the $^{204}\mathrm{Pb}$ is non-radiogenic. The other three are the final stable decay products of $^{238}\mathrm{U}$, $^{235}\mathrm{U}$, and $^{232}\mathrm{Th}$, respectively (see Fig. 1 and Table 1). If the time scale is long enough, each parent–daughter system satisfies Eq. (3), with $^{204}\mathrm{Pb}$ as the normalizing isotope. For example, the equation for the $^{238}\mathrm{U}$–$^{206}\mathrm{Pb}$ system is

$$\left(\frac{^{206}\mathrm{Pb}}{^{204}\mathrm{Pb}}\right)_{\mathrm{sample}} = \left(\frac{^{206}\mathrm{Pb}}{^{204}\mathrm{Pb}}\right)_{\mathrm{initial}} + \frac{^{238}\mathrm{U}}{^{204}\mathrm{Pb}}(e^{\lambda t} - 1), \qquad (9)$$

with analogous equations for $^{235}\mathrm{U}$–$^{207}\mathrm{Pb}$ and $^{232}\mathrm{Th}$–$^{208}\mathrm{Pb}$. In principle, isochrons can be constructed for each of these three systems, but in practice the requirement of a closed system is usually difficult to meet on account of the mobility of Pb, Th, and U. Nevertheless, direct isochron dating has been successful in certain applications, such as marine sediments (Smith and Farquhar, 1989) and ore-stage calcite (Brannon *et al.*, 1996).

Lead usually exists as Pb^{2+} with an ionic radius of 0.12 nm, which makes it the wrong charge and too large to fit into the lattice of zirconium, uranium, or thorium minerals. This means that the only lead present in these minerals can usually be considered radiogenic. [Corrections for any initial lead are made by determining the $^{204}\mathrm{Pb}$ content (natural abundance 1.4%).] For these cases the $^{235}\mathrm{U}$–$^{207}\mathrm{Pb}$ and $^{238}\mathrm{U}$–$^{206}\mathrm{Pb}$ decay equations then simplify to

$$^{207}\mathrm{Pb}_{\mathrm{radiogenic}} = {}^{235}\mathrm{U}(e^{\lambda_{235}t} - 1) \qquad (10)$$

and

$$^{206}\mathrm{Pb}_{\mathrm{radiogenic}} = {}^{238}\mathrm{U}(e^{\lambda_{238}t} - 1) \qquad (11)$$

The applicability of U–Pb dating is greatly

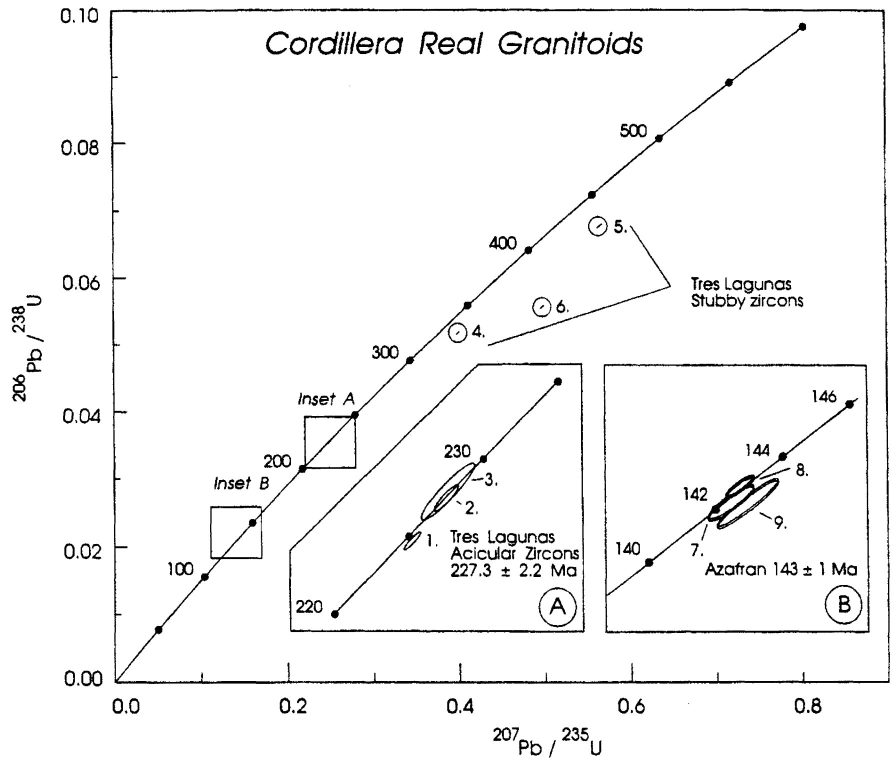

FIG. 6. Concordia plot of $^{206}\text{Pb}/^{238}\text{U}$ as a function of $^{207}\text{Pb}/^{235}\text{U}$ (from Noble *et al.*, 1997, reproduced by permission of Geological Society of America). The ages along the curve are indicated by the numbers, in units of Ma (My). Samples labeled 4, 5 and 6 are clearly discordant.

expanded by creating what are termed concordia plots. Since the decay constants are known, plots of $^{206}\text{Pb}/^{238}\text{U}$ as a function of $^{207}\text{Pb}/^{235}\text{U}$ for varying times should give a unique curve called a concordia. If there has been loss of radiogenic lead, the data will be discordant and will fall off the curve. Since the mechanisms for lead loss should be the same for the two uranium isotopes, the discordant points fall on a straight line below the concordia. Extrapolation of this discordant line to the concordia curve gives the "true" age of the sample. Figure 6 is an example of a concordia for zircons taken from Noble *et al.* (1997).

Alternatively, the ratio of Eqs. (10) and (11) gives

$$\left(\frac{^{207}\text{Pb}}{^{206}\text{Pb}}\right)_{\text{radiogenic}} = \frac{^{235}\text{U}(e^{\lambda_{235}t}-1)}{^{238}\text{U}(e^{\lambda_{238}t}-1)}, \qquad (12)$$

with the $^{235}\text{U}/^{238}\text{U}$ ratio well known to be 1/137.88. Application of Eq. (12) is called Pb–Pb dating, since it only requires knowledge of the ratio of two isotopes of lead. The Pb–Pb ratios are a reflection of the Pb/U ratios; however, they have the advantage of being quite insensitive to recent conditions that might produce uranium loss, since it is the radiogenic daughter lead isotope which is measured. Taking into account any initial ^{206}Pb and ^{207}Pb and using the isochron technique of normalizing to the nonradiogenic ^{204}Pb gives

$$\frac{\left(\frac{^{207}\text{Pb}}{^{204}\text{Pb}}\right)_{\text{sample}} - \left(\frac{^{207}\text{Pb}}{^{204}\text{Pb}}\right)_{\text{initial}}}{\left(\frac{^{206}\text{Pb}}{^{204}\text{Pb}}\right)_{\text{sample}} - \left(\frac{^{206}\text{Pb}}{^{204}\text{Pb}}\right)_{\text{initial}}} = \frac{1}{137.88}\frac{(e^{\lambda_{235}t}-1)}{(e^{\lambda_{238}t}-1)}. \qquad (13)$$

While this cannot be solved in closed form for the time t, computer integration yields isochrons as a function of time, which can be matched to the data. This technique is used when recent loss of uranium is suspected.

The Pb–Pb technique was first applied to meteorites. The Diablo Canyon meteorite produced an age of 4.55×10^9 y. Subsequent studies using Pb–Pb dating have shown that some deep ocean sediments lie on the Diablo Canyon isochron. This isochron is considered characteristic of the age of the Earth and now called the geochron. Numerous other special applications of U–Pb dating have been used to study the evolution of the Earth. For further variations and applications the reader is referred to Titayeva (1994) and Dickin (1995).

2.2 Nonequilibrium Techniques and the U–Th Decay Chains

The methods discussed in Sec. 2.1 all utilize simple parent–daughter decay, where the daughter is stable. However, inspection of Fig. 1 for the decay of ^{238}U shows that the final stable product ^{206}Pb is the result of a complex sequence of decays. Similar decay schemes connect ^{235}U to ^{207}Pb and ^{232}Th to ^{208}Pb. If conditions are right to remove and isolate one of the intervening long-lived decay products, this will then be the parent for its own decay chain. If an unstable daughter nuclide is monitored, the daughter formation and decay follows Eq. (5). Deviations from secular equilibrium also provide opportunities to gain information by monitoring the intermediate radionuclides. There are numerous possibilities, a few of which will be described here. The reader is referred to Faure (1986) and Dickin (1995) for more extensive treatments.

2.2.1 ^{238}U–^{234}U–^{230}Th System: Dating of Corals and Ocean Sediments One example of a non-equilibrium situation is the ^{238}U–^{234}U–^{230}Th parent–daughter system. In a marine environment, uranium exists as soluble carbonates which are readily incorporated into corals and shells along with calcium carbonate. In contrast, thorium is insoluble and is absorbed onto detrital particles, precipitates, and is preferentially incorporated into sediments. Therefore, the ^{232}Th/^{238}U ratio in seawater is very low (on the order of 10^{-5}) and the ^{230}Th/^{238}U ratio in seawater is about 10^{-5} times what would be obtained from ^{238}U equilibrium decay (Edwards *et al.*, 1986). Growing coral incorporates ^{234,238}U along with the carbonate, but will have very little of the daughter ^{230}Th initially. Monitoring the subsequent decay of ^{234}U and in-growth of ^{230}Th provides an important means of dating coral formations as old as 500 ky, a timescale inaccessible using radiocarbon dating.

In the ^{238}U–^{234}U–^{230}Th system, with the assumption of no initial ^{230}Th, Eq. (5) leads to

$$1 - \left[\frac{^{230}\mathrm{Th}}{^{234}\mathrm{U}}\right]_{\mathrm{act}} = e^{-\lambda_{230}t} - \left[\frac{\delta^{234}\mathrm{U}}{1000}\right] \times \left(\frac{\lambda_{230}}{\lambda_{230} - \lambda_{234}}\right)[1 - e^{(\lambda_{234}-\lambda_{230})t}], \qquad (14)$$

where the subscript "act" denotes activity ($A = \lambda N$). The δ^{234}U is a measure of the deviation of the ^{234}U/^{238}U activity ratio from unity (secular equilibrium) and is defined as

$$\delta^{234}\mathrm{U} = \left[\frac{\left(\frac{^{234}\mathrm{U}}{^{238}\mathrm{U}}\right)}{\left(\frac{^{234}\mathrm{U}}{^{238}\mathrm{U}}\right)_{\mathrm{equil}}} - 1\right] \times 1000, \qquad (15)$$

and

$$\delta^{234}\mathrm{U}(t) = \delta^{234}\mathrm{U}(0)e^{-\lambda_{234}t}. \qquad (16)$$

If the ^{234}U and ^{238}U were in secular equilibrium is seawater, the δ^{234}U would be zero and the second term on the right of Eq. (14) would vanish. However, this is not the case, and in practice isochrons are constructed of the activity ratios of ^{234}U/^{238}U as a function of ^{230}Th/^{234}U.

The dating of corals has been important in studies of sea-level stance and climatic fluctuation of the Pleistocene era. The use of TIMS has made coral dating possible with samples as small as 200 mg and analysis of growth rings. This now allows extension of the ^{14}C calibration curve to ages older than accessible by dendochronology (Bard *et al.*, 1990). Applications can also be made to shells, but in this case the possibility of secondary impurities is dealt with by successive stripping and measuring the individual fractions.

A second simplifying case occurs for ocean sediments and ferromanganese nodules (thorium coprecipitates with the Fe and Mn hydroxides), where there is essentially no parent ^{234}U to feed the ^{230}Th; this is called unsupported ^{230}Th. For example, the decay of the ^{230}Th can be followed as a measure of sedimentation rate R, with $^{230}\mathrm{Th} = {}^{230}\mathrm{Th}_{\mathrm{initial}}e^{-\lambda_{230}t}$. A graph of log(^{230}Th activity) versus depth should give a straight line with a slope $-\lambda_{230}/R$. This is usually true for shallow depths, but the effect of U-supported ^{230}Th usually shows up as depth increases. This can be corrected for by determining the ^{234}U content (which is a measure of the ^{230}Th activity in secular equilibrium with any uranium) and subtracting this from the total ^{230}Th activity.

2.2.2 ^{235}U–^{231}Pa

The radionuclide ^{231}Pa is the first long-lived nuclide in the ^{235}U decay chain

$$\begin{aligned}&^{235}\mathrm{U}(t_{1/2} = 7.04 \times 10^6\,\mathrm{y})\\ &\quad\rightarrow {}^{231}\mathrm{Th}(t_{1/2} = 25.5\,\mathrm{h})\\ &\quad\rightarrow {}^{231}\mathrm{Pa}(t_{1/2} = 3.28 \times 10^4\,\mathrm{y}) \rightarrow \ldots .\end{aligned}$$

Hence, in a closed system ^{231}Pa can be considered in equilibrium with its parent ^{235}U. However, in seawater ^{231}Pa is similar to ^{230}Th and is absorbed onto particulate matter and rapidly incorporated into sediments. This leaves the seawater rich in ^{235}U, but almost devoid of the daughter ^{231}Pa, allowing dating of corals by following the ingrowth and decay of ^{231}Pa (Edwards *et al.*, 1997). Under conditions where the system had no initial ^{231}Pa and was closed with respect to ^{231}Pa and ^{235}U, the time elapsed since closure is given by

$$t = \frac{-\ln\left(1 - \left[\frac{^{231}\mathrm{Pa}}{^{235}\mathrm{U}}\right]_{\mathrm{act}}\right)}{\lambda_{231}}, \tag{17}$$

where "act" denotes the ratio of the activities of ^{231}Pa and ^{235}U. It has been proposed that since both ^{231}Pa and ^{235}U are daughters of uranium isotopes, concordia could be constructed and used in a manner similar to the U–Pb dating of minerals. (See the discussion in Sec. 2.1.6.)

2.2.3 ^{210}Pb

Lead-210 is a short-lived ($t_{1/2} = 22.3$ y) intermediate in the decay chain of ^{238}U (see Fig. 1). It is produced in the atmosphere by the decay of ^{222}Rn, which is a noble gas and escapes from the earth at a rate of about 42 atoms/min cm^2 (Faure, 1986). With a residence time in the atmosphere of only 10 d, the ^{210}Pb is quickly removed by precipitation and becomes an excellent dating tool for snow pack and glaciers. In water columns ^{210}Pb has a residence time of 1–2 y before it becomes attached to sediment particles. Since the lead is now removed from its radioactive precursors, it decays away unsupported with a half-life of 22.3 y, making it useful for dating sediments over a period of several hundred years. Under the assumption of a constant deposition rate, the age of a sample can be found by solving Eq. (2) as applied to ^{210}Pb in units of atoms or activity,

$$^{210}\mathrm{Pb} = {}^{210}\mathrm{Pb}_{\mathrm{initial}}e^{-\lambda_{210}t}, \tag{18}$$

where $^{210}\mathrm{Pb}_{\mathrm{initial}}$ is the value at the surface. In a plot of log (^{210}Pb) versus depth, the slope gives the sedimentation or accumulation rate. The major limitation is the contribution from ^{210}Pb generated from ^{226}Ra in the sediments. This contribution is termed supported, since it should be in equilibrium with the long-lived ^{226}Ra and any intermediate decay products. The supported ^{210}Pb can be corrected for by the measurement of ^{226}Ra (or the short-lived intervening daughters).

While the ^{210}Pb itself emits a low-energy β particle that is difficult to detect, it has traditionally been quantitated by measuring the β decay of its daughter ^{210}Bi or the α decay of the ^{210}Po daughter. However, advances in γ-ray spectroscopy have made the direct measurement of ^{210}Pb possible through detection of its 46.5-keV γ ray (Böllhofer *et al.*, 1994). This has the advantage of also allowing detection of any ^{226}Ra ($E_\gamma = 186.1$ keV) or its daughters ^{214}Pb ($E_\gamma = 352.0$ keV) and ^{214}Bi ($E_\gamma = 609.3$ keV), important in correcting for any supported ^{210}Pb. Lead-210 dating is now

Table 3. Extinct radionuclides (adapted from Dickin, 1995).

Parent–daughter	Parent half-life[a]	Daughter natural abundance (%)[a]
^{244}Pu–fission products including ^{132}Xe, ^{134}Xe, ^{136}Xe	8.08×10^{7} y	26.9, 10.4, 8.9
^{129}I–^{129}Xe	1.57×10^{7} y	26.4
^{107}Pd–^{107}Ag	6.5×10^{6} y	51.839
^{53}Mn–^{53}Cr	3.74×10^{6} y	9.501
^{60}Fe–(^{60}Co)–^{60}Ni	1.5×10^{6} y (1.9251×10^{3} d)	26.223
^{26}Al–^{26}Mg	7.4×10^{5} y	11.01
^{41}Ca–^{41}K	1.03×10^{5} y	6.7302

an established method for dating marine and lake sediments. It has recently become important in supplying dates that can be correlated with anthropogenic activities, such as lead and other heavy-metal deposition and radioactive fallout.

2.3 Extinct Radionuclides

The nucleosynthetic processes that produced the naturally occurring nuclides found on Earth today also produced numerous unstable nuclides that have long since decayed away to their stable daughter products. In fact, many of our stable nuclides are the ultimate end points of the decay of short-lived radioactive species. Only the longest-lived ones are still around for us to study today. However, the evidence for now extinct radionuclides can be found in meteorites, which preserve remnants of the original solar nebula from which our solar system condensed. This evidence is in the form of the anomalous isotopic abundances of daughter nuclides. If the radiogenic component can be isolated from that which was directly produced, limits can be set on the time between the nucleosynthesis event and the formation of the meteoritic material in which the isotope was found. However, this requires a number of assumptions on the initial nucleosynthesis-produced isotopic ratios, the time over which the production occurred, and the possible mixture of sources.

Table 3 (adapted from Dickin, 1995) lists a number of extinct radionuclide systems that have been studied in meteorites. They cover a range of half-lives from 10^{5} to 10^{7} y. Combining time estimates for a number of systems provides constraints on production scenarios that cannot be obtained with a single system alone. For example, times derived from measuring ^{129}Xe and xenon isotopes in ^{244}Pu fission fragments are consistent with a delay of on the order of 100 My between nucleosynthesis and closure of the system to xenon loss. However, studies of the shorter lived radionuclides in Table 3 also provide evidence for a late injection of material into the solar nebula between 2 and 20 My before condensation.

2.4 Fission-track Methods

The kinetic energy released when a heavy nucleus such as uranium undergoes fission is on the order of 200 MeV. This large amount of energy is divided between the two fission products (and any neutrons) according to the law of conservation of momentum. If the fission were symmetric (giving two equal-size fragments), then each would carry away about 100 MeV of kinetic energy. These heavy, high-Z, energetic fragments are highly ionizing and produce damage tracks in their stopping material.

The only naturally occurring radionuclide that has a significant spontaneous fission branch is ^{238}U. Even this is very small, accounting for only 0.0001% of all ^{238}U decays. However, given the moderately large concentrations of uranium in many minerals, the effects of the stopping of fission products in the material are clearly observable. If the damage

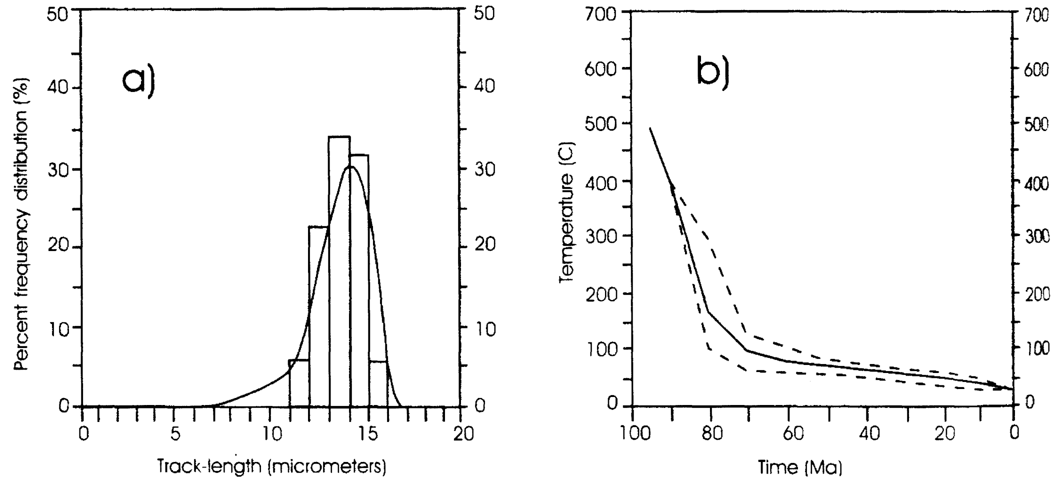

FIG. 7. Results of modeling fission track lengths (from Ortega-Rivera *et al.*, 1997, reproduced by permission of Geological Society of America). (a) Comparison of measured track-length distributions (histogram) and model length distributions (solid curve). (b) Time–temperature ranges for 250 acceptable solutions generated by the model (dashed curve.) The solid line represents the exponential-mean solution.

tracks are enhanced by etching with acid or alkaline solution, they can be counted and used as a measure of the integrated dose received by the material. The dose can be calibrated by exposing like materials to known fluxes of induced fission fragments and comparing the number of etched tracks. A thorough discussion of the analytical techniques can be found in Dickin (1995) and Ravenhurst *et al.* (1994).

How long fission tracks stay preserved depends on the material type and the thermal history. In general, the annealing process can be described by a simple Boltzmann distribution, where the annealing time can be written as a function of the material specific activation energy U and the absolute temperature T:

$$t = Ae^{U/kT}, \tag{19}$$

with A a calibration constant and k the Boltzmann constant.

Considerable work has been done on the effects of temperature on track annealing in apatites (Laslett *et al.*, 1987). As tracks anneal they decrease in length, producing a length distribution that can be modeled in terms of a time and temperature profile. The partial annealing zone (PAZ) is sensitive to temperatures as low as 60–110 °C. Figure 7(a), from Ortega-Rivera *et al.* (1997), shows a track length profile from an apatite from the Sierra San Pedro Martir pluton in Baja California. A model fit to the track distribution gives the time–temperature relationship constraints shown in Fig. 7(b). The fission-track technique is well suited to studies of cooling, exhumation, and denudation histories of tectonic formations and the effects of erosion on these formations (Johnson, 1997).

2.5 (U–Th)/He Thermochronometry

The α decays in the uranium and thorium parent–daughter systems produce radiogenic helium, which can be retained in rock masses. Recent work in apatite is providing a new means of tracking thermal histories of low-temperature processes by following the diffusive loss of He. The closure temperature in apatite is around 75 °C, with partial retention occurring between 40 and 75 °C (Wolf *et al.*, 1997). This is analogous to the partial annealing zone in fission-track dating (see Sec. 2.4) and can provide a means of extending studies on apatites to lower temperatures than accessible via fission-track analysis. The analytical details of the technique can be found in Wolf *et al.* (1996).

2.6 Thermoluminescence (TL) Dating Applications

Dating artifacts via TL has been an important part of art history and archaeology. The technique was first pioneered for dating pottery and other baked clays, being applied to both the clays and glazes. In this usage the TL light typically comes from the quartz and feldspars in the clay, with the clock reset to zero upon firing of the pot. Both bulk pottery fragments and mineral grains can be dated. In alkali feldspars with a high potassium content, the paleodose is mainly internal, coming from the decay of ^{40}K. This has the advantage of being less sensitive to the moisture content of the surroundings than the external dose.

The widespread availability of fired clay at most archaeological sites makes TL a particularly useful dating tool. While TL dating is not as accurate as radiocarbon dating for samples with ages between 1000 and 10 000 y, it is often the method of choice for ages older than 10 000 y, where the radiocarbon time scale is poorly calibrated, or for samples younger than 1000 y, where radiocarbon can give ambiguous ages (see Sec. 3.1). The ability of TL to extend to ages older than those accessible by radiocarbon is particularly important for paleontological artifacts such as burnt flint and cooking stones.

The TL dating limit depends on the lifetimes of the trapping sites and the saturation light sum. Quartz has proven to be an excellent paleodosimeter for Quarternary deposits, since it does not reach its saturation light sum until a total dose of 10^4 Gy, which means that it can be sensitive to times as long as 10^6 y, depending on the dose rate. This is in contrast to radiocarbon's practical limit of around 50 000 y. Geological applications of TL include lunar material and meteorites, volcanic eruptions, sediments, and stalagmitic calcite. Specific applications and techniques can be found in Aitken (1985) and Aitken (1990).

3. TECHNIQUES BASED ON COSMOGENIC NUCLIDES

Cosmogenic nuclides provide access to time scales much shorter than the primordial radionuclides. Since they are constantly being produced, radionuclides with half-lives as short as 53 d (as in the case of ^{7}Be) can prove useful. Table 4 lists the main cosmogenic nuclides used as dating tools today, along with their production modes, half-lives, and relevant applications. Until the advent of accelerator mass spectrometry (AMS), relatively large sample sizes were necessary to obtain nuclide concentrations, using low-level decay counting. However, not all of the nuclides in Table 4 are currently measurable by AMS at levels low enough to be useful, and decay counting is still an important analytical technique. Today cosmogenic nuclides are finding uses in a broad range of research areas, from archaeology and paleontology, to paleoclimate and ocean circulation studies, to hydrology and geomorphology, and even cosmology. The following subsections highlight a few of these, with a separate section devoted to ^{14}C.

3.1 Carbon-14

The most widely used cosmogenic nuclide is probably ^{14}C, commonly termed radiocarbon. Carbon-14 is produced in the atmosphere primarily through the reaction ^{14}N(n,p). It is rapidly incorporated into atmospheric CO_2 and becomes thoroughly mixed with the global carbon pool, showing little variation with latitude. When a plant or animal dies it is removed from active exchange with the carbon pool, and its radiocarbon content will steadily decrease as the ^{14}C decays. Carbon-14 has been a mainstay of archaeology since Libby first proposed using it as a dating tool in the 1950s (Libby, 1955), and many laboratories still specialize in radiocarbon dating through decay counting. The archaeological applications of ^{14}C are discussed in PHYSICS IN ARCHAEOLOGY.

One of the biggest challenges to obtaining accurate radiocarbon dates is the calibration of the time dependence of the atmospheric equilibrium ^{14}C/C ratio. This varies with the cosmogenic production rate through the effect of solar cycles and the Earth's magnetic field on cosmic ray flux. An additional effect on atmospheric ^{14}C has been the increasing use of fossil fuels. This has been diluting the natural radiocarbon reservoir with nonradioactive

Table 4. Cosmogenic nuclides.

Nuclide	Production modes	Half-life[a]	Applications
^{3}H	^{14}N(n, ^{3}H)^{12}C[b,c], ^{6}Li(n, α)^{3}H[d]	12.33 y	Post-bomb groundwater dating
^{3}He	^{14}N, ^{16}O(spallation)[c,e] ^{3}H(β^-decay)[b,e]	Stable	Exposure dating
^{7}Be	^{14}N(n, 3p5n)[c], ^{14}N(p, 4p4n)[c] ^{16}O(p, 5p5n)[c]	53.29 d	Soils and sediments
^{10}Be	^{14}N(p, 4pn)[c] ^{16}O(spallation)[c,e]	1.51×10^{6} y	Soils and sediments, erosion rates and exposure dating, glacial ice
^{14}C	^{14}N(n, p)[b,c] ^{16}O(p, ^{3}H)[c,e] ^{17}O(n, α)[d]	5730 y	Erosion rates and exposure dating, ocean studies, groundwater studies, soil and sediments, glacial ice, paleodating, archaeological artifacts
^{21}Ne	^{24}Mg(n, α)[e], ^{23}Na(n, p2n)[e]	Stable	Exposure dating

carbon (termed dead carbon), causing a steady decrease in the equilibrium atmospheric ^{14}C/C ratio, called the Suess effect after the individual who first observed it. Even more recently, nuclear bomb tests have elevated the atmospheric ^{14}C/C ratio.

The unit usually used to express ^{14}C in a sample is Δ^{14}C(‰), which is defined using a

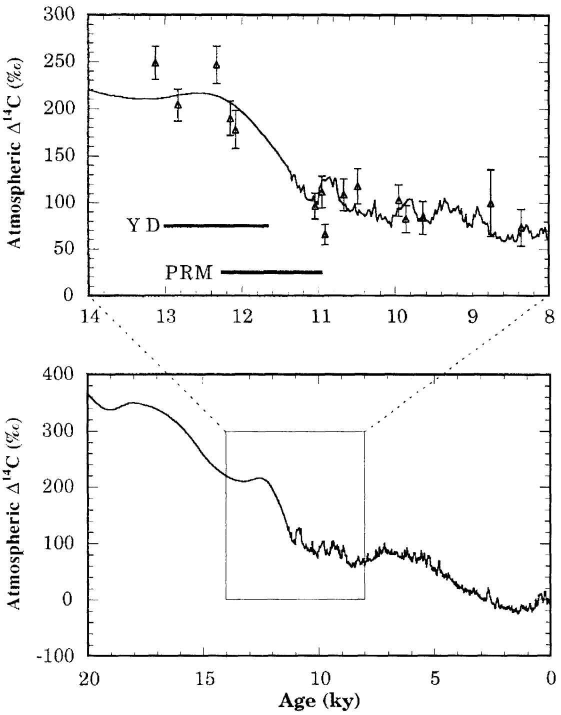

FIG. 8. Atmospheric radiocarbon expressed as Δ^{14}C [actually plotted as the negative of Eq. (20)] as a function of age, derived from bidecadal tree-ring data and U/Th coral data (obtained from CALIB program as described in Stuiver and Reimer, 1993). The triangles are the coral data from Edwards *et al.* (1993), plotted against ^{230}Th date.

prebomb-era oxalic acid carbon standard as

$$\Delta^{14}\mathrm{C}‰ = \frac{\left(\frac{^{14}\mathrm{C}}{^{12}\mathrm{C}}\right)_{\mathrm{sample}} - 0.95\left(\frac{^{14}\mathrm{C}}{^{12}\mathrm{C}}\right)_{\mathrm{standard}}}{0.95\left(\frac{^{14}\mathrm{C}}{^{12}\mathrm{C}}\right)_{\mathrm{standard}}} \times 1000. \tag{20}$$

The 0.95 is a correction factor to modern ratios. A Δ^{14}C value of zero is defined at 1950 as modern carbon. The more negative the value, the older the radiocarbon age. Positive values reflect input from bomb-produced carbon and are termed post-modern. [Note that in some cases the negative of Eq. (20) is defined as Δ^{14}C, as in Fig. 8.]

The field of dendochronology (tree-ring dating) has been a key to understanding the variation in Δ^{14}C and its correlation with absolute dates, but is limited to around 10 000 years. *Calibration* dates have recently been extended by the study of corals (which grow in layers like trees), correlating radiocarbon dates with those obtained from independent U–Th dating (Bard *et al.*, 1990; Edward *et al.*, 1993). (See Sec. 2.2.1.) Figure 8 shows Δ^{14}C as a function of age as derived from bidecadal tree-ring data and U–Th coral dates (Stuiver and Reimer, 1993). It is clear that there are regions of the curve where a single ^{14}C value does not correspond to a unique age. As the expanded region shows, there can be considerable variation over both long and relatively short times due to fluctuations in the cosmic-ray flux (see Sec 1.2.2). In cases where a series of Δ^{14}C measurements have been made at what are interpreted as regular time intervals, the ambiguity in the age determination can be reduced by matching the trend in the sequence of Δ^{14}C values. This technique is referred to as wiggle matching.

Applications of ^{14}C have expanded tremendously since AMS made measurements of small samples feasible. For example, the coral records in the Huon Peninsula, Papua, New Guinea, in conjunction with the ^{230}Th *dating*, show interesting signatures of changes in the atmospheric–oceanic exchange of ^{14}C during

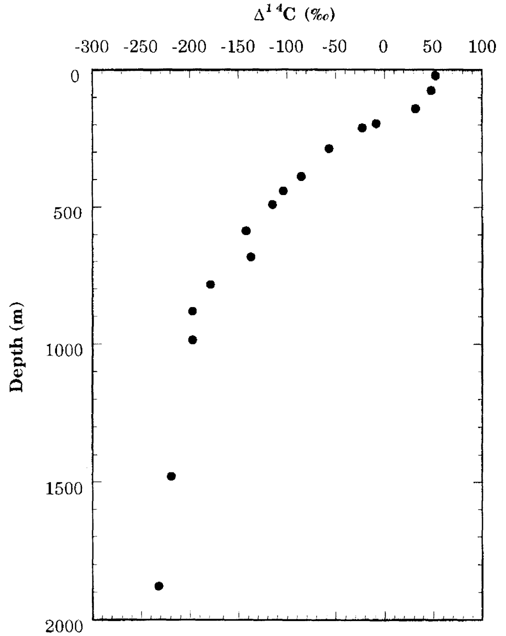

FIG. 9. Depth profile of the Δ^{14}C in ocean water, measured for a site in the Pacific Basin collected as part of the World Ocean Circulation Experiment (WOCE) (data from von Reden *et al.*, 1997).

the Younger Dryas (YD) climate event and the period of reduced melting (PRM) since the last major ice age (Edward *et al.*, 1993). These data are shown as the triangles in the expanded graph in Fig. 8. The times of the YD and PRM are marked by the horizontal bars and correspond to a rapid change in the inferred atmospheric Δ^{14}C.

Studies of radiocarbon in the oceans were carried out long before AMS was available, using large-volume samples. Now small-volume samples are being measured at the National Ocean Sciences AMS facility (NOSAMS) at Woods Hole Oceanographic Institute with a precision of better than 0.4%, rivaling that obtained using decay counting (von Reden *et al.*, 1997). Figure 9 shows a ^{14}C depth profile for a site in the Pacific basin, which is part of the data set collected in the World Ocean Circulation Experiment (WOCE). The surface waters clearly show the influence of bomb carbon. The deep waters have reached an equilibrium value. Similar results have been obtained for the Canadian Basin of the Arctic Ocean (Schlosser *et al.*, 1997). The differences in radiocarbon content of surface and deep waters provide a tool for studying ocean currents and mixing.

Another application of ^{14}C dating is the ages of sediments in lakes and peat bogs. Figure 10 shows the results of dating a sediment core from Germany and its correlation to the pollen analysis showing the history of the prevailing vegetation at the site (Kretschmer *et al.*, 1997). The time scale for ^{14}C also makes it perfect for dating many groundwater aquifer systems. This has been attempted with varying degrees of success using both the dissolved CO_2 (inorganic carbon, DIC) and the dissolved organic carbon (DOC) (Murphy *et al.*, 1989; Drimmie *et al.*, 1991). In the case of DIC, corrections must be made for any dissolution of carbonate minerals. Using DOC to obtain an age requires knowledge of the radiocarbon age of the initial input and the assumption of no addition of dead carbon by subsurface bacterial activity producing organic compounds from kerogen sources. The input function can be either contaminated with anthropogenic ^{14}C or much older than modern by reason of the long residence time of organic matter in soils. Dating of soil organic matter has been shown to be quite complex, and a detailed understanding of the maturation process at a given site is needed before radiocarbon ages can be interpreted (Y. Wang *et al.*, 1996).

3.2 *In Situ* Dating of Geological Formations

The production of radionuclides inside mineral grains from cosmic-ray interactions has been used to estimate erosion rates and exposure ages of surface land forms. This is a multidimensional problem, with the radionuclide concentration changing with the time exposed to cosmic rays and the flux of cosmic rays. The cosmic-ray flux is a function of depth (see Sec. 1.2.2) and can change over time by either surface erosion (which will increase the flux) or burial (which decreases the flux). An additional effect is the change in tilt of the surface, which changes the path length of the cosmic rays and the attenuation. Add to this the fact that the flux of cosmic rays is a function of latitude and can vary as a result of solar and geomagnetic factors, and the complexity of the problem becomes apparent.

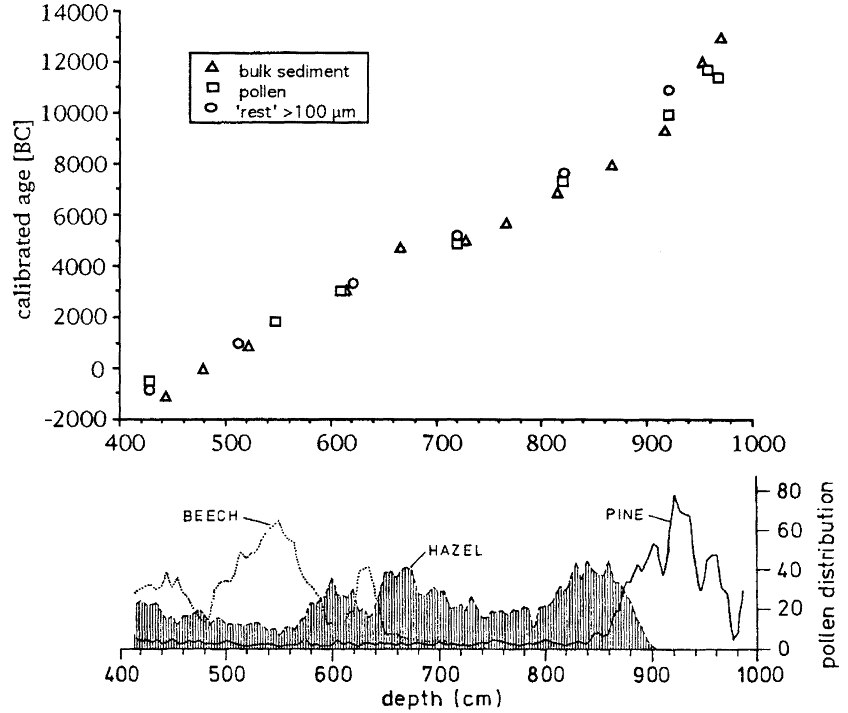

FIG. 10. Calibrated radiocarbon ages of sediment constituents as a function of depth, compared with the vegetation type determined from pollen analysis, for a site in Germany (data from Kretschmer *et al.*, 1997, drawing reproduced by permission of North-Holland Publishing Co.).

In the simplified case of a flat surface exposed to a constant flux, the concentration of the cosmogenic nuclide N_i in atoms g^{-1} is given by

$$N_i = \frac{P_i}{\lambda_i + \varepsilon/k}\left\{1 - \exp\left[-\left(\lambda_i + \frac{\varepsilon}{k}\right)t\right]\right\} + N_0 e^{\lambda t}, \qquad (21)$$

where P_i = production rate, atoms (g-ky)$^{-1}$; λ_i = decay constant, ky^{-1}; ε = actual erosion rate, cm ky^{-1}; k = scale depth, calculated as cosmic-ray attenuation coefficient Λ divided by the density ρ; t = actual time, ky; and N_0 = initial concentration, atoms g^{-1} (notation after Gillespie and Bierman, 1995). In Eq. (21) the attenuation of the cosmic-ray flux is assumed exponential with depth. However, this is not strictly true of the neutron flux generated, which peaks at a depth of about 20 cm before displaying exponential behavior (see Fig. 2).

In the case of negligible erosion, with no initial concentration N_0, Eq. (21) reduces to

$$N_i = (P_i/\lambda_i)(1 - e^{-\lambda_i t}). \qquad (22)$$

In this limiting case, the concentration of a single isotope can give the exposure age. The solutions to Eq. (22) for some commonly used cosmogenic isotopes are displayed graphically in Fig. 11. Alternatively, if an independent estimate can be found for either erosion rate or exposure age, other can be found. In either case, a steady state is eventually reached. This is shown in Fig. 12(a) for the buildup of ^{10}Be in quartz for various erosion rates. When the cosmogenic isotope is stable, a steady state is still reached as a result of the erosion rate, as shown in Fig. 12(b).

If both erosion rate and exposure time need to be determined, this can be achieved by measuring two isotopes in the same sample. Isotopes usually paired are ^{10}Be, ^{26}Al, and ^{36}Cl. Readers are referred to Lal (1991), Cerling and Craig (1994), Gillespie and Bierman

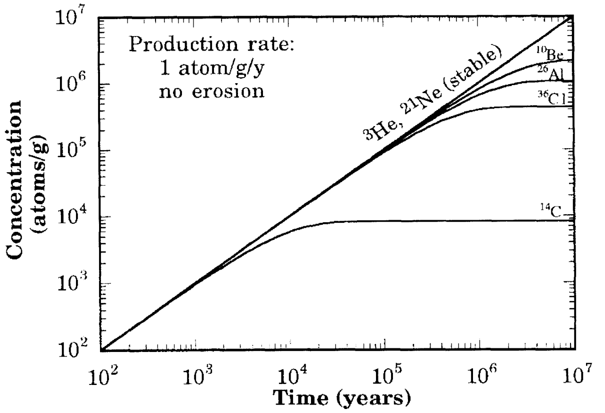

FIG. 11. Buildup of various nuclides with time for the case of no erosion [Eq. (22)].

(1995), and Clark *et al.* (1995) for discussion of the many considerations needed to obtain accurate results from this technique. An interesting application is the study of the Canyon Diablo meteorite. Surface-exposure dating of the surrounding crater using ^{10}Be/^{26}Al (Nishizumi *et al.*, 1991) and ^{36}Cl (Phillips et al., 1991) agreed with the thermoluminescence date of 49 000 ± 3000 y (Sutton, 1985). Measurements of the *in situ* ^{10}Be, ^{26}Al, and ^{36}Cl in the meteorite itself were used to estimate the production rates before the meteorite's fall to Earth. Because of the relatively short half-lives of the radionuclides, it could be assumed that

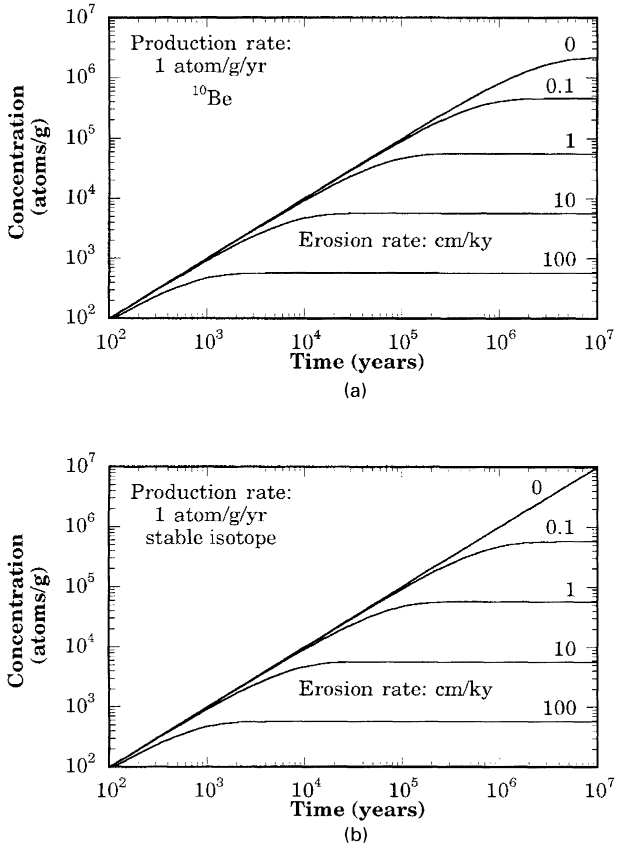

FIG. 12. Build-up of (a) ^{10}Be and of (b) a stable nuclide with time for different erosion rates, calculated with Eq. (21) using $k = 57$ cm.

they had reached equilibrium at the time of the fall, with production equaling decay. After correcting for the time on Earth, the production rate as a function of preatmospheric depth could be found. Using the ratio of the radionuclide activity to a stable noble-gas concentration ($^{10}Be/^{21}Ne$, $^{26}Al/^{21}Ne$, and $^{36}Cl/^{36}Ar$) as an integrator of the exposure period, the cosmic-ray exposure ages of six samples were found to give means of 560 ± 130 My for $^{10}Be/^{21}Ne$, 550 ± 170 My for $^{26}Al/^{21}Ne$, and 470 ± 120 My for $^{36}Cl/^{36}Ar$ (Michlovich *et al.*, 1994). Differences among samples were attributed to variations in production rates due to matrix effects (elemental composition) and irradiation geometries.

3.3 Ice Cores, Ocean and Soil Studies

3.3.1 Atmospheric Beryllium-10 in the Lithosphere and Hydrosphere Beryllium-10 has a very short residence time in the atmosphere, being strongly adsorbed onto aerosol particles and removed by wet and dry deposition. Both processes provide pathways for entrance into the hydrosphere. Profiles of ^{10}Be in ice cores and snow packs have been used as a measure of cosmic-ray flux variations and correlated with other cosmogenic isotopes, such as ^{14}C and ^{36}Cl. Arctic and Antarctic ice cores show clear evidence of the effects of the 11 y sunspot cycle (Beer *et al.*, 1990; Steig *et al.*, 1996). The influence of geomagnetic variations is less evident, with conflicting reports on the importance of latitudinal mixing (Raisbeck *et al.*, 1985; Mazaud *et al.*, 1994; Steig *et al.*, 1996).

Under the right conditions, ^{10}Be can be used as a dating tool for sediments and soil cores. Beryllium becomes attached to surface soils and can produce ^{10}Be-rich soils. If the mobility and initial deposition rate can be approximated, then a depth profile can give an age estimate (Graham *et al.*, 1997). More often, however, the concentration profile is affected by climatic variations, which can produce decreases by increased dissolution (wetter) or enrichment from glacial melt or erosion runoff. Dry climates produce more windblown soils, which are usually enriched in ^{10}Be (Gu *et al.*, 1996). Graham *et al.* (1997) studied two cores from the Wanganui region of New Zealand that had been previously characterized by magnetic analysis (Turner and Kamp, 1990). A large sixfold enhancement in ^{10}Be during the Matuyama–Brunhes magnetic transition has been interpreted as only partly due to the reversal. Since the date coincides with the beginning of an interglacial period of warming, the enhancement could be due to increased erosion and soil input and/or melting of adjacent ice sheets.

In the oceans ^{10}Be both attaches to particles and has a soluble phase, which lengthens the residence time to hundreds of years. Beryllium-10 concentration profiles in deep ocean waters are consistent with that of deep sea sediments. L. Wang *et al.* (1996) have shown that the direct atmospheric contribution (as separated by leaching with NaOH) is relatively constant, while that derived from the lithosphere is influenced by climate factors that increase erosion and runoff and by changes in ocean circulation patterns.

3.3.2 Aluminum-26 in the Oceans Another potential cosmogenic nuclide for ocean studies is ^{26}Al. The majority of the ^{26}Al in the oceans is atmospheric in origin. Once it enters the ocean, it is rapidly scavenged and locally deposited. This is in contrast to ^{10}Be, which can travel considerable distances from its source before being deposited. While the atmospheric $^{26}Al/^{27}Al$ ratio is readily measured with AMS, dilution from ^{27}Al derived from eroded crustal material has put determination of ^{26}Al in bulk sediment cores close to the AMS detection limit. A new leaching technique using NaOH now allows separation of the ^{26}Al-enriched atmospheric component and brought the $^{26}Al/^{27}Al$ ratios well within the capabilities of AMS (Wang *et al.*, 1996). When compared with ^{10}Be it may be possible to distinguish the effects of ocean dynamics and climate from variations in the cosmogenic input.

3.4 Groundwater Dating

3.4.1 Natural Sources Naturally occurring (nonanthropogenic) cosmogenic radionuclides that have the potential of dating groundwaters include ^{14}C, ^{36}Cl, ^{39}Ar, ^{81}Kr, and ^{129}I. All of these are produced in the atmosphere and enter groundwaters through wet and dry deposition, either dissolved in water droplets or attached to aerosol particles. The half-life of ^{14}C (5730 y) makes it well suited for dating waters up to around 50 000 y. The potential uses of ^{14}C and their associated complications have been discussed in Sec. 3.1. Argon-39 is relatively short-lived ($t_{1/2} = 269$ y) and can be used as an indicator of more modern water. Krypton-81, with a half-life comparable to that of ^{36}Cl, has not found widespread use on account of the analytical difficulties of measurement. Should these be overcome, ^{81}Kr may prove to be a nuclide with the fewest interfering contributions as a tool for groundwater dating (Lehmann *et al.*, 1993). The remaining nuclides, ^{36}Cl and ^{129}I, have the potential to provide ages for groundwaters that are well beyond the reach of ^{14}C. They are readily measured via AMS as ratios to their stable isotopes, $^{36}Cl/Cl$ and $^{129}I/I$. Background atmospheric levels are well above the detection limits of 1×10^{-15} for $^{36}Cl/Cl$ and 1×10^{-14} for $^{129}I/I$, providing the ability to follow their decays through several half-lives. With half-lives of 3.01×10^5 y for ^{36}Cl and 1.57×10^7 y for ^{129}I, these two nuclides could provide a range of ages from 0.1 to 80 My (Fabryka-Martin *et al.*, 1987; Frölich *et al.*, 1991).

Chloride is soluble in aqueous systems and is generally considered to be a conservative tracer in groundwaters, although there may be evidence of retention of the bomb pulse in surface soils. Aside from radioactive decay, factors that influence the $^{36}Cl/Cl$ ratio are changes in the chloride and cosmogenic ^{36}Cl of the recharge water, introduction of salt from ancient trapped brines or formation waters, diffusion of salts from the aquifer material, and subsurface production of ^{36}Cl (Fabryka-Martin *et al.*, 1989; Nolte *et al.*, 1991). Much the same is true for ^{129}I, except that the atmospheric input is expected to vary less with time by reason of an additional atmospheric contribution from volcanoes emitting ^{129}I from ^{238}U fission and the large buffering capacity of the oceans for ^{129}I. The residence time of ^{129}I in the oceans is long enough for mixing to occur with little decay. This is in contrast to ^{36}Cl, which is negligible in the oceans, because of its shorter half-life, and which has a very pronounced temporal dependence on the cosmic-ray production.

The subsurface production mechanism for ^{129}I is directly as a fission product of ^{238}U. In the case of ^{36}Cl, the main subsurface production mode is from the $^{35}Cl(n,\gamma)$ reaction on chloride in the water itself. The neutrons come from the interaction of α particles, emitted in the U–Th decay chain, with light elements such as K and Ca in the surrounding minerals, via (α, n) reactions. In some settings, as in the Stripa mine in Sweden, these subsurface sources dominate and the $^{36}Cl/Cl$ and $^{129}I/I$ ratios increase with depth, limiting their direct use as dating tools (Andrews *et al.*, 1986, 1989). It may actually be possible to use the buildup of these isotopes to obtain residence-time estimates.

While subsurface production will increase isotopic ratios, the introduction of old (dead) chloride or iodide from the aquifer material or from salt in the initial recharge water will decrease the ratio. It is well documented that the chloride concentration in rainwater decreases with distance from the coast as the influence of marine chloride decreases (Bentley *et al.*, 1986; NADP/NTN, 1990). In a study of the Aquia aquifer in southern Maryland, U.S.A., the chloride profile was found to vary with flow distance in a manner consistent with the amount of marine chloride in the recharge water, as governed by changing distance from the sea in the period covering the last glacial maximum (Purdy *et al.*, 1996). The variation in total chloride concentration can be corrected for by multiplying by the $^{36}Cl/Cl$ ratio to obtain the concentration of ^{36}Cl directly, usually expressed as atoms L^{-1}. However, this quantity is now sensitive to dilution and/or concentration effects caused by changing climatic conditions at recharge (changes in rainfall and/or evapotransporation), as well as variations in the cosmic-ray flux. Unfortunately, the time scale of interest is outside the range of good flux monitors; otherwise, ^{36}Cl concentration in confined aquifers might be a good measure of paloeclimate.

The initial promise of a simple technique for dating groundwater has not been fulfilled. However, cosmogenic isotopes have provided another experimental dimension to test models of groundwater systems and to provide constraints on ages within a given set of conditions.

3.4.2 Anthropogenic Sources The activities of man in the nuclear age have produced additional sources of nuclides commonly identified with cosmogenic processes. The bomb tests in the late 1950s and 1960s produced large pulses of tritium (^3H), ^{14}C, ^{36}Cl, and ^{129}I. Atmospheric levels of tritium and ^{36}Cl have mostly returned to prebomb levels (Bentley *et al.*, 1982 and Fig. 3), with the notable exception of nuclear reactor and fuel reprocessing sites (Milton *et al.*, 1994). This is not true of ^{129}I, which is being continually released by the nuclear power industry in quantities sufficient to have maintained elevated levels. All except tritium have half-lives long enough to serve as tracers of modern input for the far future. Even tritium, with its 12-y half-life, is still readily detectable (directly or as its decay product ^3He), and its short half-life can be used for modern age determinations (Schlosser *et al.*, 1988). The so-called bomb pulse can therefore serve as a dating tool for modern input. This might better be called a tracer, but its detection puts a definite time frame to a process, be it the advance of a contaminant plume in groundwaters (Solomon *et al.*, 1995) or the movement of currents in the ocean (Santschi *et al.*, 1996).

3.5 Silicon-32: The Potential

The widespread use of ^{32}Si as a dating tool has been hampered by the difficulty in achieving $^{32}Si/Si$ ratios below modern levels through AMS (Morgenstern *et al.*, 1996). This has limited studies to events that have elevated ratios or to the use of laborious processing for decay counting, requiring large sample sizes. The half-life of ^{32}Si is also poorly known, but recent work using AMS may improve this. The great lure of ^{32}Si is that, with a half-life of around 140 y, it fills a gap in dating that is left between tritium and ^{14}C. Exploratory studies (Morgenstern *et al.*, 1995, 1996) show promise as a dating tool in glacial ice, groundwaters, and sediments, and as a tracer for ocean circulation (Somayajulu *et al.*, 1987).

4. PALEOMAGNETISM

Paleomagnetism as a dating technique relies on the fact that the Earth's molten core is not static but dynamic, causing the resultant magnetic field of the earth to vary over time. When heated to a high enough temperature, usually 500–700 °C, certain minerals, such as hematite and magnitite, acquire magnetic alignments to the Earth's magnetic field, which persist upon cooling. These remnant fields can be measured and compared with the known reversals in the Earth's magnetic field. If a single date can be fixed by an independent technique, then the correspondence of the changing fields allows dating of the remaining samples. Details of magnetic analysis and its use as a dating tool are presented in PHYSICS IN ARCHAEOLOGY and in Aitken (1990).

5. AMINOSTRATIGRAPHY AND AMINOCHRONOLOGY

Amino acids are the building blocks of proteins. Once an organism dies, chemical changes due to hydrolysis take place, which gradually break the proteins into smaller groups called peptides. Amino acids may exist as internal constituents of a peptide chain, as terminal amino acids at either end of a protein or peptide, as a cyclic structure formed from two small peptides, or as free amino acids. The specifics of the diagenetic process are dependent on protein composition and thus the organism involved. After fossilization of shell material as much as 50% of the original protein content may be lost. However, that which remains is relatively stable and can be used as a relative dating tool.

Natural amino acids (except glycine) in proteins from living organisms exist in a form which has a unique stereospecific configuration due to the spatial arrangements of their atoms. This is termed L and is distinct from another spatial configuration of the same molecule (termed D). When synthesized in a laboratory, equal amounts of L and D are formed, but nature produces only L to give a ratio of D/L of 0.0. Over time some amino acids change their configurations from L to D, such that the equilibrium ratio of D/L is equal to 1.0 in very old fossils. This process of conversion is called racemization, and the 50–50% mixture is termed racemic. When an amino acid contains two groups that have this symmetry difference, but only one changes, the term epimerization is used. This is true of leucine, which can exist

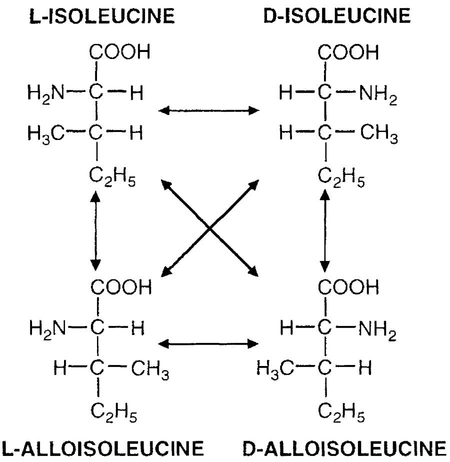

FIG. 13. Stereochemical configurations of isoleucine (after Mitterer *et al.*, 1993).

as epimers isoleucine or alloisoleucine, each of which also has L and D configurations. This difference is demonstrated in Fig. 13 (after Mitterer, 1993). The general term racemization is usually also applied to epimerization.

The rate at which racemization occurs is a very sensitive function of temperature. For this reason, it is most often used as a relative measure in aminostratigraphy, the ordering of what are termed aminozones by their D/L ratios for a specific amino acid. These zones can be dated if a specific group or zone can be correlated with a known age, as determined by an independent technique such as radiometric dating. Aminochronology is the application of these calibrated D/L ratios to predict ages for uncalibrated samples. This involves modeling the time dependence of the racemization for the appropriate temperature conditions (Wehmiller, 1993).

Racemization rates are also dependent on the specific type of organism studied. For example, under the same conditions of temperature, floraminifera from the genus *G. tumida* has a different rate of racemization from that of the genus *O. universa*. This effect is shown in Fig. 14(a), where the ratio of D-alloisoleucine to L-isoleucine is plotted as a function of age for the two genera, obtained from the same deep-sea sediment core (Müller, 1984). In some cases concordia plots for two genera can be constructed and used to determine age in the same manner as those for radiogenic nuclides (see Sec. 2.1.6). Figure 14(b) shows this for the data displayed in Fig. 14(a).

The very sensitive temperature dependence of the rate of racemization can be used in the framework of a kinetic model to predict temperature variations in Quaternary deposits during the last ice age. This technique has been applied to mollusk shells in the Mississippi Valley. Radiocarbon and thermoluminescence dating were used to obtain the time scale. Figure 15 shows the effective diagenetic temperatures (EDT) derived from modeling the rates of epimerization of isoleucine in five genera of gastropods (Oches *et al.*, 1996). The results are plotted along with the mean annual air temperature from 1951 to 1980.

Paleontological applications of aminostratigraphy and aminochronology can be found in Wehmiller (1993) and the references therein. Specific applications in archaeology are discussed in Aitken (1990).

6. CHLOROFLUOROCARBONS

An example of an anthropogenic source that can be turned into a modern dating tool is the release of compounds classified as chlorofluorocarbons (CFCs). First manufactured in the 1930s, these compounds were valued for their stability and used extensively as refrigerants and propellants until they became implicated in the destruction of stratospheric ozone. They are highly problematic because they have been accumulating rapidly in the atmosphere and have residence times of 120 y for CCl_3F (trade name F-11) and 60 y for CCl_2F_2 (trade name F-12) (Derra, 1990). It is just this stability which makes them excellent tracers of modern processes.

The detection of CFCs in groundwaters indicates post-1945 input, and studies have correlated CFC concentrations with tritium dating. Its use as an actual dating technique requires accurate profiles of the change in atmospheric CFC concentrations and the temperature of the recharge zone over time. Sorption onto soils is also a consideration. Details of the use of CFCs and the analytical techniques required can be found in Busenberg and Plummer (1992).

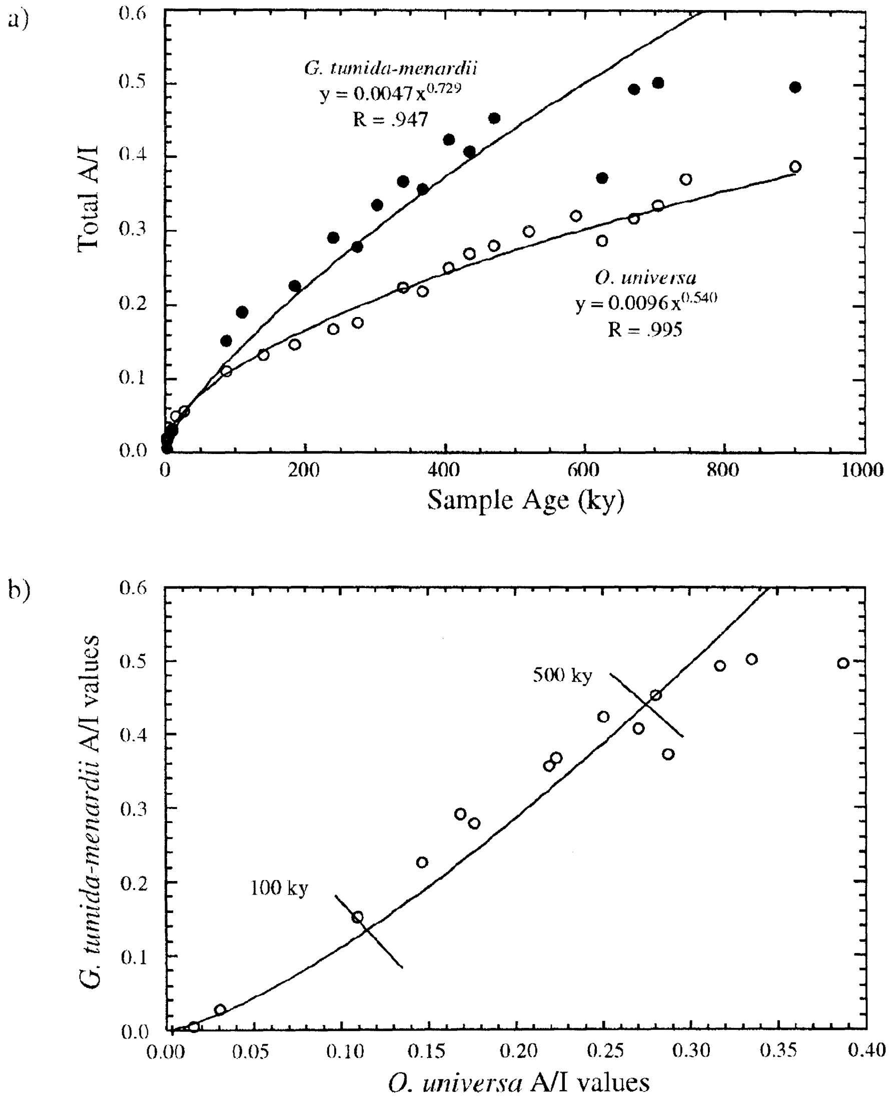

FIG. 14. (a)Ratio of D-alloisoleucine to L-isoleucine (A/I) as a function of time for floraminifera *G. tumida-menardii* (solid circles) and *O. universa* (open circles), measured in the same deep-sea sediment. (b) Concordance in the (A/I) ratios for *O. universa versus G. tumida-menardii*, plotted from the data displayed in part (a). Data from Müller (1984).

7. CONCLUSION

The application of techniques that can provide either absolute or relative chronologies is central to a wide range of research in the fields of geology, hydrology, oceanography, archaeology, paleontology, cosmology, and the environmental sciences. This article has provided an overview of techniques used today and some of the possible applications. Each has its strengths and weaknesses, requiring different sets of assumptions for validity. Hence, the study of a specific process or system is best served when a range of dating tools is

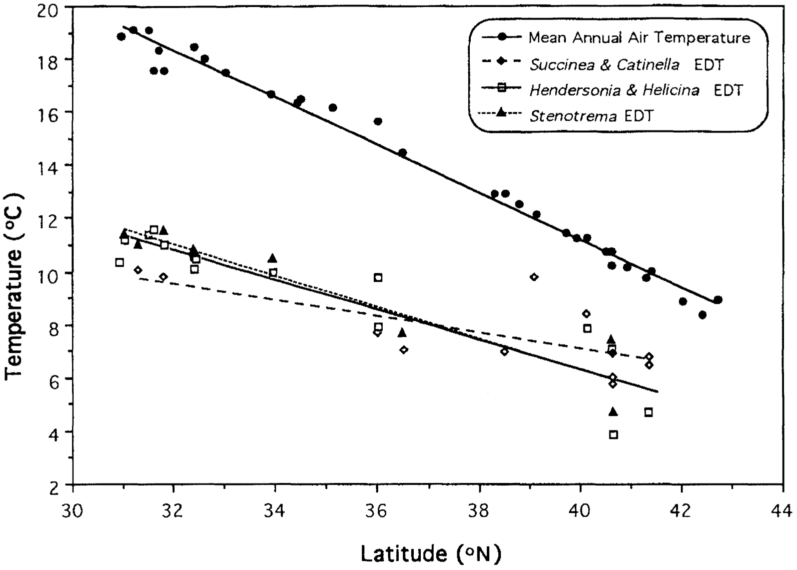

FIG. 15. Temperature profile for ice-age gastropods as a function of latitude in Mississippi Valley loess, as derived from modeling the epimerization rates of leucine. The mean annual air temperature for the period 1951–1980 is shown in the upper curve for comparison (from Oches *et al.*, 1996).

drawn upon to corroborate results. As in the cases of AMS and TIMS, analytical advances are constantly making these tools accessible to new areas of research.

GLOSSARY

Alpha Particle (α): Nucleus of a helium atom, consisting of two protons and two neutrons.

Anthropogenic: Influenced by the impact of man.

Apatite: A group of hexagonal minerals consisting of calcium phosphate together with fluorine, chlorine, hydroxyl, or carbonate.

Basalt: A dark-colored igneous rock, commonly extrusive, composed primarily of calcic plagioclase and pyroxene. Apatite and magnetite are almost always present.

Beta particle (β): A positive or negative electron that is emitted from the nucleus during radioactive decay.

Calcite: A common rock-forming mineral, $CaCO_3$, a chief constituent of limestome and most marble.

Connate: Water trapped in the interstices of sedimentary rock at the time the rock was deposited.

Dose: A measure of energy deposited in a material by ionizing radiation (α, β, γ).

Feldspar: A group of abundant rock-forming minerals of the general formula $M\mathrm{Al(Al,Si)_3O_8}$, where M can be K, Na, Ca, Ba, Rb, Sr or Fe.

Floraminifera: Large single-celled animals with a calcareous shell of calcium carbonate or calcite.

Gamma ray (γ): High-energy electromagnetic radiation emitted when a nucleus converts from a higher energy state to a lower.

Gastropod: A class of mollusks that includes snails and slugs.

Glauconite: A green mineral closely related to micas and essentially a hydrous potassium iron silicate.

Hematite: A common mineral containing Fe_2O_3, found in igneous, sedimentary and metamorphic rocks.

Hydrosphere: The waters of the Earth, as distinguished from the rocks (lithosphere), living things (biosphere) and the air (atmosphere).

Igneous: A rock or mineral that has solidified from molten material, e.g., magma.

Lithosphere: The solid portion of the earth.

Loess: A blanket deposit of buff-colored calcareous silt, homogeneous, nonstratified, weakly coherent, and porous; considered to be windblown dust of the Pleistocene age.

Magnetite: A black, opaque, strongly magnetic mineral of the group $(Fe,Mg)Fe_2O_4$.

Muon: A weakly interacting particle, similar to an electron but more massive.

Nuclide: A specific type of nucleus, with a given number of protons and neutrons.

Paleo: Old or ancient.

Pleistocene: The early epoch of the Quaternary period, which ended around 8000 y ago.

Pluton: An igneous intrusion.

Quarternary: Geologic time period from present back to 1.8 My ago.

Quartz: Crystalline silica, an important rock-forming mineral, SiO_2.

Radiogenic: Formed as the result of radioactive decay.

Radionuclide: A nuclide that is unstable and decays to another nuclide.

Tectonic: Pertaining to the forces involved in or the resulting structures of tectonics.

Tectonics: Branch of geology dealing with the broad architecture of the outer part of the earth.

Zircon: A mineral, $ZrSiO_4$.

INTRODUCTION

This article focuses on interferometric techniques, which are various methods for obtaining and analyzing an interferogram (fringe pattern) in an interferometer (see Interferometers and Interferometry). An interferogram is the recorded interference signal between two beams of light exiting from the same radiation source. An interferogram carries information about the phase (the difference between the two wave fronts of the beams), the spectral content of the source, and its spatial distribution. These three phenom-

ena, and the major interferometric techniques used to collect these data, provide the general topics discussed in this article. First is a discussion of phase measurement (see Secs. 1 and 4); next is a brief examination of the spectral distribution of the source (see Sec. 6), followed by a look at the spatial distribution of the source (see Sec. 7). By combining techniques it is possible to measure more than one of these phenomena at a time (see Sec. 6.3).

In the discussion of phase measurement a distinction between techniques that detect phase at a single point and those that detect across the plane of an interferogram is made. Techniques that measure phase are used to image test-object characteristics such as surface topography, optical-system quality, homogeneity of media, relative position of targets, and existence of gravity waves. Measuring the spectral distribution of radiation is one of the oldest applications of interferometry; a description of two basic interference spectrometers is provided in this article. The techniques that astronomy has developed for testing the spatial distribution of source radiation in the measurement of stellar diameters are also briefly described. Finally, because phase can represent so many characteristics, a number of techniques adapted from those based on phase measurement are mentioned. Experimental mechanics tests for object displacements; refractometry and ellipsometry measure the material refractive index and thin-film thickness; and optical-fiber interferometers sense temperature and rotation. All these are applications based on interferometry. This article covers neither interference phenomena nor basic types of interferometers, as these topics were discussed in Interferometers and Interferometry and Optics, Linear.

1. PHASE ACROSS THE PLANE

The techniques that measure the phase across the plane employ a two-beam interferometer to record an interference signal in the form of an interferogram (fringe pattern). These interferograms, consisting of fringes of equal thickness called Fizeau fringes (see Interferometers and Interference), carry information about the phase, which corresponds to the relative difference between the test and the reference wave front. Phase variation across the plane can represent surface shape, material homogeneity or thickness, or optical-component quality. A simple way to approximate the maximum deviation of phase from the plane involves introducing tilt between the test and reference wave fronts. In this way almost straight and parallel fringes are introduced into the interferogram, Fig. 1(a). Phase deviation from the plane is seen as a departure from straight lines in the fringe pattern, Fig. 1(b). In the two interferometers most commonly used for surface contouring, the Fizeau and Twyman–Green (see Interference and Interferometry), the spacing between two neighboring fringes corresponds to a surface height difference of 1/2 of the source wavelength used for testing (1 fringe $= \lambda/2$). The maximum surface height deviation from the plane, Fig. 1(b), can be found by measuring the maximum fringe deviation from a straight line $[\Delta(x, y)]$ and the average spacing between two neighboring fringes (S). However, the relationship between fringe spacing and surface height depends not only on the wavelength used for measurement but also the interferometric configuration and the indices of refraction of the media the beam passes through. Interferometric techniques used to measure the phase across the plane typically use a coherent light source such as a laser so as to achieve good-contrast fringes; these techniques may involve single or multiple interferogram analysis to retrieve the phase.

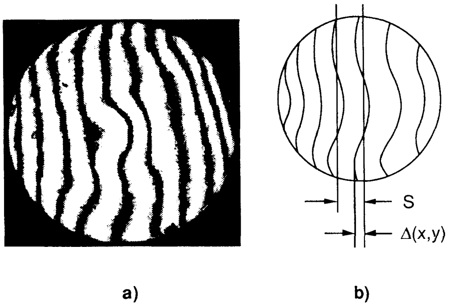

FIG. 1. (a) Typical interferogram for surface contouring. (b) Surface height deviation from a plane $= (\lambda/2)[\Delta(x, y)/S]$.

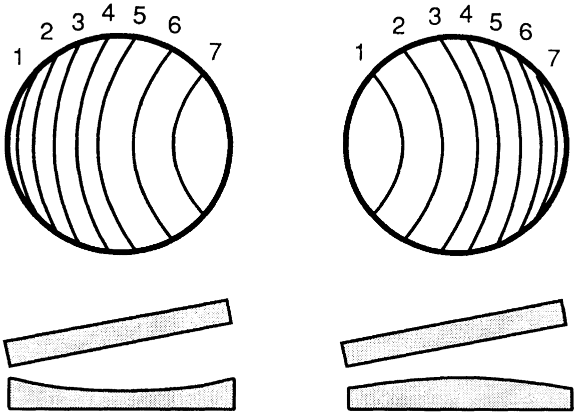

FIG. 2. Interferograms for (a) concave and (b) convex test surfaces relative to a flat reference surface.

1.1 Fringe Tracking

Until the late 1970s, fringe tracking (Yatagai, 1993) was the main way to analyze interferograms quantitatively, and although this method required only a single interferogram, it was relatively imprecise; the accuracy obtained was only one tenth of the fringe spacing. Fringe tracking works by recording the positions of the fringe intensity maxima and minima; the rest of the data are interpolated in order to create a phase map across the plane. Fringe tracking requires that the fringes be ordered so as to reflect changes in the phase between fringes, a process simplified by introducing tilt between the reference and test wave fronts. However, the direction of the tilt must be known beforehand in order to determine the shape of the tested surface correctly, *i.e.*, concave or convex (Fig. 2). If closed fringes are present in the interferogram, then fringe ordering also requires some knowledge about the tested element.

1.2 Interferogram Plus Intensities

The phase across the plane can be determined at each point without interpolation if the intensity distribution of each beam is recorded separately and one interferogram is taken. After these three intensity distributions have been determined, the phase variation can be calculated from the following equation that describes the intensity distribution I in an interferogram:

$$I = I_1 + I_2 + 2(I_1 I_2)^{1/2} \cos \varphi(x, y), \qquad (1)$$

where I_1 and I_2 are the intensities of the two beams, $2(I_1 I_2)^{1/2}$ is the interference visibility (modulation) and $\varphi(x, y)$ is the measured phase. Michelson or Mach–Zehnder interferometers (see INTERFERENCE AND INTERFEROMETRY) can use this method since the beams in the reference and test arms can be blocked separately. However, blocking each beam separately is not always possible, as when using a Fizeau interferometer, and alternative methods for retrieving the phase must be used.

1.3 Temporal Phase Measurement—Temporal Heterodyning

Temporal phase-measurement techniques (also known as temporal heterodyning, phase stepping, or phase shifting) introduce multiple times a known increment in the relative difference between the test and reference beams, called a phase shift. At least three interferograms are necessary to determine the phase encoded in the intensity distribution, Eq. (1), that can be rewritten as

$$I = I_1 + I_2 + 2(I_1 I_2)^{1/2} \cos[\varphi(x, y) + m\tau] \qquad (2)$$

where τ is the phase shift induced m times. The

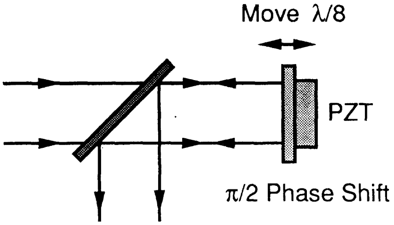

FIG. 3. Phase shift generated using a mirror moved by a piezo-electric transducer (PZT).

most common way to accomplish this phase shift is by changing the optical path difference between the interfering beams through a shift of the reference mirror along the optical axis, Fig. 3, although other ways exist—for example, by tilting a glass plate, moving a grating, rotating a half-wave plate or analyzer, or using an acousto-optic modulator (Creath, 1993). While some of these ways of shifting the phase alter the optical path between the interfering beams, others change the optical phase of one of the beams; nevertheless, both methods lead to an incremental difference (phase shift) between beams. Figure 4 shows three typical interferograms registered in the temporal phase measurement technique.

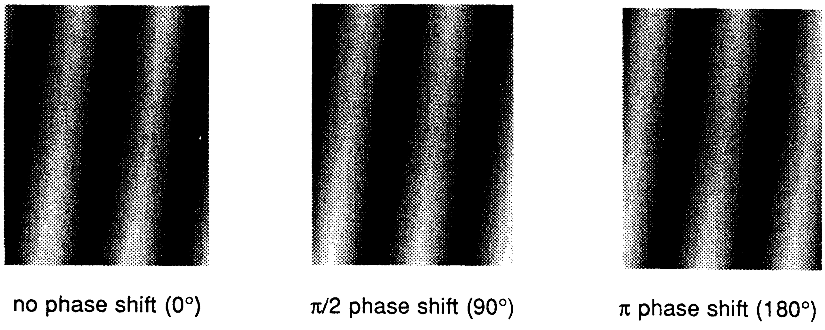
The measurement precision can be improved using more samples. An example of a common algorithm employing five intensity samples $I_1, \ldots, I_5$ with a relative $\pi/2$ phase shift to retrieve the phase $\varphi(x, y)$ is (Creath, 1993)

$$\varphi(x, y) = \arctan\left(\frac{I_1 + I_5 - 2I_3}{2I_2 + 2I_4}\right) \tag{3}$$

Because an arctangent function is not continuous and gives multiple solutions, an unwrapping procedure is employed to remove the discontinuities in the retrieved phase and essentially automatically orders the fringes (Robinson, 1993). Unwrapping procedures assume that the maximum phase discontinuity equals the difference between two neighboring solutions (2π, which is a property of the arctangent function). The values of the phase, which are measured in radians, are then converted into the values that the phase represents—for example, surface height or thickness variations. Temporal phase measurement is 10–100 times more precise than tracking the position of the fringe maxima and minima, since the repeatability of temporal phase measurement is 1/100–1/1000 of a wavelength.

Temporal phase-measurement techniques generally require that each interference fringe be sampled at least twice per fringe spacing; this constraint limits the slope of the phase that can be measured. However, a few techniques work around this limitation (Greivenkamp and Bruning, 1992). An often-used solution, white-light interferometry (see Sec. 1.5), is suitable when measuring rough surfaces or surfaces with discontinuities where sampling twice per fringe is not possible (Larkin, 1996).

Finally, although temporal phase-measurement techniques usually capture interferograms sequentially in time, and only phase not varying in time can be analyzed, a few techniques modify the configuration of the interferometer so the that *time-varying phase* can be measured, *e.g.*, gas flow. These techniques record interferograms simultaneously using multiple cameras. However, accomplishing



no phase shift (0°) π/2 phase shift (90°) π phase shift (180°)

FIG. 4. Interferograms showing sequence of phase shifts.

this end requires complicated hardware and alignment is critical (Kujawinska, 1993).

1.4 Single Interferogram Analysis—Spatial Heterodyning

Measuring time-varying phase can also be accomplished through the analysis of a single interferogram. Two common techniques discussed below require that a large tilt be induced between the reference and test wave fronts and that the direction of the tilt or knowledge about the tested object be known beforehand. In addition, like the temporal phase-measurement techniques described above, these techniques also require a phase unwrapping procedure in order to obtain a continuous phase map, and each fringe must be sampled at least twice per fringe spacing.

1.4.1 Fourier-Transform Technique In the Fourier-transform technique (Takeda, 1990) the discrete Fourier transform of a single interferogram is calculated revealing three distinct spectral orders, typical for a consinusoidal function, which also represents fringes (see FOURIER AND OTHER MATHEMATICAL TRANSFORMS; Ramirez, 1985). The number of almost parallel fringes from the induced tilt between the reference and test wave fronts must be large enough to separate the spectral orders to enable filtering one of these orders at the spatial frequency of the fringes. The inverse Fourier transform is then performed and the phase encoded in the interferogram is retrieved from the arctangent function of the real and imaginary parts of the inverse Fourier transform.

1.4.2 Synchronous Detection Synchronous detection (Womack, 1984) calculates the phase by sequentially applying a temporal phase-measurement technique algorithm to a few consecutive intensity samples across the plane of a single interferogram. A known phase shift is induced between adjacent sampling points, rather than between interferograms as discussed above, by tilting one wave front with respect to the other. This phase shift manifests itself as a set of straight parallel fringes. Fringe spacing must be chosen carefully so that the phase difference between adjacent sampling points is close to the phase shift required by the algorithm employed. Uniform sample reflectivity and intensity of both beams are assumed in this technique.

1.5 White-light Interferogram Analysis

Interference fringes can also be observed by use of a light source with a low degree of coherence such as a halogen lamp. Interferograms obtained with these "white light" sources show fringes of good modulation only when the optical paths of the two beams match closely. This modulation characteristic becomes important when one is trying to determine large discontinuities in phase where temporal phase-shifting interferometry is unable to assign the correct order to the fringes. *White-light interferometry* (also known as *low-coherence interferometry*) allows for the easy identification of the fringe with the best visibility because the contrast falls off so quickly. For example, Figs. 5(a) and 5(b) show interferograms of a step object; the interferogram in Fig. 5(a) is achieved with a laser as a source, and in Fig. 5(b) a white light source is used. In Fig. 5(a) there are multiple solutions to the ordering of the fringes. Thus determining the height of the step (size of the phase discontinuity) is impossible without additional information. In Fig. 5(b) the fringes can be ordered fairly simple by tracking the highest visible fringe, and the step height can then be easily determined. White-light interferometry is generally used for measuring rough surfaces or any surface with discontinuities where sampling twice per fringe is not possible.

To measure a surface using white-light interferometry, the surface is scanned in height relative to the interferometer while frames of data are acquired. As the separation between the surface and the interferometer changes, the interference fringes will intersect heights on the test surface where the optical paths are equal. A complete scan conceptually includes a three-dimensional volume of data corresponding to the location of the white-light fringes in space. The highest-contrast fringe or the peak of the fringe modulation can be used to determine the height at a single point on the test surface. This simple approach has spurred a number of new techniques for determining surface structure (Larkin, 1996). Some techniques follow

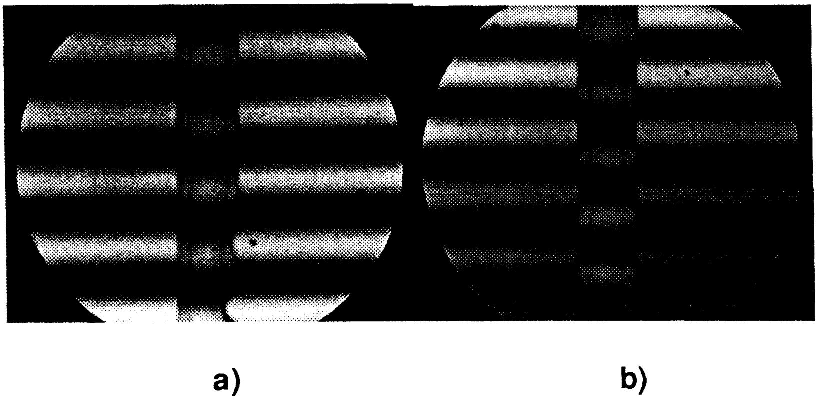


FIG. 5. Interferogram of a line feature with (a) a laser source and (b) a white-light source.

the highest-contrast fringe and others look at the peak of the fringe modulation. The relative position of these two quantities depends upon the phase change upon reflection of the light from the test surface.

1.6 Summary

The various interferogram techniques described in this section complement one other. The temporal technique and the single-interferogram techniques are used for high-precision measurement of smooth surfaces, while the fringe-modulation peak-sensing technique can examine very rough and discontinuous surfaces. Moreover, interferometric techniques analyze not only static but also time-varying phase. Techniques such as synchronous detection, Fourier transform, and temporal-phase measurement employing a spatial separation of interferograms can measure time-varying phase.

2. MEASUREMENT SENSITIVITY AND LIMITATIONS

2.1 Measurement Sensitivity

The sensitivity of an interferometric measurement can be changed by altering the test wavelength, the angle of incidence of the test beam illumination, and the number of passes through or reflections from the tested element. Varying the sensitivity of the interferometer allows for the measurement of rougher or smoother test objects. For example, a source that emits a shorter wavelength will produce a greater number of fringes in an interferogram; this choice of source wavelength increases the sensitivity of the interferometer and allows for the testing of smoother objects with high precision. A large angle of incidence of test beam illumination decreases sensitivity by producing fewer fringes in the interferogram and allows for rougher test-object measurement.

2.2 Removal of Systematic Errors

The reference wavefront in an interferometric setup is not ideal, for it carries information about imperfections in both the reference mirror and the optical system of the interferometer. If an ideal surface were available, all systematic errors could be measured and then subtracted. However, because such a surface does not exist, a set of multiple measurements is necessary in order to subtract these systematic errors (Schultz and Schwider, 1976). In addition, because various interferogram analysis techniques contain systematic sources of error, ways have been developed to decrease this error. For example, phase-shifting interferometry is vulnerable to phase-shifter miscalibration. Methods of calibrating the phase shifter precisely and the use of error-reducing algorithms help reduce any systematic errors (Creath, 1993).

2.3 Reduction of Nonsystematic Errors

High-precision interferometric measurements require special laboratory conditions. Care needs to be taken to ensure vibration and acoustic isolation as well as temperature stability and controlled air flow within the exposed optical path. If the laboratory conditions are not well controlled, nonsystematic errors may dominate a measurement. However, as long as these errors are random, statistically independent measurements can be averaged to reduce their effects and improve measurement precision and accuracy.

3. FORM MEASUREMENT

Testing form requires the measurement of phase across the plane. Form is defined as object shape or optical-system quality, in order to differentiate it from other measurable quantities such as object displacement and vibration. This section divides the examination of form measurement into optical-component testing and engineering-surface testing. The optical-component testing section is broken down into the types of components tested because similar components are tested in similar interferometric configurations. The engineering-surface testing section is organized around measurement techniques because the wide range of engineering surfaces requires a variety of different testing methods. The interferometric technique used to measure form depends on both the features of the tested object, such as its size, shape, or roughness, and the type of data that needs to be obtained.

3.1 Optical-System and -Component Testing

Interferometric techniques have proven extremely useful in testing optical systems and components, especially with the strict tolerances imposed on high-precision components and the smooth wave fronts generated by optical systems. The techniques detailed below for testing optical elements are applicable to most types of interferometers but are mainly used with the Fizeau or Twyman–Green interferometers (see INTERFEROMETERS AND INTERFEROMETRY, Secs. 2.1 and 2.4). The two interferometers have different strengths. The Fizeau interferometer is less sensitive to vibration than the Twyman–Green because the two optical paths of the Fizeau interferometer are virtually common. However, because the test and reference optical paths differ in length, the Fizeau requires a source with higher coherence than a Twyman–Green does.

3.1.1 Flats Optical flats are typically measured against a reference flat in a collimated beam. Often the flatness is specified as the maximum surface irregularity over a given surface area. Commercially available instruments can routinely measure surface irregularities as small as 1/100 of the source wavelength. If more accurate measurements are needed, flat surfaces can be tested relative to a liquid surface (Bünnagel, 1956); the surface of the liquid, which must be clear and highly viscous, works as a reference flat because its radius equals that of the Earth's and for a diameter of 0.5 m the maximum error is $\lambda/100$ for $\lambda = 500\,\text{nm}$. However, practicalities such as the influence of vibration and dust settling on the surface are problems. If a good flat is not available to test against, three flats can be tested in triple combinations in order to obtain absolute line profiles of each flat (Dew, 1966; Fritz, 1984).

3.1.2 Spherical and Aspheric Surfaces Spherical surfaces may be tested for their departure from spherical shape by comparing them with an ideal spherical reference wave front. When a spherical surface is tested in a Fizeau interferometer, Fig. 6, a transmission reference sphere is placed in the common path of the beams and the radius of the beam incident on the tested spherical surface must fill and match the radius of that surface.

Aspheric surfaces are difficult to test against a spherical wave front because they may depart too much from a spherical shape and generate too many fringes to resolve the interferogram. Null lenses and computer-generated holograms or real holograms (Offner and Malacara, 1992) are used to produce a wave front matching a perfect aspheric wave front, thereby reducing the number of fringes in the interferogram. Shearing interferometry reduces the number of fringes by interfering the tested wave front with its own replica, which can be

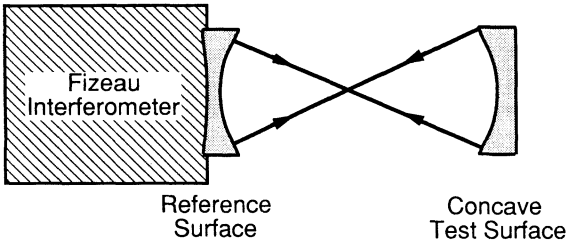

FIG. 6. Configuration for testing a concave spherical surface in a Fizeau interferometer.

displaced laterally, rotated, radially expanded or contracted. The number of fringes varies with the amount of shear, and fringes do not represent the shape of the aspheric surface directly (Malacara, 1992; Mantravadi, 1992).

3.1.3 Prisms Although prism angles may be measured with an autocollimator and a goniometer, interferometers are the most accurate method for measuring angle deviations. The procedure simply involves inserting the test prism and return flat into the test arm of the interferometer. Prisms with roof angles of 90° may be put into the test arm with (Fig. 7) or without the return mirror, as the beam can be retroreflected back to the system. The maximum deviation from 90° that a phase measuring interferometer can measure is about 1 min of arc.

3.1.4 Light Sources The quality of an optical wave front exiting from a light source may be tested using a point-diffraction interferometer or a special configuration of a Mach–Zehnder interferometer (Greivenkamp and Bruning, 1992). Both setups induce a spherical reference wave front through the use of a pinhole in the reference arm.

3.1.5 Homogeneity Homogeneity can be measured by preparing a plane-parallel sample and placing it in the test arm of an interferometer. A sample does not have to be specially prepared if it is submerged in a refractive-index–matching oil. Systematic errors can be subtracted by making a measurement before placing the sample in the test arm. Surface-independent measurements (Schwider, 1990) require multiple takes to remove variations due to the test sample's surface; this is done to isolate the refractive-index variations in the sample.

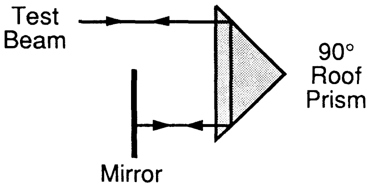

FIG. 7. Configuration for testing a 90° roof prism.

3.2 Testing Engineering Surfaces

Interferometry can also be used to measure the shape and properties of surfaces not used as optical components, such as machined metal or molded plastics. Because testing engineering surfaces is rather a specialized application of interferometric techniques, this section focuses on the methods developed to test these surfaces. The types of surfaces to be tested vary from very large ones that require overall testing of shape to very small ones that require a high resolving power to measure their microroughness. Speckle interferometry or holography may also be used for testing engineering surfaces, but since these methods can also be used for determining object displacement and vibration, two parameters important in experimental mechanics, they are discussed in the nondestructive testing section.

3.2.1 Fringe Projection Many engineering surfaces are too complex to be measured with standard interferometric techniques. Rowe and Welford (1967) devised a simple approach for measuring surface contours by projecting interference fringes or a grating onto an object and then viewing the fringes from another angle. Fringe projection is related to optical triangulation, which uses a single point of light and light sectioning; a single line is projected onto an object and then viewed from a different direction.

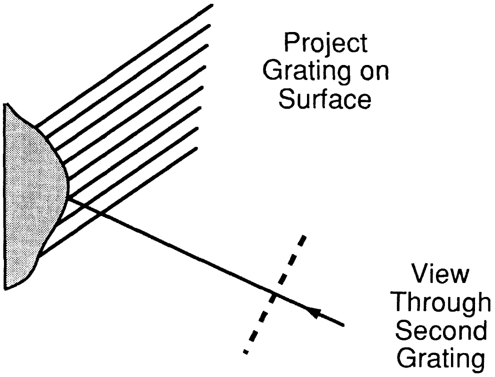

FIG. 8. Moiré technique for testing engineering surfaces.

3.2.2 Moiré In optics the term moiré (Rayleigh, 1874) refers to a pattern arising when two gratings of approximately equal spacing are superimposed. Interferometry using moiré (Patorski, 1993) can be implemented in a number of ways. A common approach is to project interference fringes (or a grating) onto an object and view them through a second grating placed in front of the viewer; see Fig. 8.

These techniques produce fringes corresponding to contours of equal height on the object. The contour interval is determined by the fringe (grating line) spacing and the angle between the illumination and viewing directions. Phase shifting can be introduced by shifting one grating or the projected fringes. Moiré and fringe-projection interferometry complement conventional interferometry, as they can contour objects with an effective contour interval of 10 μm and larger.

3.2.3 Interference Microscopy Interference microscopy combines an interferometer and a microscope into one instrument and is used for measuring engineering surfaces that demand testing with high resolving power. Interference microscopy uses three types of interferometric objectives: Michelson, Mirau, and Linnik (all are modifications of the Michelson interferometer). In a Michelson interferometer objective, which is used for small magnifications, a beam-splitter cube and reference mirror are inserted between the objective and the tested surface. At magnifications above five times, the working distance, which refers to the space between the last surface of the lens and the tested surface, becomes too small to squeeze in a beam splitter cube; instead a Mirau interferometric objective (described in OPTICAL INSTRUMENTATION, Sec. 3.2.1) is employed. For magnifications of one hundred times and above, a Linnik interferometric objective (Linnik, 1933) is used since the working distance for such high magnification is even smaller and the Mirau design is impossible to implement. In a Linnik configuration a beam-splitter cube placed before the light reaches the objective directs the beam onto two objectives; one beam is directed to the reference mirror and the other is directed to the test surface. Any type of phase-across-the-plane analysis technique discussed in this article may be used with these microscopes. Other interference microscopes are reviewed by Steel (1983).

3.2.4 Fringes of Equal Chromatic Order Interferometry Fringes of equal chromatic order (FECO) interferometry (Fig. 9) is based on multiple-beam interference between two highly reflective and nearly parallel plates and results in very sharp fringes (Tolansky, 1970). Multiple-beam interference magnifies the extent of the deformation, thereby making it easier to detect small imperfections on the tested surface. FECO uses a white-light source and is combined with a spectrometer to test thickness variation and surface roughness, which are determined from the width of the fringes. Small sections of the test surface are observed through a spectrometer that displays fringes of equal chromatic order. A FECO interferometer can achieve a precision level of $\lambda/500$ and is capable of distinguishing hills from valleys by use of the direction of the bending of the colored fringes. However, the test surface must be overlaid with a highly reflective coating and the reference surface rms (root mean square) roughness should be better then $\lambda/20$.

4. PHASE AT ONE POINT

Phase-at-one-point interferogram detection is commonly used to measure length, the spectral content of a source (see Sec. 6), or its polarization (see Sec. 8.4). For length measurement these interferometric techniques

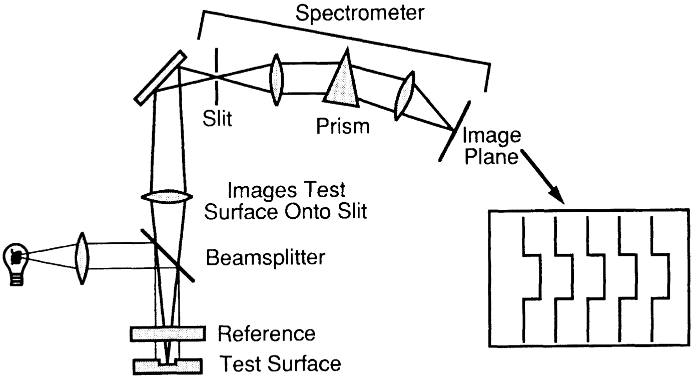

FIG. 9. Interferometer for measuring fringes of equal chromatic order (FECO).

(Hariharan, 1985; Steel, 1983) generally utilize a single detector to measure the phase at a single point of the interferogram where the fringe spacing is much larger than the size of the detector. The interferometric techniques that test the phase at one point measure length with very high precision, up to $1/10^4$ of a fringe, and are extensively used to measure relative and absolute distance. A few common single-point–phase detection techniques are described below. While measuring length is an important application of these techniques, the phase at a single point may represent other parameters, such as changes in pressure, temperature, or rotation.

4.1 Heterodyne Interferometry

Heterodyne interferometry observes interference between two beams with slightly different optical frequencies. This frequency difference is usually achieved by introducing a frequency shift into one of the beams. This frequency shift may be a result of a linear change in the phase difference and is achieved by rotating a radial grating, combining stationary and rotating quarter-wave plates, or moving a mirror in one of the arms of the interferometer. When the two beams interfere, a photodetector records a traveling interference signal at the beat frequency, which is equal to the difference in the two optical frequencies of the beams.

Heterodyne interferometry is often used to detect small changes in length. This detection is accomplished by evaluating changes in the beat frequency between the stable laser and the test (slave) laser frequency. Heterodyne interferometry measures changes in length by measuring changes in frequency.

4.2 Fringe Counting

These techniques essentially count the changes in intensity as they scan across a point detector while increasing the optical path difference between two beams. If the signal is lost for any reason, the measurement must be repeated. Two basic approaches to phase detection using fringe counting are often used. The first is based on observing the intensity changes in two interferograms. Into one interferogram an additional $\pi/2$ phase shift is introduced between interfering beams in order to determine the direction of the phase-difference changes (signals are in quadrature). The $\pi/2$ phase shift is induced by use of a special beam splitter or through polarization effects. The phase change can be detected to within a fraction of the fringe by observing the circular pattern formed by the two intensity signals mapped onto the horizontal and vertical axes on an oscilloscope. A full circle is traced each time one full fringe is scanned. The drawback to this method is that any changes in the intensity signal (such as source intensity variations) could be interpreted as a fringe.

The second approach avoids this problem; it is based on a heterodyne system that detects the interference of beams of different

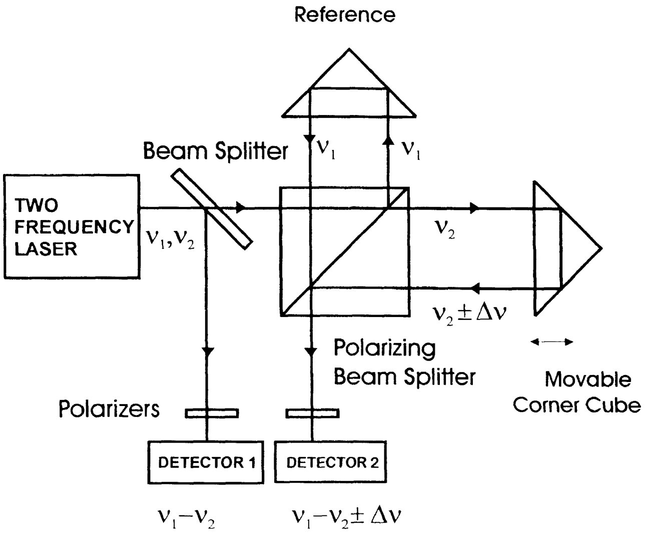

FIG. 10. Distance-measuring interferometer based on heterodyne system.

optical frequencies. Figure 10 shows a distance-measuring interferometer based on a heterodyne system that uses fringe counting. The differing frequencies can be obtained by using either a laser with two output frequencies or a single-frequency laser with two acousto-optic modulators. Either way the beams need to be orthogonally polarized. The first detector records the traveling interference reference signal at the beat frequency, which is equal to the difference in the two optical frequencies of the source. A polarizing beam splitter directs the beam of ν_1 into the reference arm and ν_2 into the test arm of the interferometer. Corner cubes return these beams to the second detector where the polarizer allows them to interfere. When the test corner cube is stationary, an intensity signal at the reference beat frequency is observed; when the test corner cube is in motion, it introduces a Doppler frequency shift in the returning beam and a different beat frequency is observed at the second detector. Signals from both detectors are forwarded to a differential counter and the change in the length of the test arm is determined.

4.3 Phase Locking

Phase-locking interferometry measures small changes in phase by locking the phase difference between the beams while detecting changes in the intensity signal (Moore, 1979). Locking the phase difference is accomplished by offsetting the phase of one of the beams and then subjecting that phase to sinusoidal modulation introduced by an oscillating mirror. This procedure induces intensity modulation that can be expressed as

$$I = I_1 + I_2 + 2(I_1 I_2)^{1/2} \cos(\varphi + \delta + a \sin \omega t). \tag{4}$$

The amplitude value a of the phase oscillation $\sin \omega t$ is much smaller than the source wavelength. The offset phase δ is set so that the average phase difference satisfies

$$\varphi + \delta = m\pi, \tag{5}$$

where m is an integer. Under this condition the intensity signal goes to zero and there is no intensity modulation due to mirror oscillation. When the average phase difference changes because of changes in tested phase φ, the intensity signal starts to modulate with its magnitude being proportional to the changes in the phase. This signal is then filtered and used to produce a feedback signal that tells the phase modulator how to alter the phase offset δ so that the condition $\varphi + \delta = m\pi$ is satisfied and the intensity modulation due to mirror oscillation is eliminated.

5. APPLICATIONS OF PHASE AT ONE POINT

5.1 Length Measurement

Phase-at-one-point detection in interferometry is very often applied to the precise measurement of length (Steel, 1983). In fact, interferometric techniques really established their value when they were applied to the measurement of material standards such as length, wavelength, line, and gauging.

5.2 Gravity-Wave Detection

Single-point phase detection has recently been employed to detect gravity waves. Much as accelerating charges produce electromagnetic waves, accelerating masses emit gravity waves. Gravity waves produced by collapsing supernovas, binary systems of neutron stars, and black holes affect the dimensions and spacing of all material objects. The movements that signal the existence of gravity waves can be detected by observing the small changes in phase at a single point in an interferometer. To register these changes requires an interferometer of very high sensitivity. A simple Michelson interferometer would need unrealistically long arms or high laser power to achieve the required accuracy. A number of new interferometers have been devised that should have sufficient sensitivity to detect gravity waves (Saulson, 1994). One of these has been coined the Laser Interferometric Gravitational-wave Observatory (LIGO). Its interferometric setup (Fig. 11) places identical Fabry–Pérot resonant optical cavities into each arm of a Michelson interferometer. The Fabry–Pérot arm cavities effectively increase the optical path length of each arm on account of the multiple reflection of light inside the cavities. The Fabry–Pérot mirrors act as inertial test masses suspended like pendulums from seismically isolated platforms. Passing gravity waves change the relative length of the resonant Fabry–Pérot cavities; this change alters the phase of the light and the phase change is picked up by the detector, thus revealing the existence of passing gravity waves. In order to detect the phase, the frequency of the laser is locked so that it is in resonance with the length of one cavity and then the length of the other cavity is adjusted to achieve the same resonance. The system detects the dark interference fringe, which allows most of the light to be reflected back to the source and back out again into the system with a recycling mirror. This additional mirror and the first surfaces of the test masses create the cavities where the light builds up, which effectively increases the optical path length and the illuminating power of the laser. The LIGO interferometer allows the detection of movements as slight as 1/1000 the diameter of a proton (10^{-18} m) and enables the identification of the presence of matter at distances of more than 70×10^6 light years from Earth. The distance separating the mirrors, more than 4 km, makes the LIGO interferometer the world's largest precision optical instrument and is pushing the limits of technology.

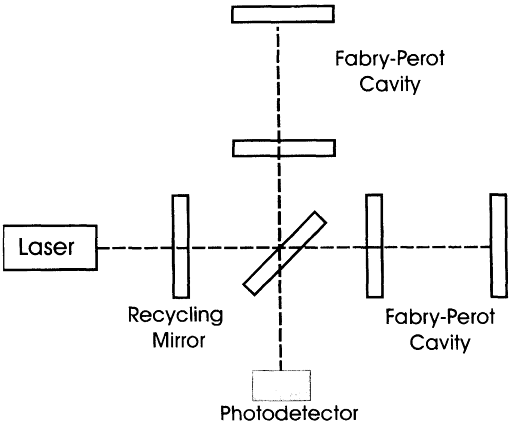

FIG. 11. Gravity-wave detection interferometer.

5.3 Other

Interferometry is used for monitoring processes such as plasma etching, film etching rate, uniformity of etching, and substrate temperature (see Plasma Etching). Phase-at-one-point detection can be also used for measuring refractive index and electron density of a plasma. Temperature, pressure, strain, and rotation can be detected by optical-fiber sensors (see Sec. 8.2). Phase detection has also been used to measure the speed of light (Steel, 1983).

6. INTERFERENCE SPECTROSCOPY

Interferometric spectrometers analyze the spectral distribution of a radiating source rather than examining the phase difference as the techniques discussed previously do. Generally, spectrometers measure not just the spectrum of radiation but rather the combination of the radiating source, the detector sensitivity, and the transmittance of the interferometer. In addition, a perfectly monochromatic spectral line will result in different spectral energy distributions when detected by different types of spectrometers. This characteristic of spectrometers is called the response of the system, and it is dependent on the spectrometer's instrumental function, which determines when two spectral lines of frequencies ν_1, ν_2 (or λ_1, λ_2 in terms of wavelength) can be still resolved by the instrument. The resolving power of the spectrometer is then determined by

$$\Re = \nu/\Delta\nu = \lambda/\Delta\lambda \tag{6}$$

An important characteristic of a spectrometer, especially when faint spectra are studied, is its "light-gathering power", which is defined by the invariant known as *étendue*. For example, dispersive spectrometers, like grating or prism spectrometers, generally use a narrow slit; these systems have smaller étendue than those spectrometers that do not use this type of slit. Two types of interferometric spectrometers and their techniques for recovering the spectral content of a radiating source are discussed below, a Fabry–Pérot etalon and a version of a Michelson interferometer.

6.1 Fabry–Pérot Spectrometer

The Fabry–Pérot interferometric spectrometer (Fabry and Pérot, 1899; Vaughan, 1989) employs multiple interference between two high-quality and highly reflective plates, which can be either fixed (etalon) or variably separated. Fixed plates yield a set of circular (spatial) sharp fringes for different wavelengths of the source. This setup is often used to measure the separation of two planes in etalons (standards), the thickness of a thin film, or the wavelength of a source (Hariharan, 1985).

The instrumental function of Fabry–Pérot plates separated by distance d is the *Airy function*

$$A(\nu) = T^2/[(1-R)^2 + 4R\sin^2(\psi/2)], \tag{7}$$

where R and T are the reflectance and transmittance of the plates and $\psi = (4\pi\nu nd/c)\cos\theta$, where n is index of refraction of the medium between the plates and θ is the angle of incidence. The Airy function has a set of narrow peaks that are separated by a frequency difference equal to $c/2dn$; this frequency difference describes the *free spectral range* where the fringes will not overlap. The half-width of the peaks $\Delta\nu$ is described by

$$\Delta\nu = c/2ndF, \tag{8}$$

where F is the *finesse* of the system,

$$F = \pi\sqrt{R}/(1-R). \tag{9}$$

The limited spectral range of the etalon can be overcome by separating the ranges in order to determine the frequency they represent without any ambiguity; however, this procedure is accomplished by imaging fringes onto a slit of the spectrometer, which then limits the étendue of the system.

The scanning Fabry–Pérot interferometric spectrometer has significantly higher étendue and is often used as a spectrometer for testing faint light sources. In this system the optical separation between the two plates changes linearly and the transmitted intensity signal (section of spectrum) is recorded by a point detector placed in the focal plane of the lens, which is placed behind the interferometer. Many modifications can be introduced to increase the performance of this spectrometer. For example, spherical mirrors may replace plates and thus increase light usage efficiency.

6.2 Fourier-Transform Spectroscopy

Interferometry may also be used to obtain the spectral energy distribution of a source through a technique called Fourier-transform spectroscopy (Michelson, 1902; Vanasse and Sakai, 1967; Bell, 1972). Fourier spectroscopy records the variation in intensity at a single point while varying the optical path difference between interfering wavefronts in a two-beam interferometer, which is typically a Michelson with the effective source at infinity. The optical path difference is realized by moving one of the mirrors, as in phase-measurement techniques. The detected intensity of the interference signal is the sum of independent interference signals for each spectral component and differs with the spectral content of the tested source. This intensity can be represented by

$$I(\tau) = \int G(\nu)[1 + \cos(\tau 2\pi\nu)]\,\mathrm{d}\nu \qquad (10)$$

where τ is the introduced optical path difference and $G(\nu)$ is the spectral distribution of the source. Since the recorded intensity signal is not the direct spectrum signal as in the Fabry–Pérot interferometer but rather the cosine Fourier transform of the spectrum, the Fourier transformation of the recorded signal must be calculated to achieve the spectrum of the source. The intensity of the interference signal must be sampled at least twice per fringe (as in phase-detection techniques). Because the fringe spacing in an interference signal corresponds to the wavelengths of the source, the minimum wavelength that can be detected is limited (as the slope is limited in phase-across-the-plane detection). Unequal sampling intervals and finite changes in optical path difference will introduce errors into the calculated spectrum. A process called *apodization*, where a measured interference signal is multiplied by a symmetrical signal with gradually decreasing values, like a triangle function, reduces the magnitude of errors in the calculated spectrum.

Fourier spectroscopy may be relatively difficult to implement; but when compared with prism or grating spectroscopy, Fourier spectroscopy has a very high étendue and better resolution than either of the other two methods. Another advantage of Fourier spectroscopy is its *multiplex advantage*: the signal-to-noise ratio is significantly improved as a result of simultaneous registration of all spectral components of radiation. Major applications of this technique include detection of emission spectra and absorption spectra of aqueous solutions, gases, and transient species. Because of its efficient use of light, Fourier spectroscopy is used often in astronomy to record spectra (usually infrared—see SPECTROMETERS, INFRARED) from very faint sources.

Fourier transformation is a powerful tool in interferometry; it can be used with either a coherent or an incoherent spectral source to analyze the phase across the plane. In addition, Fourier techniques are used for analyzing both the spatial and spectral distribution of a radiating source.

6.3 Spectral Imaging

The interferometric instruments described so far have been able to acquire either phase or spectral information about an object. However, many disciplines such as astronomy, robotic vision, or remote sensing are interested in obtaining both types of information at once. Recent progress in optics and electronics has allowed researchers to register multiple spectral images, thus spurring the development of new spectral imaging techniques (Itoh, 1996). Many of these techniques combine interferometric methods or couple interferometry with other optical testing procedures. For example, a double Fourier spatio-spectral interferometer merges a Michelson interferometer for Fourier spectrometry with a Michelson stellar interferometer for star diameter determination.

7. INTERFERENCE IMAGERY

Interference imagery (Steel, 1983) is an interferometric technique for testing the spatial distribution of a radiating source and is often used in astronomy to measure stellar diameters that are nearly impossible to resolve with conventional telescopes. In 1921 Michelson first developed a method for testing stellar diameters; his stellar interferometer could resolve distant objects with angular diameters on the order of 10^{-2} arc s (Michelson, 1921; see also INTERFEROMETERS AND INTERFERENCE, Sec. 1.3.2). Since that time, interferometric techniques have become more precise, using visible light as well as radio waves to measure spatial distributions. The resolution of stellar interferometers depends on both the distance between the mirrors (antennas) and the number of mirrors (antennas) used. Stellar interferometers are sometimes referred to as long-baseline or very-long-baseline (VLBI) interferometers or aperture-synthesis arrays.

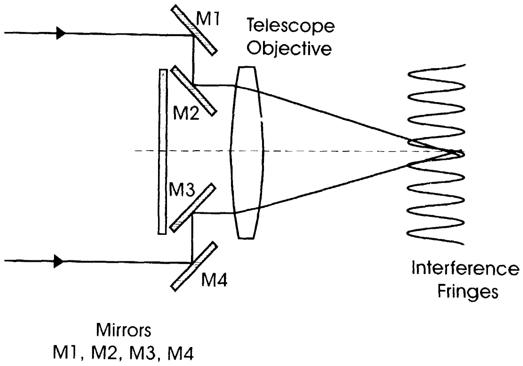

FIG. 12. Michelson stellar interferometer for measuring stellar dimensions.

Stellar interferometers today test many parameters in order to achieve maximum precision, including the phase across the plane for fringe tracking and heterodyne techniques for delay.

7.1 Michelson Stellar Interferometry

A Michelson stellar interferometer is a two-beam interferometer that uses wave-front division rather than amplitude division as the interferometers and techniques described thus far do. A Michelson stellar interferometer (Fig. 12) consists of two widely spaced mirrors (whose separation can be changed) pointed at the same stars. Light from the two mirrors is combined to form interference fringes on the image plane of a telescope. If the interferometer is pointing at two stars, two point sources, then two slightly shifted interference patterns of mean wavelength λ, one from each star, are formed. Because the source radiation from the stars is spatially incoherent, the sum of the interference patterns' intensities observed on the detector forms a new fringe pattern. The visibility of these new fringes depends on the shift between the interference patterns from each star. This shift is dependent on both the angular separation θ of the stars, which is fixed, and the separation d between the mirrors, which is referred to as the baseline and varies. The visibility of the fringes versus the mirror separation is plotted in Fig. 13(a). This visibility of the fringes is an envelope function of the Fourier transform of the spatial distribution of the source. Thus, if the mirror separation d is found for which the visibility of fringes equals zero, then the distance between the stars can be calculated.

When one is measuring the diameter of a star, the star is treated not as a point source but as a set of incoherent point sources that fills the star's diameter. The visibility of the fringes, Fig. 13(b), changes in a different fashion than for two point sources. By adjusting the separation of the two input mirrors until the fringe visibility reaches zero, which occurs when the spacing between the two mirrors is approximately $1.22\lambda\theta$, where θ is the stellar diameter, the diameter of the star can be determined but only in the direction of the mirror separation. Another procedure records the fringe pattern and then calculates the zero fringe visibility in order to determine the stellar diameter. In practice stellar interferometers are difficult to build, since the optical paths between the arms of the interferometer need to match as stars emit incoherent light. Stabilizing a system such as this requires very stable mechanical construction of the interferometer

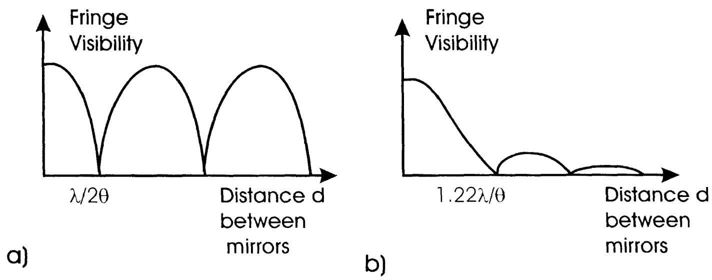

FIG. 13. Fringe visibility in a Michelson stellar interferometer for (a) two point sources and (b) a disk source.

and correction for atmospheric turbulence. In addition, if a star is not radially symmetrical, the mirrors need to be rotated or an additional set of mirrors implemented in order to determine the diameter of the star in a different direction. Finally, if radiation from the stellar source is not uniform, measurements that employ multiple separations of the mirrors need to be taken.

7.2 Stellar Intensity Interferometry

A major step in the development of stellar interferometers was the invention of the intensity interferometer by Hanbury Brown and Twiss (1954). The intensity interferometer is essentially a Michelson stellar interferometer that observes the intensity variation coming from each mirror separately; these intensity variations are then electronically correlated. The detectors in the intensity interferometer can be separated by thousands of kilometers, thereby significantly increasing the resolution of the system.

7.3 Radio Interferometry

Radio astronomy uses radio waves with wavelengths ranging from millimeters to hundreds of meters for observations in a different spectral range. Similarly, as stellar interferometry increases the resolution of visible light telescopes, radio interferometry, which is based on stellar interferometry (Steel, 1983), improves the resolution of radio telescopes (see RADIO TELESCOPES). Radio interferometry may use antennas for radiation collection instead of lenses and mirrors, but its principle of operation is still based on interference phenomena. Radio interferometry has many uses, ranging from listening for signs of earthquakes and volcanic activity to measuring the thickness of ice sheets and monitoring sea levels (see GEODESY).

7.4 Stellar Speckle Interferometry

Stellar diameters can be determined using a single telescope and a technique developed by Labeyrie (Labeyrie, 1976; Dainty, 1984). This technique allows a telescope to measure angular distances at its diffraction limit regardless of the light conditions. Individual speckles formed at the focus of the telescope have angular sizes determined by the diffraction limit of the telescope. When short exposures are made, the speckle pattern can be frozen in time. By taking the square modulus of the Fourier transform of a speckle pattern and averaging a number of these, a fringe pattern will be seen whose spacing is proportional to the stellar diameter or separation.

8. OTHER APPLICATIONS

In addition to the applications discussed so far in this article, there are many other applications that do not fit into the previous categories. These include the nondestructive testing of mechanical displacement and strain, the use of optical fibers in interferometers, the measurement of polarization and material properties, and interference between particles rather than waves. Since it is not possible to describe every application, this section highlights a few of these other applications.

8.1 Nondestructive Testing with Interferometry

Nondestructive evaluation of the mechanical properties of technical components is increasingly important for process control during manufacturing. Information about components' deformation due to an applied force or a change in temperature can be delivered by different interferometric techniques. As these techniques are applied to experimental mechanics, changes in phase can represent the displacement both in and out of the plane of the object.

8.1.1 Holographic Interferometry Holographic interferometry is an often-used technique because both amplitude and phase and in- and out-of-plane displacement information can be obtained about a surface as a known force is applied to it. These results can be compared with simulations generated by finite-element analysis to see whether mechanical parts behave as they are modeled. For example, holographic interferometry can provide information about whether a part in an airplane motor will perform as expected when it is stressed and loaded while in operation. The mathematical theory and basics of holographic (hologram) interferometry are outlined in OPTICAL HOLOGRAPHY, Sec. 4.3.

Recent developments in nondestructive testing using holographic interferometry have enabled holograms to be made in media that are erasable and reusable (Hariharan, 1994). Phase-measurement techniques can be applied to holographic interferometers to make quantitative analysis possible. Quantitative data enable a better comparison with simulation data for structural analysis. Applications include the testing of airplane tires, audio speakers, turbine blades, satellite fuel tanks, musical instruments, and infrastructure such as pipes and bridges.

8.1.2 Speckle Interferometry Speckle interferometry is similar in many ways to holographic testing; the difference is that information about object displacement is derived from the speckle patterns. Correlating speckle patterns before and after a force is applied yields information about the surface displacements. When speckle techniques were first developed, they relied on film as the recording medium. Sensor arrays have replaced film as the recording media, and advances in signal processing have allowed for fast quantitative analysis of object displacements (Jones and Wykes, 1983).

8.1.3 TV Holography By combining holographic and speckle interferometry, it is possible to record holograms on a CCD (charge-coupled device) sensor array and do image processing essentially to create digital holograms (Creath and Wyant, 1992; Kreis, 1996; Rastogi, 1997). Because the hologram must be resolvable with a TV camera, the frequency information content has to be within the Nyquist sampling limit of the sensor. Another consideration is that image processing must remove the self-interference terms from the hologram so that the cross-interference term is not corrupted. Many different approaches have been developed to perform this processing. Displacement measurements are easily obtained by computationally subtracting two holograms. Vibration analysis can be carried out stroboscopically or by adding a known vibration to the system and looking at the difference in frequency. Instruments using these techniques can be made to be quite insensitive to vibration. These instruments are often portable so that measurements are not limited to laboratory settings.

8.1.4 Grating Interferometry High-sensitivity grating interferometry (Patorski, 1993; Post *et al.*, 1994), has become an important method in experimental mechanics to measure, with submicrometer sensitivity, the in-plane displacements of nearly flat objects under load. In conventional high-sensitivity grating interferometry, the object under test with a reflection-type grating adhered to it is illuminated by two coherent beams symmetrical to the grating normal. The interference between the two diffraction orders reflected from the grating is recorded, resulting in a map of the in-plane displacements. Polarization techniques can be used in this system for phase shifting.

8.2 Optical-fiber Interferometry

Optical-fiber interferometers do not differ in principle from conventional two-beam interferometers; the difference is that in optical-fiber interferometers the beams travel through single-mode optical fibers, allowing for compact construction of an interferometer (Hariharan, 1985; also see SENSORS, OPTICAL, Sec. 2.8).

Optical-fiber interferometers are often used as optical sensors to detect changes in pressure or temperature, as these effects alter the optical path length of the fiber. The sensitivity of the interferometric system increases as longer fibers are used; thus optical-fiber interferometers find their advantage in combining compactness with sensitivity, since long optical paths can be contained in compact areas.

The optical-fiber interferometer can use a Sagnac-type (Vali and Shorthill, 1976) interferometric configuration to sense rotation (see INTERFEROMETERS AND INTERFEROMETRY). This is done by replacing the ring cavity of a conventional Sagnac interferometer with a multiturn loop made of single-mode optical fiber. The phase of the counterpropagating beams can then be detected using a phase-sensitive detector (Ezekiel, 1984).

8.3 Refractometry

Refractometers use interferometric techniques to measure changes in the refractive index of solids, liquids, or gases more precisely than any other method (see REFRACTOMETERS, OPTICAL). The first interferometer to measure a refractive index was devised by Michelson. Later Rayleigh and Jamin interferometers were developed specifically for this purpose (INTERFEROMETERS AND INTERFEROMETRY).

8.4 Ellipsometry

Ellipsometry (Azzam and Bashara, 1987; ELLIPSOMETERS) employs light polarization to characterize surfaces, interfaces, and thin films. In an ellipsometer linearly polarized incident light reflects from the test surface as elliptically polarized light. By superimposing two orthogonal components of an electric field, the elliptically polarized light can then be measured. Ellipsometry is a variation of common-path polarization interferometry where one of two copropagating orthogonally polarized waves acts as the reference for the other. Some ellipsometers use interferometric arrangements (mainly Michelson) to measure the index of refraction or film thickness over an entire surface, not just at a single point.

8.5 Atom Interferometry

Waves are characterized by phase and amplitude while particles are characterized by position and momentum. Both atoms and light can be treated as waves and particles, and both can be described by similar sets of equations. However, atoms have mass; therefore atomic waves obey a different dispersion relationship than does light. As the interference of wave fronts is an inherent feature of interferometry, atom interferometry (Adams *et al.*, 1994; Berman, 1996; see also INTERFERENCE AND INTERFEROMETRY) observes atom interference patterns. (Similarly, electron and neutron interference patterns are observed in electron and neutron interferometry.) Using methods similar to classical interferometry, atomic interference patterns are analyzed for modulation and fringe spacing and position. With much better precision than other interferometric methods, atom interferometry is able to detect and test gravitational and inertial effects, atomic properties, and some effects in quantum mechanics. Atom interferometry replaces the optical elements from conventional interferometers with microfabricated elements that diffract or split thermal atom beams, and tunable lasers that manipulate the trajectories of neutral atoms.

GLOSSARY

Fringe Order: The number assigned to a fringe in a single interferogram; it represents the direction of the changes in the recorded phase wavefront.

Optical Path: The length of the path that light takes through the medium multiplied by the index of refraction of the medium.

Optical Phase: Optical path of the light modified by phase changes on reflection of the light from the medium, where the phase changes depend on angle of incidence of the light and on the medium's complex index of refraction.

Phase Shift: The controlled change of the optical phase between interfering wavefronts.

Phase: Optical phase difference between test and reference wavefronts. The phase retrieved from an interferogram may represent the shape of the tested surface, its slope, or its displacement, among other things.

INTRODUCTION

A number of low-energy collision processes can result in electron attachment to a hydrogen atom, producing a negatively charged ion. Being loosely bound, the electron can easily be removed, making a neutral atom once again. An important objective of negative-ion sources is how to attach this extra electron onto a hydrogen atom and keep it there throughout the extraction process. Early attempts to extract negative ions yielded currents in the microampere range. Two significant discoveries allowed the extracted current to increase by many orders of magnitude. These are covered in Secs. 1.1, 1.2, and 1.3.

The negative-ion source development, at the Budker Institute of Nuclear Physics, was motivated by the invention of charge-exchange injection into proton storage rings (Budker *et al.*, 1967). However, one inconvenience of the charge-exchange method is that it required negative-ion beams to start with. Ironically, one of the preferred embodiments for negative-ion sources also used a charge-exchange principle. Another negative-ion source develop-

ment at Ecole Polytechnique found an increase in beam current thousands of times more than expected through discovery of new atomic processes, brought about by a series of insightful experiments.

Originally needed for high-energy physics, and then for the Strategic Defense Initiative, application spread to high-energy neutral-beam heating and current drive for fusion plasma-confinement experiments. These activities led to a massive effort to develop and optimize these sources. Results of this development enabled applications, such as nuclear-physics materials studies, using the spallation neutron source and the next generation of semiconductor chip manufacture.

All these negative-ion sources involve the generation and maintenance of a plasma, consisting of positive ions, negative ions, and electrons, while optimizing the actual negative-ion generation and extraction. In each case there are several significant parameters which must be jointly optimized. We discuss many of the issues and some of the laboratory data and the theory necessary to guide the development of these negative-ion sources.

1. PHYSICS OF HYDROGEN NEGATIVE-ION PRODUCTION

In this section several types of hydrogen negative-ion production mechanisms that have found use in ion sources are discussed. Embodiments that illustrate the principles are presented along with some degree of comparison. Surface production from cesiated surfaces (Dudnikov and Derevyankin 1994; Belchenko *et al.*, 1973, 1997) is considered in some detail in Sec. 1.1. Volume sources are of two forms:

1. dissociative attachment of vibrationally excited hydrogen molecules, considered in Sec. 1.3, and
2. charge exchange, considered in Sec. 1.2.

1.1 Cesiated-Surface Production (Dudnikov, Belchenko, Dimov)

Positive ions hitting a molybdenum surface convert into negative ions with a significant probability (Greer and Seidl, 1984; Seidl *et al.*, 1980, 1982; Melnychuk *et al.*, 1991). As many as a third of the positive ions hitting a suitably cesium-coated surface will result in a negative ion being produced on or near this surface (Seidl *et al.*, 1984). Since positive ions are generally easier to create than negative ions, this surface process represents a significant advantage. Moreover, since there is a force at the surface due to the plasma sheath fields, the negative ions once generated are accelerated approximately normal to the surface, which means that the shape of the cesiated surface itself may have a significant influence on the ion optics. This allows for the possibility of focusing the negative-ion beam and in some cases amplifying the beam current. Many surface sources make use of this feature. If it were not for the fact that the negative-ion "temperature" or transverse energy can be fairly high (7 eV for a 150-V plasma-sheath potential drop) these sources would probably lead the other concepts of negative-ion sources, since the current density can be as high as 1 A cm^{-2} of H$^-$, and early results by Belchenko *et al.* (1994), of the Institute of Nuclear Physics (INP), yielded 11 A of total current.

1.1.1 Cold-Cathode Penning (Dudnikov Source) While this is apparently the first source using surface production from cesiated surfaces, the actual beam formation occurs as a result of charge exchange and is therefore considered in Sec. 1.2.2.

1.1.2 Semiplanotron (Belchenko Source) This form was developed by Belchenko, Dimov, and Dudnikov at the Institute of Nuclear Physics at Novosibirsk (Belchenko *et al.*, 1973), and two views of an embodiment (Belchenko and Kupriyanov, 1990) can be seen in Fig. 1.

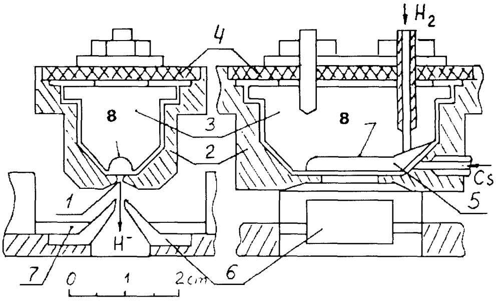

FIG. 1. Two views of semiplanotron surface source showing 1, emission slit (0.5 × 10 cm^2); 2, anode; 3, cathode; 4, insulator; 5, cathode groove; 6, extraction electrode; 7, mild steel inserts; and 8, converter.

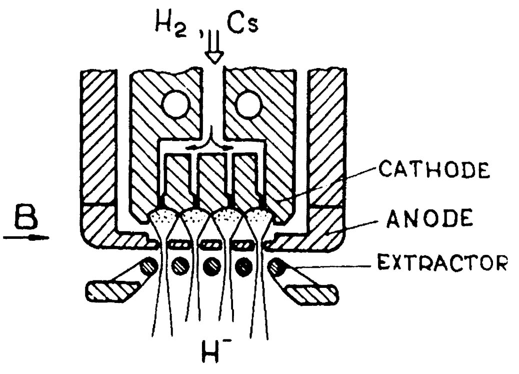

FIG. 2. Multibeamlet variation of semiplanotron.

A Penning discharge is established in region 5; this discharge consists of H^+ ions and electrons formed adjacent to a cesiated plate, 3, biased negatively by 100–300 V. If the cesium coating on the converter 8 is very thin (Seidl *et al.*, 1982), a significant amount of negative ions will result from double electron attachment to the incident positive ions or from electron attachment to sputtered hydrogen atoms. These H^- ions will accelerate through the 100–300-V sheath, go through the Penning discharge, 5, and be ready for extraction at 1. Since the H^- ions have about 100–300 V of energy, the inevitable plasma sheaths will have less of an effect than if their energy were smaller. This is one of the advantages of this mode of operation; another is that an amplification of beam current density occurs at 1 because of the concave shape of 8. However, the H^- ions, upon formation at the surface, acquire a transverse energy of a few electronvolts (Ehlers and Leung, 1980; York *et al.*, 1983), which results in a high beam emittance.

This configuration was used in multiple-beamlet configurations as illustrated in Fig. 2. 11 A of H^- were extracted from a 600-beamlet configuration with geometric focusing (Belchenko *et al.*, 1984, 1993). This multibeamlet configuration could be useful in certain applications, such as neutral injection into magnetic-confinement fusion experiments where high beam currents are needed without a concomitant increase in brightness.

1.1.3 Hot-Cathode Semiplanotron (Stirling, Soloshenko Source) This source was developed at ORNL (Dagenhart *et al.*, 1980, 1983, 1984; Stirling *et al.*, 1984), at Kiev (Soloshenko 1997; Goretsky 1996), and at BINP (Bashkeev *et al.*, 1990). It is illustrated in Figs. 3 (end view), 4 (top view) and 5 (oblique view). Referring to the end view, electrons are emitted from a filament and ionize hydrogen gas in a Penning discharge, which is confined in a strong magnetic field (see regions labeled "positive ion arc column" in Fig. 4, or the region labeled "discharge" in Fig. 3). The discharge starts at an anode aperture and passes

next to the converter surface shown most clearly in Fig. 3. This anode aperture is intended to reflect the electrons back into the main part of the column in front of the converter where they can continue to ionize the gaseous hydrogen. Since the plasma is so dense (electron density up to $10^{14}\,\mathrm{cm}^{-3}$), it requires a thick anode to provide field penetration into the column. This device has produced 650 mA of H^- for 10-s-long pulses (Dagenhart *et al.*, 1983). An oblique view is shown in Fig. 5, which shows how the electrons are captured at only a small loss. As in common with the Belchenko source, Sec. 1.1.2, positive H^+ from the plasma is attracted to the converter, which is biased relatively negative. The positive ions are converted into H^- at the surface, and these H^- are accelerated back through the sheath ($\approx$100–300 V) and continue on through the extraction aperture. An advantage of this source over that of the cold-cathode semiplanotron is in long-pulse, or cw, applications. A disadvantage is lower current densities.

1.1.4 Planotron/Magnetron A Planotron, whose principle of operation is depicted in Fig. 6 (Sluyters, 1979; Prelec, 1977a,b, 1980), differs from the semiplanotron in that the electrons in the primary discharge can go around the cathode in an $\boldsymbol{E} \times \boldsymbol{B}$ cycloidal drift determined by the applied magnetic field and the electric field that develops between the plasma and the cathode. The extra path made by the electrons, compared with the semiplanotron, in many cases provides less loss than the reflections made on a negatively biased anode Penning configuration (shown in Fig. 4). Other than providing an $\boldsymbol{E} \times \boldsymbol{B}$ recirculating electron stream, the source operates similar to the semiplanotron. An improvement made by Alessi and Sluyters (1980) is to increase the space in the back of the magnetron channel. This is depicted in Fig. 7 and has resulted in a 50% increase of H^- ion current to 600 mA. The increased negative-ion extracted current is depicted in Fig. 8. Also shown is the amplification (×5) of the beam current effected by the focusing due to the groove. This source was also developed at the Fermi National Laboratory (Schmidt *et al.*, 1977, 1979, 1980).

The magnetron geometry is also scalable to multiple apertures for high current (250 mA for several hours) (Prelec 1984). An example is shown in Fig. 9.

1.1.5 Field-Free Surface Source Developed at Lawrence Berkeley Laboratory (LBL) (Ehlers and Leung, 1980; Leung and Ehlers, 1980), Los Alamos Scientific Laboratory (LASL) (York *et al.*, 1983; York and Stevens, 1984), and the National Laboratory for High Energy Physics, Japan (KEK) (Takagi *et al.*, 1984; Mori 1987), the concept is shown in Fig. 10. Ions are generated on a spherical cesium-coated converter surface as shown and, as a result of the presence of a plasma, immediately accelerate down the 100–300-V sheath normal to the surface. These ions "self-extract" by moving through the intervening plasma at high speed to an awaiting accelerator, shown at the right of the figure. The electrons are contained in the plasma by cusp-field confinement pro-

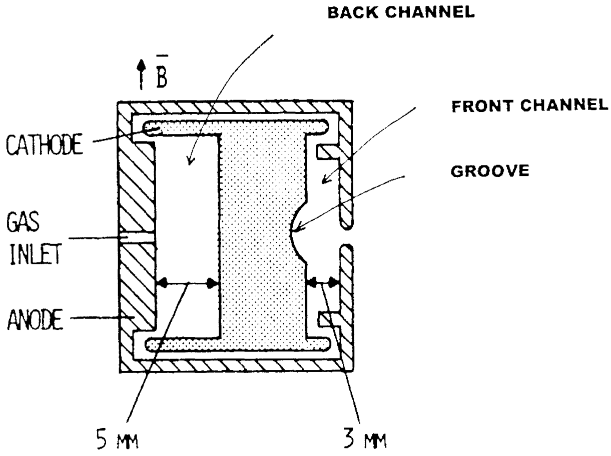

FIG. 7. The asymmetric magnetron configuration.

vided by many small magnets on the ion source chamber. 20 mA of H$^-$ were extracted at 10% duty cycle (York and Stevens, 1984; Takagi *et al.*, 1984); 400 mA of H$^-$ were extracted from the LBL source (Ehlers and Leung, 1980). A variation (Kwan *et al.*, 1993) produced 35 mA of D$^-$ current.

This source is called field-free because the magnetic fields in the region of negative-ion production are small. An example of the field penetration (Lietzke *et al.*, 1984) is shown in Fig. 11. The cusp field enables confinement of plasma electrons because electrons approaching them start spiraling towards the cusp and reach a point where their longitudinal energy gets totally converted into transverse energy, and so they are reflected. Without such cusp fields the wall of the source would have to be biased highly negative ($3kT_e$), repelling the electrons electrostatically. The trouble with this arrangement is that all the positive ions are attracted to the wall and are lost (albeit at a smaller rate than the electrons would be lost if the walls were not biased). However, when the electrons are trapped by the cusp field the wall can be biased positively, or at least less negatively, and thus electrostatically confine the positive ions as well (Stirling *et al.*, 1979) for volume sources discussed in the next section.

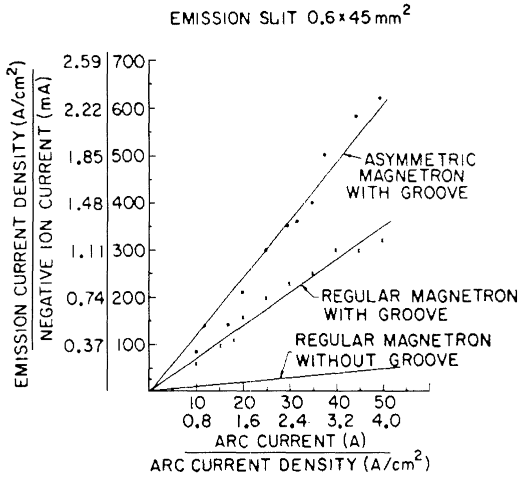

FIG. 8. H$^-$ current versus arc current for the normal magnetron with flat cathode, normal magnetron with grooved cathode, and asymmetric magnetron with grooved cathode.

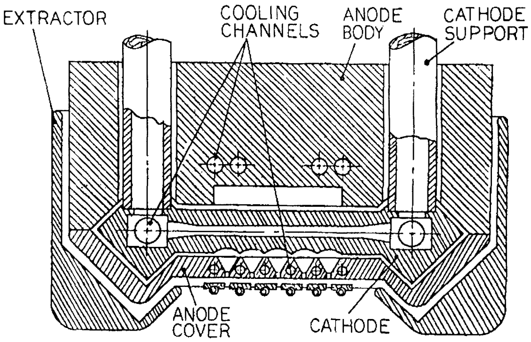

FIG. 9. Cross section of a steady-state multi-aperture magnetron source.

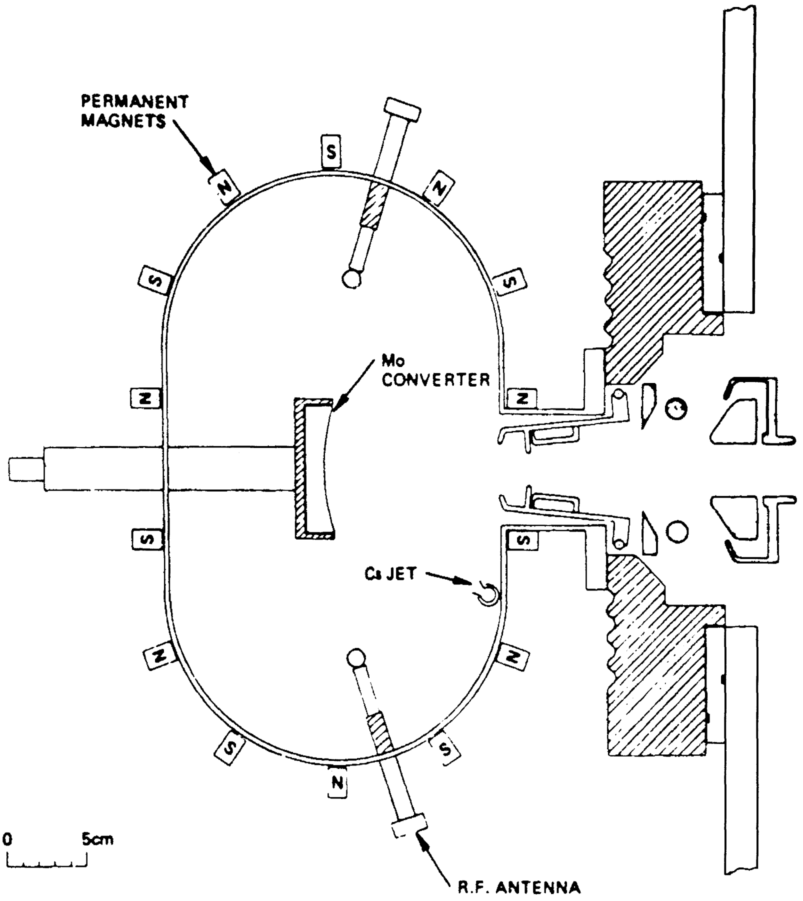

FIG. 10. Schematic diagram of the LBL self-extraction negative-ion source.

1.2 Charge-Exchange (Non-Liouville) Beam Production

One of the earliest negative-ion sources consisted of generating first a positive-ion beam and accelerating it by at least a few kilovolts and then, by running it through a gas cell, causing the positive-ion beam to undergo double charge exchange, turning it into a negative-ion beam (Semashko *et al.*, 1987). This process is inefficient compared with today's ion sources and resulted in a rather poor-quality beam. What we discuss here are the modern varieties, starting with the Penning source of Dudnikov, in which the negative ions are produced directly on a surface within the source and then in turn undergo charge exchange before extraction. This effectively lowers the ion temperature by an order of magnitude from that of the originating surface-produced negative ions.

Unfortunately, an unlucky accident occurred, which inhibited development of the low-energy, charge-exchange negative ion source—especially in the West. An inadvertent error in what is perhaps the most widely used data compilation (Barnett *et al.*, 1977) mistakenly tabulated a charge-exchange cross-section for the process

$$H^0 + H^- \rightarrow H^- + H^0,$$

that was too low by as much as a factor of eight at energies around 100 eV (Fig. 12). This was corrected in the next edition of the work (Barnett *et al.*, 1990). Anyone using these

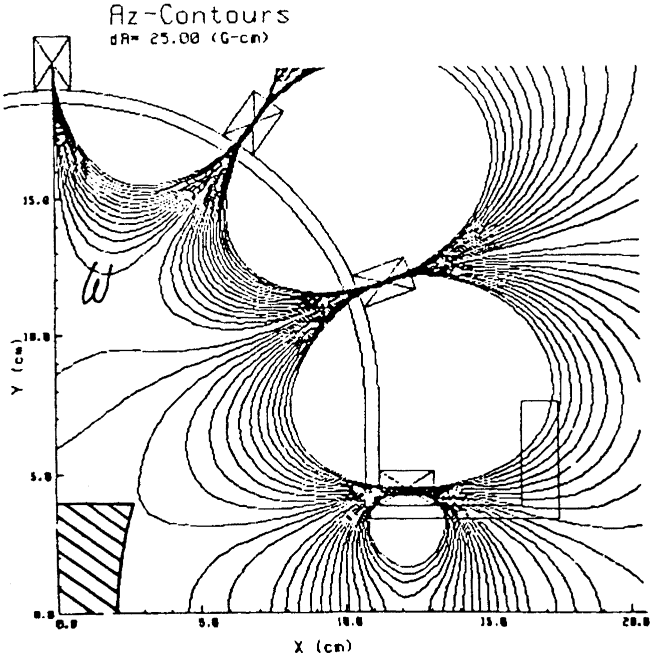

FIG. 11. Calculated magnetic field structure in one quadrant of the plasma chamber showing the filament filter and exit filter in relation to the filaments and the converter.

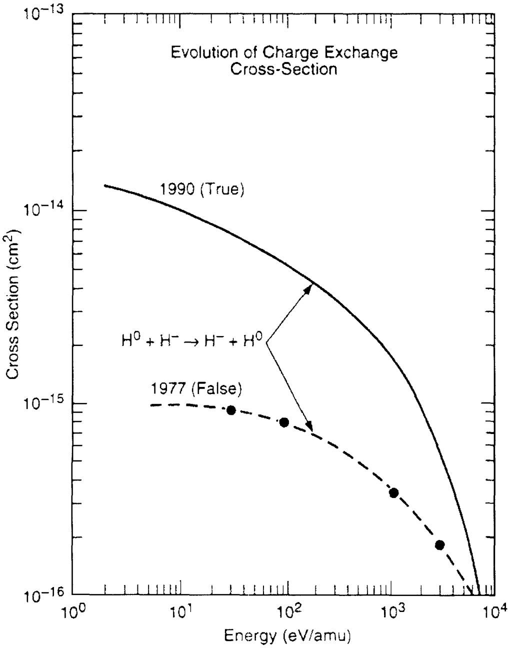

FIG. 12. Charge-exchange cross section, as published in 1977 and 1990, showing a large discrepancy especially at low energy.

erroneous data would underestimate the charge-exchange probability at these energies, resulting in the possible rejection of viable concepts. An illustration of the confusion that can arise is recorded in the comments published after the paper of Alessi and Sluyters (1980). Indeed, the discovery of the low-energy charge-exchange source was made on the other side of the world (Siberia), where the Western database might have received less attention.

1.2.1 Dudnikov Source

1.2.1.1 Cold-Cathode Penning (Dudnikov Source) The earliest negative-ion source using cesium, this configuration (see Figs. 13 and 14) is capable of prodigious output on account of a very interesting combination of brilliant inventions (Dudnikov, 1972; Belchenko et al., 1973; Dudnikov, 1980; Derevyankin and Dudnikov, 1984). This embodiment starts with a cesiated surface converter labeled as shown in Fig. 14 for initial production, but there the similarity ends; a significant variation allows a large non-Liouvillian increase in beam brightness. The negative ions once created undergo charge exchange (see Fig. 15) and may be extracted (sideways). The advantage of this

source over the direct surface extraction described in the previous section is that the charge-exchanged ions have a "temperature" that is likely to be an order of magnitude lower than that of the surface-produced ions.

An embodiment of one of the early versions of this source is illustrated in Fig. 13 showing the placement of magnets, hydrogen feed, cesium chamber, anode, and cathode. The region bounded by the anode and cathode is depicted in Fig. 14 showing the anode, cathode, converter, direction of magnetic field, and special anode chamber between the central discharge region and the accelerator. FIG. 15. Ion motion due to surface-produced ions and charge-exchanged ions within the Dudnikov source.

motion ensuing in this device is depicted in Fig. 15. Within this region, first positive ions (mostly H^+) and electrons are generated from a striker arc forming a dense, almost neutralized plasma (up to $10^{14}\,cm^{-3}$) with a plasma potential positive with respect to the cathode. In the absence of a magnetic field, the plasma potential would also be positive compared with the anode (which in turn is biased positive with respect to the cathode). However, the strong magnetic field inhibits the flux of electrons to the anode by means of the Lorentz force ($\boldsymbol{F} = q\boldsymbol{v} \times \boldsymbol{B}$), which is perpendicular to the direction of motion. The positive plasma ions are attracted to the cathode, and they intercept at an energy on the order of a hundred volts. Then, through surface production processes described above, a negative ion may be emitted [as many as one for every three incident positive ions (Seidl *et al.*, 1982)] and accelerate back down the plasma sheath, acquiring an energy of about a hundred electron volts. Because of the magnetic field the ions move largely perpendicular to the cathode (in helices). The hole in the anode shown for acceleration of these ions (*e.g.*, right side of Fig. 14) is not generally reachable by these negative ions, since they are largely confined along magnetic field lines to the region between the cathodes. These surface-produced ions would not be especially desirable for beam formation, since they have several electronvolts of random transverse energy upon leaving the converter surface (cathode) (Seidl, 1994). What is done instead is to let the surface-generated H^- ions undergo charge exchange with the gas—largely atomic H^0 under these conditions:

$$H^- + H^0 \rightarrow H^0 + H^-.$$

Some of these charge-exchanged ions do get out into the accelerator region via the anode hole depicted in Fig. 15. The virtue of this process is that the charge-exchanged ions are expected to have a much lower ion temperature than the surface-produced ones, since they originated from the much slower moving neutral atomic hydrogen gas.

Another aspect to this revolutionary source is the anode web, now known as a collar, shown in Figs. 14 and 16. Some of the effects of this web are still being explored, but a preliminary study by Allison *et al.* (1980) showed that there was an optimum web thickness whereby the extracted beam could be increased by over a factor of two (see Fig. 16). Additional meaning will be discussed in Sec. 2.2. At LANL a large effort was undertaken to vali-

date, scale up, and deploy this Dudnikov source (Allison, 1977; Allison *et al.*, 1980) for various purposes; the 4X (Smith *et al.*, 1984, 1985), 8X (Smith *et al.*, 1993), and 16X sources and the ORNL-produced "VITEX" (Dagenhart *et al.*, 1987) are examples of such scaleups.

Additional attempts to get to a higher duty factor operation include the rotating Dudnikov source (Smith *et al.*, 1980) (Fig. 17); 160 mA of H^- were reported in the 1X source.

1.2.2 Semiplanotron and SITEX Variation

By focusing the ions ahead of the extraction aperture (Dudnikov, 1980; Fig. 18), the charge-exchange reaction can be made to dominate. This was possibly achieved inadvertently in some SITEX experiments (Dagenhart *et al.*, 1984; Stirling *et al.*, 1984), because the beam-profile measurements correspond to a significantly lower ion temperature at the source as deduced from Liouville's theorem—although the charge-exchange mode

was not anticipated by the authors. An optimized configuration is shown in Fig. 19 (Dudnikov *et al.*, 1997). The benefit of this variation is that the advantage of high–current-density surface production can be combined with the current amplification due to geometrical focusing to produce high-density, low-temperature, charge-exchanged volume production. The focused surface-produced ions are focused to a region just before the extraction aperture where they undergo charge exchange with a gas (a supersonic jet may enhance the charge-exchange reaction rate). This is shown in Fig. 19. This source has the potential to deliver an H^- beam with a virtual source size of 10 μm, an emission current density of $3\,\mathrm{A\,cm^{-2}}$, an ion temperature of $\frac{1}{2}$eV, and a normalized brightness of $10^{13}\,\mathrm{A\,mrad^{-2}}$, which is very high (Dudnikov, 1993; Gudharay *et al.*, 1994).

1.2.3 Elizarov Source The Elizarov ion source (Antipov *et al.*, 1990) is taken from the positive-ion sources used in the Russian ion-thruster rocket-engine space program. A current of 1 A of H^- was extracted (Elizarov, 1972). The source (Fig. 20) consists of a hollow cathode (1) with an abundance of Cs. A cesium plasma is formed in region 9. Holes drilled in the outside of this region's cylindrical hollow cathode (2) allow plasma to escape initially into region 3, in which a radial magnetic field $\boldsymbol{B}$ is present. A series of Penning-discharge spokes is obtained. The H^- ions

drift through charge exchange toward the extraction electrodes toward region 8, with anode 1 in combination with the externally applied magnetic field providing an intraplasma field. A source built as in Fig. 20 produced 1000 mA. The Elizarov source may also be configured to produce enhanced current density in a non-Liouvillian manner. This is achieved by forming a conical channel with resistive walls or separate wall electrodes to produce the intraplasma electric fields (in combination with the transverse magnetic field). An embodiment is shown in Fig. 21.

1.3 Excited-State Volume Production (Bacal)

Researchers at Ecole Polytechnique (Bacal *et al.*, 1977) invented a pure hydrogen hybrid multicusp volume negative-ion source. It con-

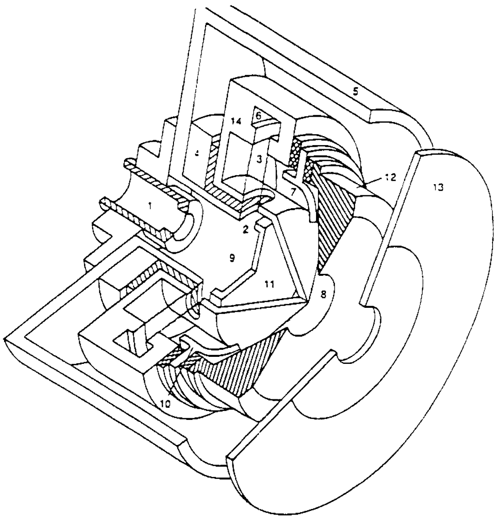

FIG. 20. Compression variation of Elizarov ion source. Shown is the cesium feed, 1; the cesium-hydrogen plasma, 9; the extraction, 2, of the cesium hydrogen plasma into the weak radial Penning discharge, 3, generated by cathode, 6; magnetic pole pieces 5, 11, 12 abide 7; funnelling electrodes 11, 12; beam extraction 8; and accelerator electrode 13.

sisted of two distinct plasmas. One, called a driver plasma (in most configurations confined by cusp field magnets; see Sec. 1.1.4) consists of a conventional discharge where hot electrons are created, causing ionization of the gaseous hydrogen and generation of vibrationally excited hydrogen molecules:

$$H_2 + e^- \rightarrow H_2^* + e^-. \qquad (1)$$

These excited hydrogen molecules drift into a second plasma region, called the target plasma, where the electron energy is arranged to be much lower (≈ 1 eV). Then the reaction

$$e^- + H_2^* \rightarrow H^- + H^0 \qquad (2)$$

has a high probability.

For the 7th vibrational level of H_2^*, for example, the reaction is 10^5 times greater than the corresponding reaction for ground-state H_2. Absence of high-energy electrons in the target plasma region reduces the rate of H^- destruction processes. An illustration of this separation in regions for energetic electrons (>3 eV) and cold electrons (≈ 1 eV) is shown in Fig. 22. The isolation of the target plasma, where cold electrons dominate, from the driver plasma, with its dominantly energetic electrons, occurs because of the presence of filter fields. Electrons going from the driver plasma to the target plasma need to undergo hundreds of collisions (some of which are inelastic) with neutral H_2, which reduces their energy so that when (and if) they finally arrive at the target plasma they are cooled. The filter fields provide a path length for the electrons that is several orders of magnitude higher than what would obtain without it, and thus increase the probability of energy-losing collisions.

1.3.1 Early Versions Two early embodiments are shown in Figs. 23 and 24 (Bacal *et al.*, 1984, 1986, 1987, 1988). In the first concept, the hot electrons are confined to the larger radii by direct insertion of multiple magnets between the filament region (driver plasma) and the target plasma. The extraction hole is shown in the bottom. In this configuration there is an opportunity for geometrical amplification of excited molecules into this excited region. The magnetic filter between the driver plasma and the target plasma is furnished by the external cusp fields, with the filaments shown being in the fringe of these cusp fields. In this case the target plasma is actually divided in turn by the fringe fields of the confining cusp fields, which serve to decrease the electron temperature in the post-extractor region, shown explicitly in Fig. 24 (Bruneteau 1986; Bacal *et al.*, 1988) and is described in the extraction section (Sec. 2). In any event, the fields further retard transport of high-energy electrons, which would otherwise quickly destroy the newly formed negative ions. The main driving force for this flurry of activity in volume sources was the requirements of the neutral particle-beam (NPB) "Star Wars" program of the 1980s where low beam emittance was critical.

1.3.2 Variations More recent embodiments of the volume source use cusp-field confinement of the driver plasma and are typified by the devices produced in the UK (Holmes and Green, 1984, 1987; McAdams *et al.*, 1984, 1987), France (Bacal and Leung, 1984), Japan (Okumura *et al.*, 1987), and the United States (Leung and Ehlers, 1984). In

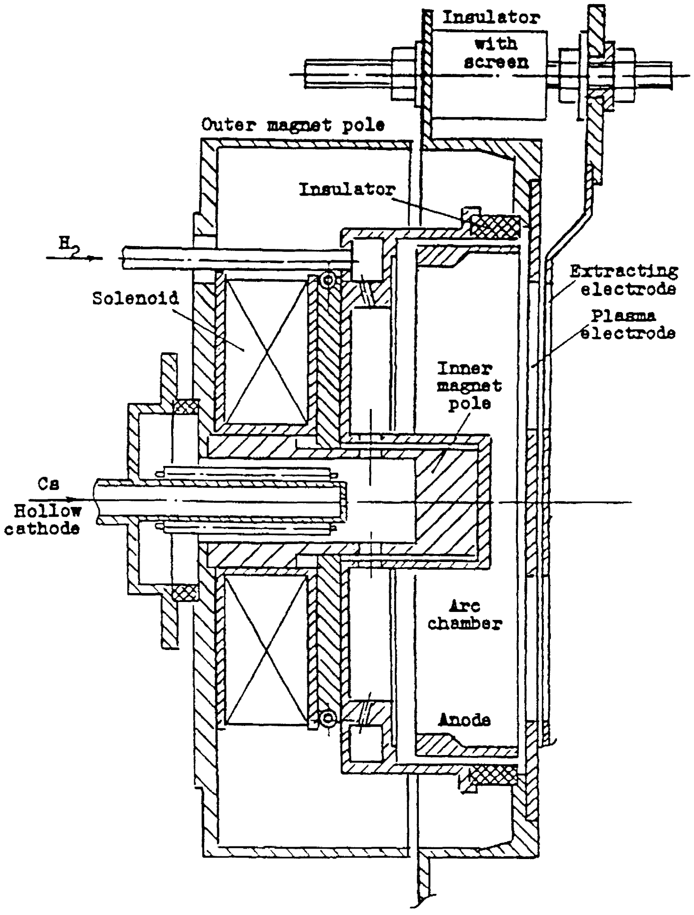

FIG. 21. Schematic diagram of Elizarov ion source.

these sources the filaments are kept totally inside the cusp field for maximum efficiency of gas ionization. The cusp fields surrounding the driver plasma enable superior confinement, since all but the lowest-energy electrons can be confined by mirror trapping resulting in their being bounced back into the plasma. The need for electrostatic electron confinement is thus reduced or even eliminated. The magnetic cusp fields also allow some reflection of the positive ions back into the driver plasma. This effect can be enhanced by biasing the containment wall less negative (or even positive) relative to the plasma.

Several more recent embodiments of this source have been vigorously pursued. One source pursued at Culham (McAdams *et al.*, 1987) (Fig. 25) employs cusp-field confinement on all but one side, as shown. The magnetic filter in this approach is provided by the two rows of linear cusp-field magnets that provide a transverse magnetic field throughout the device. A plasma with hot electrons (driver plasma) is situated on the filament side of these filter fields, while the negative-ion generation (target) plasma is shown on the extraction side.

Large-scale, multiaperture sources of this general type are being designed and built at the Japan Atomic Energy Research Institute (JAERI) (Okumura *et al.*, 1986). The electrons have to be collected locally in these sources, since the apertures are very close together. In addition, the proximity of apertures precludes the use of collars and filter-field tailoring, both of which may be useful, as discussed in Sec. 2. These sources have produced 3 A of H^- (by 1991). On a $\frac{1}{5}$-scale cesiated hydrogen source, 3.9 A of H^- at 73 keV were extracted

at NIFS (Kuroda *et al.*, 1996) and 14 A of H^- were extracted and accelerated to 125 keV in a cesium-seeded source. At JAERI, 10 A of H^- were produced (Inoue 1993); 13.6 A of H^- were extracted without cesium and accelerated to 125 keV (Takeiri *et al.*, 1996); and 5.9 A of D^- were extracted to 400 keV, with cesium (1.7 A of D^- without cesium) (Okumura *et al.*, 1996).

Multibeamlet ion sources of this type are also being actively developed at JAERI as shown in Figs. 26 and 27. The former shows the arrangement of edge magnets, which provide the plasma configuration and the magnetic filter. Also shown is the electrostatic accelerator including a thick extraction grid. This thick electrode is intended to catch the tangentially extracted electrons, assuming that no secondary electrons are produced from this surface being bombarded with 10-keV electrons, tangentially. These volume sources have been found to work better with the injection of Cs, as shown, which usually results in a significant (frequently a factor of 3) increase in the negative-ion output accompanied with a decrease in extracted-electron output (sometimes a factor of 1/100). Possible explanations will be discussed in Sec. 2.2. Another version is named the Kamaboko source (shown in Fig. 27) because the plasma containment vessel is said to be shaped like a fish. This source has been developed for thermonuclear fusion experiments and has delivered 18.4 amps of H^- current at 350 keV energy. The current density at the source is about 10 mA cm^{-2} (Ohara, 1998).

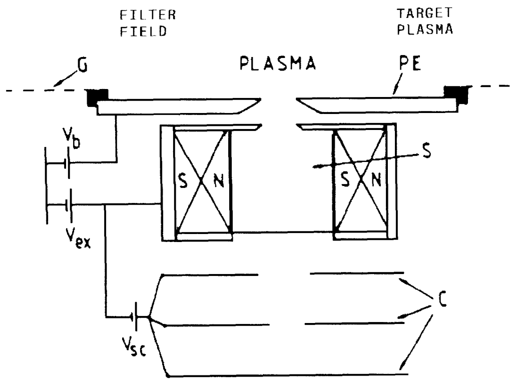

FIG. 24. Blowup of extractor region.

Development of simple beamlet sources, now mostly for accelerator applications for high-energy physics and materials science (spallation neutron sources), has proceeded along several lines. One of those is the spallation-neutron source design initiated at Berkeley (Leung, 1998).

In 1993, a variant of the Bacal source employing cusp fields, a magnetic filter, and a

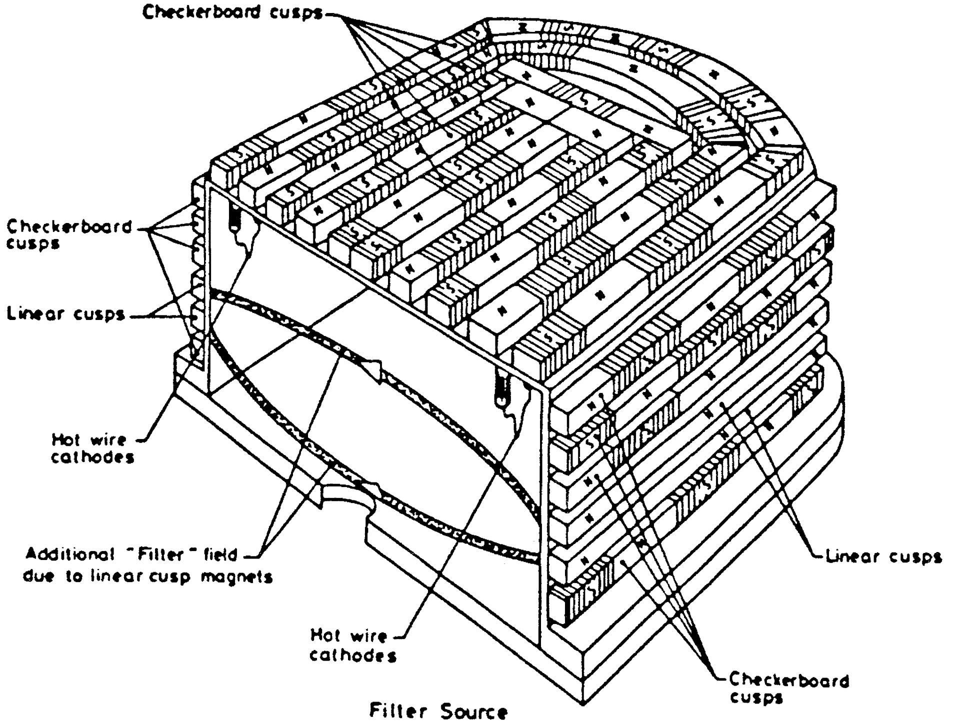

FIG. 25. Culham volume source showing a variation in the magnetic-filter configuration and cusp-field confinement on the end wall as well.

collar electrode (introduced earlier in the Dudnikov source) was produced at LBL (Leung 1994). Current densities of 250 mA cm^{-2} have been extracted for small apertures with gas pressures of 50 m Torr and $e^-/H^- \geq 100$. Ion currents of 30 mA have been extracted with a 5.4-mm-diam aperture (Leung, 1991).

An illustration of a collar arrangement is shown in Fig. 28. Notice that the target and driver plasmas are isolated from each other by the "magnetic" insulation provided by the filter fields. This insulation derives from the lower mobility of the electrons across the magnetic field, enabling the buildup of potential differences. This also means that the target plasma may be biased somewhat independently with respect to the driver plasma. The driver-plasma potential is usually determined largely by the outer walls of the ion source, which supply the arc current. The electrons drift into the target plasma via collisions. Each electron undergoes on the order of 100 collisions between the electrons and the H_2 within the filter fields and 200 collisions within the collar region. Each collision serves to cool the 8-eV electrons with the cold H_2. In addition, as depicted by the bottom half of Fig. 29, the electrons bounce off the collar electrode many hundreds of times. The probability of being captured by the collar electrode is very small per approach, but is magnified by as much as two orders of magnitude during the electron transport from the driver region to the extraction sheath. This probability is very sensitive to the plasma self bias Φ_0, so that any reduction in Φ_0 would increase the absorption per pass exponentially. A conceptual diagram is shown in Fig. 28 and a "how it goes together" diagram is shown in Fig. 30. This source uses a collar electrode, which is known to increase H^- output, especially with the addition of cesium. Discussion of this effect appears in Sec. 2.2.6.

1.3.3 rf Plasma Generation In this type of source, rf energy is injected and used to generate and maintain the plasma, instead of a filament, hollow cathode, or cold cathode.

Antenna lifetime has been studied by Peters (1998), and so far in a particular configuration the mean lifetime is somewhat under a week with continuous operation. The magnetic filter shown in Figs. 28 and 30 allows tailoring of the magnetic field to the collar geometry, which could be important. An rf-driver volume ion source was pursued at LBL (Leung 1991, 1994; Kwan *et al.*, 1993). Development in antenna design is continuing to achieve long-pulse operation at high power (Lee *et al.*, 1998). For long-term reliable operation without injection of impurities, filaments might be replaced by rf injection by antennas or horns. Several sources of this variety have been built (Fig. 28). Recent data are questioning the reliability of present development (Peters, 1998).

1.3.4 Penning Source A Penning configuration for the driver plasma is possible with a natural insulation of the driver and target plasmas taking place through the configuration of the end walls (see Fig. 31). This configuration was explored at ORNL and was named the VITEX, for Volume Ion Transverse EXtraction (Dagenhart *et al.*, 1987).

1.3.5 Toroidal Discharge One embodiment (Alessi and Sluyters, 1990), which combines the geometry of the driver plasma indicated in Sec. 1.3.1 with magnetic cusp confinement, is shown in Fig. 32. It produces 35 mA with an $e^-/\mathrm{H}^- = 5$ and 20 mA with $e^-/\mathrm{H}^- = 3$ (Alessi and Prelec, 1991). The normalized rms emittance of this source is measured to be 0.32π mm-mrad for a 13-mA beam, which corresponds to an ion temperature of 0.6 eV, an unusually low value (Alessi and Sluyters, 1990). This source generates a plasma in region 1 by electron-impact ionization from the electrons generated by the filament and accelerated through the plasma sheath surrounding the filament. This driver plasma is confined by the cusp fields on the edge of the container as shown. By drifting through the magnetic fields within the plasma, low-energy electrons arrive in the target region 2. The device was subsequently embellished (Alessi *et al.*, 1994) by providing a stronger conical intraplasma magnetic field (Fig. 33). This increased strength provides fewer unwanted high-energy electrons in region 2. The conical shape ensures that the maximum pos-

sible flux of low-energy electrons appears in the dissociative attachment regions. Also, because of the diverging magnetic fields near the extraction aperture 3, electrons are discouraged from being extracted. This is very important as indicated in Sec. 2.2.4. This concept has been subsequently explored at LANL (York *et al.*, 1993) with some variations in the filter-field configuration. H^- ion currents of $20\,\mathrm{mA\,cm^{-2}}$ (without cesium) and $40\,\mathrm{mA\,cm^{-2}}$ (with cesium) have been achieved.

1.3.6 Adding Cesium The effect of adding cesium to a volume source is generally that the negative-ion current increases by as much as a factor of 3. Also, and no less important, the extracted electron current decreases by a factor of as much as a hundred. This is shown in Fig. 34. Adding cesium in the compact multicusp source described in Sec. 1.3.2 increased the current from 7 to 34 mA. The current density with cesium was as much as $1.2\,\mathrm{A\,cm^{-2}}$ (Leung *et al.*, 1989). The addition of cesium in the toroidal filter source being explored at Brookhaven National Laboratory (BNL) (York *et al.*, 1993) provided a doubling of the negative-ion current and a reduction of e^-/H^- extracted from 5:1 to 2:1.

2. PHYSICS OF HYDROGEN NEGATIVE-ION EXTRACTION

It is one matter to produce negative ions as discussed in Sec. 1 but quite another to extract them into a beam with low emittance. In this section we discuss two classes of extraction: direct extraction from surface sources and extraction from volume sources. Each has its peculiarities, and the physics and computational issues of each are discussed.

2.1 Ion-Extraction Physics for Surface Sources

Surface sources are divided into two categories depending on whether the magnetic field is large or small.

2.1.1 Low-Field Surface Sources For direct-extraction sources, the extraction physics may seem relatively straightforward, since the negative ions travel through the intervening plasma at a high energy of 100 eV. However, for the cases where there is a large distance between the converter and the extraction region, finite-T_e effects may be important and need to be treated with care.

For volume extraction, all situations need special treatment since the analysis used for positive-ion extraction is not appropriate. Lawrence Berkeley Laboratory proposed a direct-extraction negative-ion source (Ehlers and Leung, 1980), which is shown in Fig. 35. Measured beam widths are shown in Fig. 36. The common interpretation of the large beam width at the focal point is that it is due to the high ion temperature ($\approx 7\,\mathrm{eV}$) coming off the converter. While this is a significant cause for this beam divergence, another one is the high space-charge forces within an imperfect ($T_e > 0$) plasma in which they are transported. An illustration of this latter effect is provided in Fig. 37, which shows the ion trajectories for three different plasma electron temperatures. At higher electron temperatures, deviations from perfect plasma neutrality occur, causing the beam optics to deviate from the idealistic case of Fig. 37 (top) with $T_e = 0.25\,\mathrm{eV}$. The solution of the Vlasov–Poisson equations for this type of source is usually done with the assumption (Whealton *et al.*, 1984, 1987, 1988) that the sum of the positive ions and electrons is a Boltzmann distribution. The temperature, denoted as the electron temperature, is actually that of the Boltzmann distribution. This type of analysis is expected to give a lower bound to various optical aberrations, since it neglects any Bohm ion-acoustic instabilities at the beam edge and also neglects finite negative-ion temperature (as much as 6 eV) coming off the converter. Finite ion temperatures in the limit of zero plasma temperature were considered separately (Anderson, 1984). For finite plasma temperature, $T_e = 4\,\mathrm{eV}$, which is the range commonly expected, noticeable but perhaps not drastic deviations occur; for $T_e = 16\,\mathrm{eV}$, which is higher than expected, the crossover essentially disappears, and the optics are seriously affected for this geometry. Other geometries could produce better options for these high–electron-temperature situations. The fraction of beam transmitted and beam diver-

gence as functions of electron temperature in eV, derived by the accelerator potential, are given in Fig. 38, showing the regions of single vignetting and multiple vignetting.

A more extreme situation of imperfect transport is shown for the Los Alamos Meson Pion Factory (LAMPF) injector (Whealton *et al.*, 1984), on account of a much more elongated region between the converter and extraction. The idealistic case of 0.0009 eV shows the optics as intended (York, 1983). However, even for $T_e = 0.1$ eV, which is far lower than expected, deviations from a perfect crossover point are expected. For the more realistic electron temperature of 10 eV, as shown by Whealton *et al.* (1984), the optics are significantly affected.

2.1.2 High-Field Surface Sources The long transport region that was at least conceivable in the field-free sources discussed in the previous section is not possible in the high (magnetic)-field sources where the transport region must be short compared with an ion gyroradius. For the SITEX source, Fig. 39, the negative-ion trajectories from the converter in two dimensions (2D) are shown in Fig. 40 (Whealton *et al.*, 1984), and a scheme to use a finite ellipsoidal segment converter to obtain an approximately round beam is shown by the

3D calculation of Fig. 41 (Whealton *et al.*, 1985). The ellipsoidal connector ion source was designed such that the magnetic field was parallel to the surface and a Penning discharge would feed positive ions to the converter. A better scheme is to use the magnetron architecture described previously and also to use the charge-exchange focusing technique. An optimized version of all this is discussed in Sec. 1.2.2.

2.1.3 Dudnikov Source The Dudnikov source is considered to be a volume-production source since the actual ions extracted are

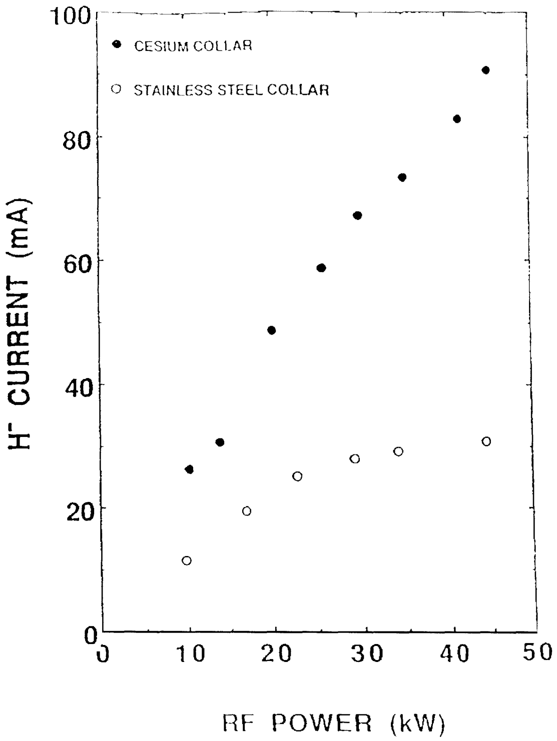

FIG. 34. Effect of cesium on negative-ion production.

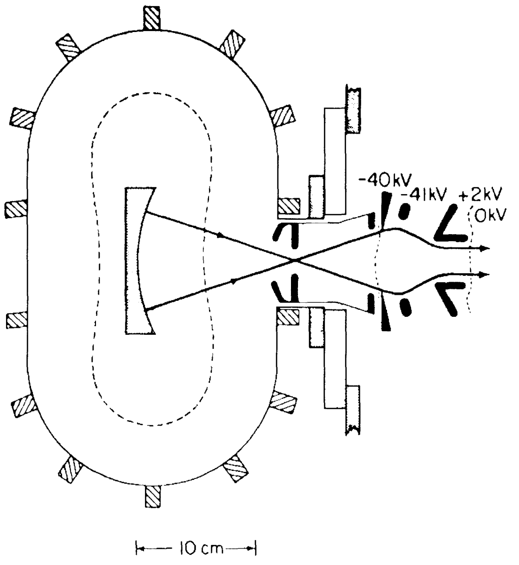

FIG. 35. Field-free converter source considered at LBL showing converter, ideal ion envelope, various vignetting and accelerating electrodes and cusp-field plasma containment.

produced through charge exchange from surface-produced H^-. Initial attempts to model this source assumed perfect symmetry with positive-ion extraction, showing something like Fig. 42 (Smith *et al.*, 1984) in 2D, and Fig. 43 (Bell *et al.*, 1985) in 3D. This approach generally was at significant variance with experiments that showed a variation of ion current with extraction voltage. The oblique sheath produced by the $E \times B$ drifting electrons, which also must share the transverse space-charge limit, is important but was not considered at the time. The existence of a drift region just before the extraction plane was suggested by Dudnikov and has an optimum thickness that is the balance between negative-ion depletion and extracted-electron depletion. The electron current decreases much faster with thickness than the ion depletion (Allison *et al.*, 1980).

2.2 Ion-Extraction Physics for Volume Sources

Negative-ion extraction from volume sources is less robust than extraction from

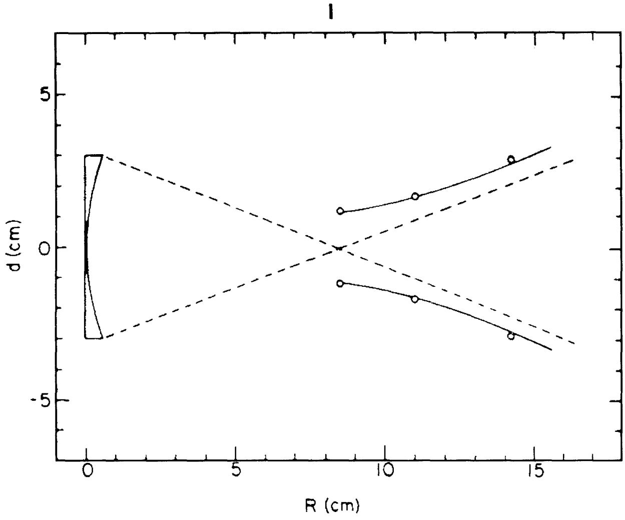

FIG. 36. Measured beam width (FWHM) compared with the idealistic zero-ion-temperature envelope trajectory.

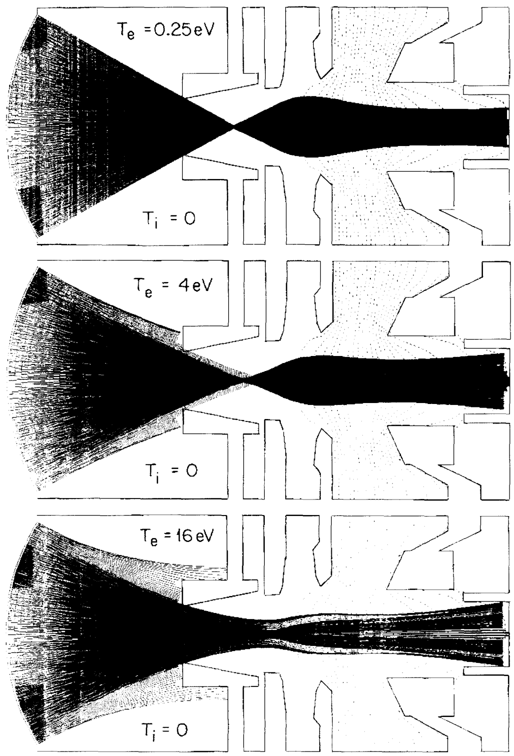

FIG. 37. Ion trajectories, still assuming zero ion temperature but considering a finite electron temperature.

surface sources, where the ions are rocketing toward the extraction aperture at energies of 100 eV or more. In fact, volume negative-ion extraction is less robust than volume positive-ion extraction for a number of reasons. For volume sources, creation of initial energies on the order of only 1 eV are expected. If the intraplasma electric fields accelerated the negative ions toward the extraction aperture, as is largely the case with positive ions in positive-ion sources, then the low initial kinetic energy of the negative ions would not be so important. The ionic flow is illustrated in Fig. 44(a) for a steady-state positive-ion source. For cases where ion-acoustic plasma-sheath instabilities develop, the situation is typified by Fig. 44(b). These positive ions, whether stable or otherwise, are electrostatically attracted toward the extraction region and either are extracted or intercept the plasma electrode. Unfortunately, these very intraplasma electric fields that tend to accelerate the positive ions toward the extraction region accelerate most of the newly formed negative ions in the opposite direction, toward the source plasma (Whealton *et al.*, 1987).

2.2.1 Asymmetries Between Positive- and Negative-Ion Extraction

For positive-ion extraction, the analysis is well developed (Whealton, 1981) using the following form of the Vlasov–Poisson equations:

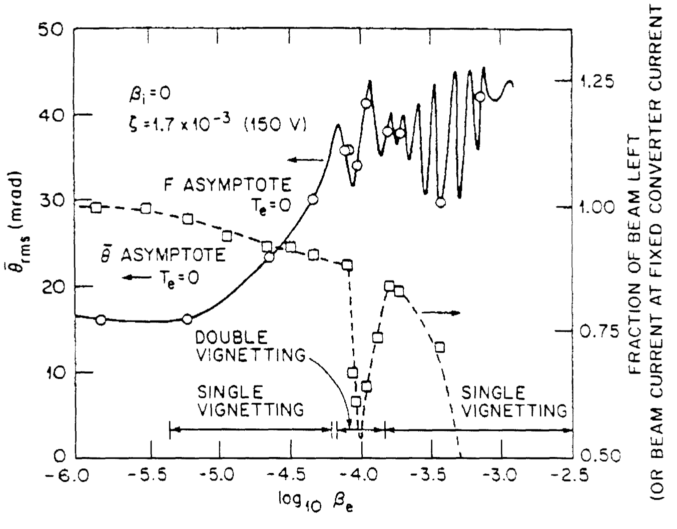

FIG. 38. Beam divergence and transmission as functions of electron temperature assuming an ion temperature of zero.

$$\nabla^2\varphi(\mathbf{r},t) = -\int f(\mathbf{r},\mathbf{v},t)\,\mathrm{d}\mathbf{v} + \exp[-\varphi(\mathbf{r},t)], \tag{3}$$

$$\frac{\partial f(\mathbf{r},\mathbf{v},t)}{\partial t} + \mathbf{v}\cdot\nabla f(\mathbf{r},\mathbf{v},t) + \{\mathbf{v}\times\mathbf{B} - \nabla\varphi\}\cdot\nabla_v f(\mathbf{r},\mathbf{v},t) = 0, \tag{4}$$

where φ is the electrostatic potential; f is the ion distribution function, which is a function of position $\mathbf{r}$, velocity $\mathbf{v}$, and time t; $\mathbf{B}$ is the magnetic field.

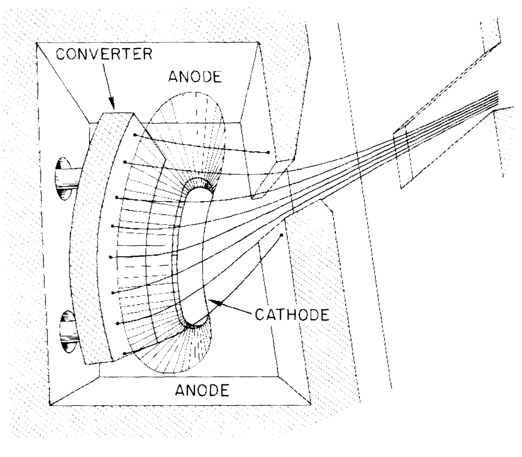

FIG. 39. Elevation view of the ORNL SITEX surface negative-ion source showing the converter, surface negative-ion trajectories, Penning discharge as projected from anode slot and extractor slot.

The first convergent solution to these equations in 2D was obtained by Cooper *et al.* (1974), for a partial sheath, and by Whealton *et al.* (1978) and Whitson *et al.* (1978) for a full sheath in 2D. The three-dimensional solution came later (Wooten *et al.*, 1979, 1981; Whealton *et al.*, 1986) and ion-acoustic time scales yet later (Whealton 1985).

The first asymmetry between negative-ion sources and a reversed-potential positive-ion source is that the electrons cancel charge imbalance excursions in positive-ion sources much better than positive ions do in negative-ion sources. This observation led to the heuristic model of Whealton *et al.* (1989), which appears to be in agreement with the laboratory data of Bacal and Stevens; see Figure 45. An example of the actual trajectory computations, at points A, B, C, and D in Fig. 45(c), is shown in Fig. 46. The plasma sheath condition in these cases varies from extremely underdense (A) to extremely over-dense (D), all falling within the laboratory observations at Ecole Polytechnique. Similar results were obtained for the LASL data [Fig. 45(a)]. It is common to model negative-ion extraction from volume sources using the above model (Tanaka *et al.*, 1998; Watanabe *et al.*, 1996; McAdams, 1994; Cowan, 1994; Bell *et al.*, 1985; McGaffey *et al.*, 1984; Smith *et al.*, 1984; Gudharay *et al.*, 1994; Chan, 1993, 1994; Maeser *et al.*, 1996; Whealton *et al.*, 1986, 1988), an example of which is shown in Fig. 47. How-

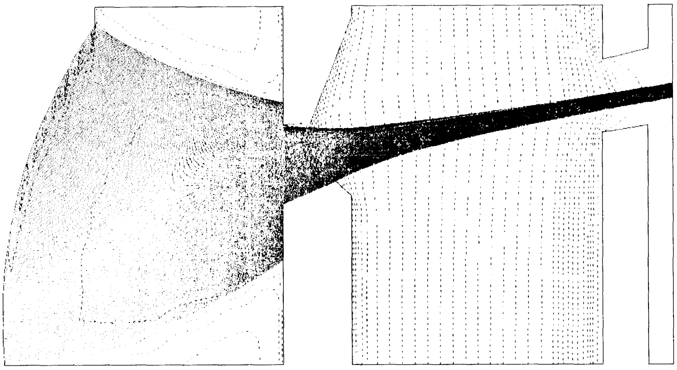

FIG. 40. Computer simulation (2D) of trajectories of negative ions from converter and extracted into slot beam.

ever, this procedure has little meaning, since it assumes that the positive ions are in equilibrium (which is not true) and neglects any explicit consideration of plasma electrons, which could be very important. Furthermore, the model assumes that the negative ions enjoy the same downhill run from plasma to extraction that positive ions have in positive-ion sources.

2.2.2 Saddle-Point Extraction The second asymmetry between negative-ion sources and reversed-potential positive-ion sources arises from the observation that the plasma electrode is biased negative to the local plasma potential for negative-ion sources just like in positive-ion sources and for the same reason—to contain the plasma electrons electrostatically. Therefore, in a positive-ion source, there is a continuous, monotonic downhill run for the positive ions generated deep in the plasma from formation through extraction. For negative ions, there is a saddle point formed within the plasma, since the plasma potential lies intermediate between those of the plasma electrode and the acceleration electrode. This saddle point is shown in Fig. 48, which for illustrative purposes is calculated in the limit of zero space charge (vacuum fields). For the positive ions [Fig. 48(a)], there is acceleration toward extraction in the region where $A_z < 0$ until they reach the saddle range ($A_z = 0$), after which they decelerate, turn around, and either return to the plasma or intercept the plasma electrode. The created negative ions, shown in Fig. 48(b), are electrostatically repelled from the extractor in regions labeled $A_z < 0$ and are electrostatically attracted toward the extractor in the region $A_z > 0$. A large volume of negative ions created is repelled from the extraction region. There is no extraction sheath in this case, since the plasma density is zero. This observation of a potential hill was made ten years ago (Whealton *et al.*, 1987) but has attracted scant attention. Recent notice has resulted in a heuristic model of a virtual cathode (Becker *et al.*, 1998), which may eventually provide a useful approach. Another approach in order to avoid the complex nonlinear theoretical problem is to use steady-state intraplasma fields derived from experiments and then plot trajectories

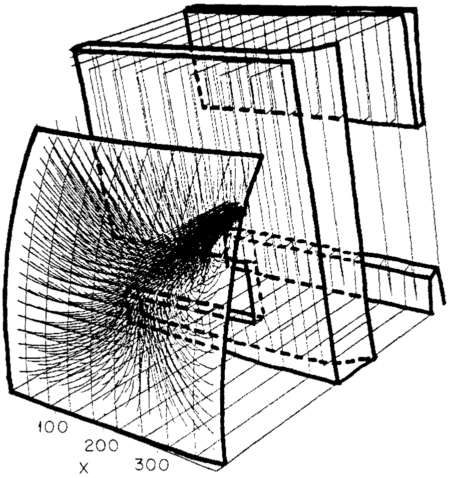

FIG. 41. Computer simulation (3D) of trajectories of negative ions from connecter and extracted into finite slot beam. The slot ends have been tailored as shown to minimize aberrations from slot end effects.

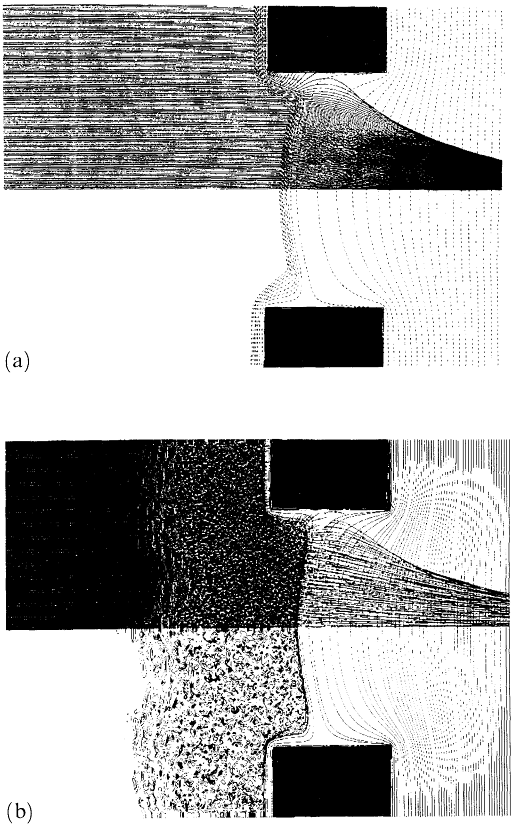

FIG. 44. (a) Plot of ion trajectories (solid lines) and equipotentials (dotted lines) in the extraction region bounded by an electrode (solid) with an aperture for ions. Beam current due to accelerator electrode interception. (b) Same as (a), except that an ion time-scale solution to the Vlasov-Poisson equations is shown for positive-ion extraction (electrons are still Boltzmann) in a region where the Bohm sheath stability criteria is not satisfied, resulting in ion-acoustic waves in the presheath and concomitant rms emittance growth.

numerically through these fields (Riz and Pamela, 1996). This makes the theoretical problem linear and straightforward. Unfortunately, the experimental measurements of plasma potential have, so far, not been resolved to provide reliable fields. Furthermore, ion-acoustic instabilities may further complicate the measurement so that a steady-state treatment of ion kinetics is questionable. Negative ions formed on one side of the ridge go toward the source plasma instead of the extraction aperture. In these cases, the location and control of such ridges could be important.

A third asymmetry results in electrons being extracted along with the negative ions, unlike the case for positive-ion sources. A fourth asymmetry is that the Bohm sheath-stability criterion is expected to be violated more extensively within certain regions for negative-ion sources than is the case for positive ion sources, at least in the absence of cesium. An illustration of the consequences of the violation of the Bohm stability criterion is shown in Fig. 44(b) [although this example is for a single Vlasov positive-ion model (Whealton *et al.*, 1987)]. An example of an actual situation where ion-acoustic instabilities may occur is illustrated in Fig. 49, where the ion temperature appears to be increasing with plasma density. This instability occurs when any process that increases the negative space charge in the pre-extraction region causes the curvature of the potential to become positive (as evidenced from the structure of the Poisson equation). Evidence for the existence of ion-acoustic instabilities in the extraction sheath is present in the disparity between ion temperatures measured in the beam, normally 1–7 eV, and within the plasma (Bacal *et al.*, 1990) of

0.1–0.7 eV. Analysis capable of considering sheath-produced ion-acoustic waves, as a result of the Bohm instability, will be a necessary future step in the accurate modeling of negative-ion sources. These instabilities may actually increase the availability of negative ions for extraction. Still another process, known as stochastic resonance, can occur whereby some negative ions are pushed over the hill by the fluctuating fields.

FIG. 47. The 500-keV accelerator and beam orbit simulation.

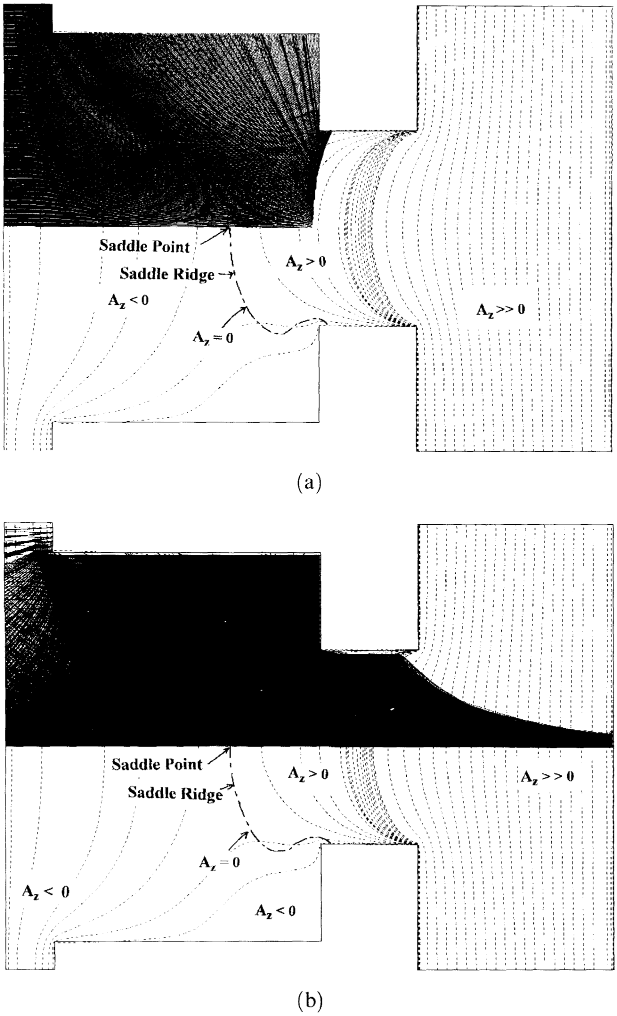

FIG. 48. (a) Positive-ion trajectories shown for negative-ion source with geometry similar to that shown in Fig. 28 or 30. Equipotentials are shown by dashed lines. In this very low-density case (the length of the figure is one Debye length), a saddle point in the potential is clearly shown; the region where volume-produced negative ions are kicked in the direction of the extraction are denoted by $A_z > 0$; regions denoted by $A_z > 0$ indicate that created negataive ions are given a kick back into the plasma. The positive-ion trajectories shown all end up hitting the electrode since they are repulsed by the beam accelerating fields. (b) Volume-created negative ion trajectories for the same case as discussed as above.

2.2.3 Double-Vlasov Model For negative ions it is useful to consider the plasma positive ions using a Vlasov description. It is necessary to consider these plasma positive ions kinetically, Eq. (5), because they are far from equilibrium, executing at most two passes through the region. It is still appropriate to consider the electron density in the presheath to be a Boltzmann distribution since the electrons are collision dominated and generally have to transverse a magnetic field in the pre-extraction region. A description is as follows:

$$\frac{\partial f_+}{\partial t} + \boldsymbol{v} \cdot \nabla f_+ + [\boldsymbol{v} \times \boldsymbol{B} - \nabla\varphi] \cdot \nabla_v f_+ = \delta(S_1), \tag{5}$$

$$\frac{\partial f_-}{\partial t} + \boldsymbol{v} \cdot \nabla f_- - [\boldsymbol{v} \times \boldsymbol{B} - \nabla\varphi] \cdot \nabla_v f_- = G(\boldsymbol{r}), \tag{6}$$

$$\frac{\partial f_e}{\partial t} + \boldsymbol{v} \cdot \nabla f_e - \frac{M}{m_e}[\boldsymbol{v} \times \boldsymbol{B} - \nabla\varphi] \cdot \nabla_v f_e = \delta(S_2), \tag{7}$$

$$\nabla^2\varphi = \int [f_+(\boldsymbol{v}) - f_-(\boldsymbol{v}) - f_e(\boldsymbol{v})]\,\mathrm{d}^3v - \mathrm{e}^{-\varphi}. \tag{8}$$

A case with significant plasma density (which corresponds to 1000 Debye lengths λ_D for the length of the device) is shown in Fig. 50. At these densities, positive ions falling downhill from the center of the plasma, as shown in Fig. 50, are accelerated until they reach the saddle

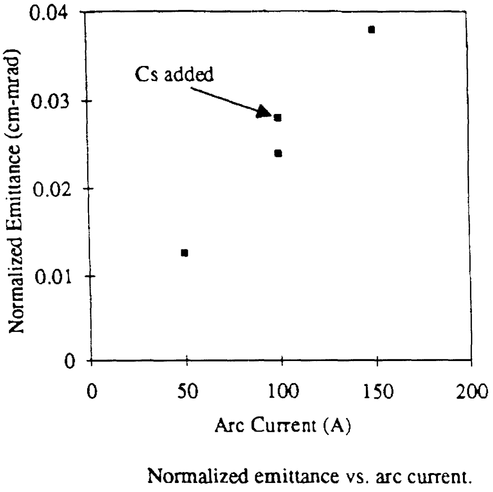

FIG. 49. Normalized emittance as a function of arc current. This indicates that the ion "temperature" depends on plasma density. Increasing ion-acoustic waves in the presheath is a likely explanation for this effect.

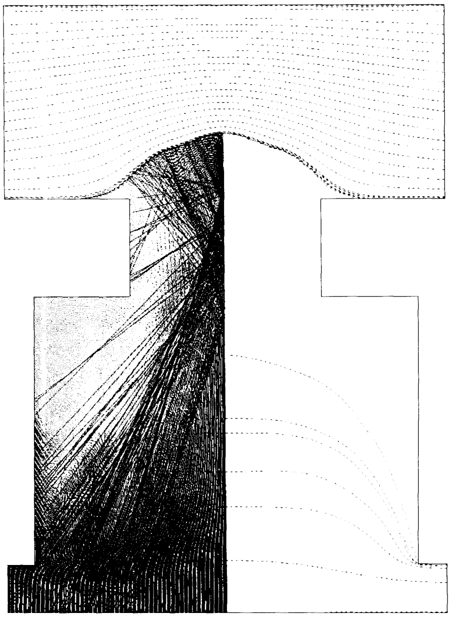
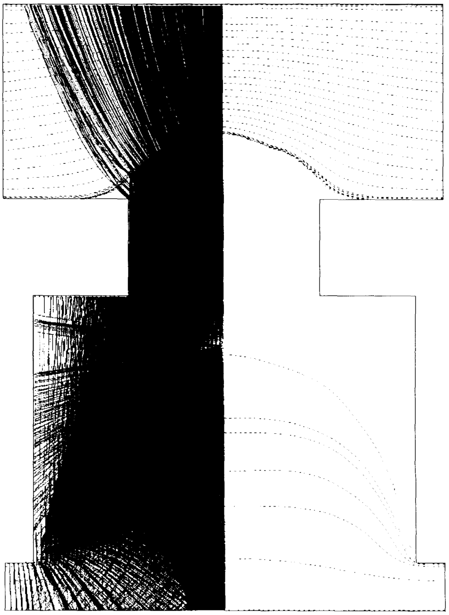
ridge. Then the positive ions are repelled by the accelerator fields and are attracted into the plasma electrode as shown. This is in contrast to the case for positive ions, shown in Fig. 44(a), some of which can get extracted. For volume-produced negative ions, the trajectories are shown in Fig. 50(b). Here, only a fraction of the negative ions produced are extracted, and the rest are attracted to the body of the plasma since they are repulsed by the plasma electrode.

2.2.4 Transverse Space-Charge Limits

When the extracted current depends on extraction voltage [see Fig. 9a of Ando (1994), or Fig. 9 of McAdams *et al.* (1987), or Fig. 45], which is usually the case at high currents, the beam is said to be transverse space-charge limited (TSCL). This is because the extraction voltage has very little effect on the negative-ion generation rate, and so the beam is limited by interception on one or more electrodes. This interception comes about as a result of poorly matched optics because of an oversupply of space charge (like charges repel—Coulomb's law). An example of experimental results is shown in Fig. 45, which illustrates this space-charge–limited flow. This is further substantiated by noting that the separate curves



(a)



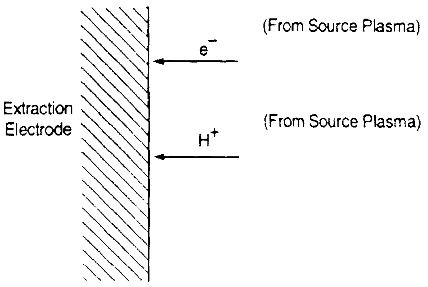
(b)

FIG. 50. (a) Same as Fig. 48(a), except that the plasma density is higher. Instabilities have been suppressed by space charge under relaxation. (b) Same as Fig. 48(b), except that the plasma density is higher.

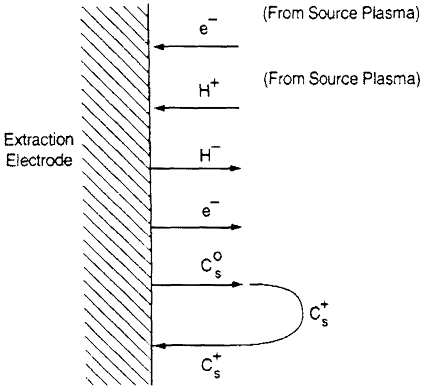
in Fig. 45(b) actually scale by the Child–Langmuir proportionality [a consequence of dimensional analysis for positive ions (Whealton and Jaeger, 1977)], as proven by the coalescence of the curves in Fig. 45(b) into one curve, Fig. 45(c). The very nature of a transverse space-charge limit means that if the generation rate is increased (beyond any decrease in electron space charge), the beam current actually decreases. This is seen for example in Fig. 45(b), where at 200 V, the extracted H^- current for an arc current of 50 A is less than that for 30 A. The reason for this decrease is that the excess negative-ion beam generation not only gets intercepted by the electrodes but causes some of the formerly transmitted ions to be intercepted by the accelerator structure.

2.2.5 Effect of Cesium In volume sources the addition of cesium can cause an increase in the negative-ion current by up to a factor of 3 and a decrease in electrons extracted by a factor of as much as 100. One reason for the increase in negative-ion current extracted is that cesium converts positive ions into negative ions at a suitably coated surface. However, since the source typically operates at the space-charge limit, addition of more negative ions by surface production does not account for the increase in negative-ion beam current. Alternatively, the concomitant decrease in electrons extracted (frequently a factor of 100) may increase the partition of the space-charge limit occupied by the negative ions. If, for example, the electrons extracted were 100 times the ion current, not unusual for a negative-ion source operating without cesium, then the electrons could be taking up as much as two-thirds of the space-charge limit. The elimination of most of these electrons frees up two-thirds of the transverse space-charge limit, enabling the ion current to be 3 times higher, if one assumes that no emission limit exists at these higher currents.

An important question is how the presence of cesium so drastically decreases the number of extracted electrons. The effect of cesium on negative-ion output and electrons extracted varies from source to source, but the cases where the effect is greatest usually involve the application of magnetic fields and frequently such accoutrements as a collar electrode (see Sec. 1.3). What occurs is that the self-biasing of the plasma with respect to the extraction electrode can change with the presence of cesium from that which it would have without it. What determines the self-bias is the flux of positive and negative charges from the electrode. For a noncesiated electrode, in the simplest case, positive ions are drawn into the electrode and are balanced by the flux of the much more mobile electrons shown simplistically in Fig. 51(a). In this simple case, the positive charge flux is balanced by retarding the source-plasma electrons electrostatically. This retardation of electrons is done by a self-biasing of the plasma positive with respect to the electrode, as shown in Fig. 52. As an example for H^+ and a Boltzmann equilibrium electron distribution, a bias V_b of $3.6\,kT_e/e$, as shown in Fig. 52, will effect a balance between the electron and ion fluxes.



(a) Without Cesium



(b) With Cesium

FIG. 51. Charge balance in ion source (a) without and (b) with cesium.

A cesium coating, with its lower work

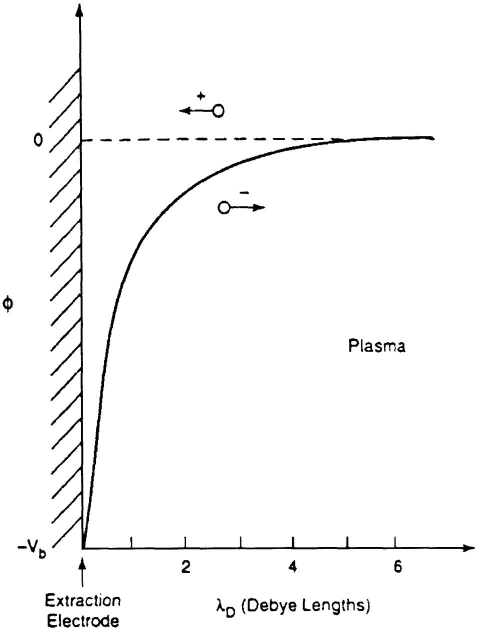


FIG. 52. Positive and negative charge flow near negatively biased electrode.

function, allows other processes to occur. One process is the conversion into negative ions of the positive ions intercepting the surface. Another process is the ejection of electrons from the surface. Finally, from neutral sputtered cesium (due to positive-ion bombardment) come positive ions, Cs^+, due to ionization by electrons and H^+; these ions return to the electrode. The Cs^+ has been observed to be a dominant species of positive ions (Ogasawara *et al.*, 1998). All three of these new processes, due to the cesium coating, cause an additional net flux of positive ions, as shown in Fig. 51(b). All of these additional processes tend to lower the magnitude of the negative wall bias so that more plasma electrons are absorbed by the extraction electrode.

To see what a profound effect this has on the electrons extracted, we need to have the transport configuration typified by Fig. 29. This is the simplest case without cesium, with only the positive ions and electrons shown. The electrons execute multiple bounces with the extraction collar electrode. The increased probability of absorption on each pass, due to decreased magnitude of bias, will dramatically decrease the number of electrons arriving at the extraction sheath. An illustration of the various additional surface mechanisms due to cesium is shown in Fig. 53.

Therefore, the reasons why a cesium coating can reduce the electrons extracted are twofold:

1. The self bias of the target plasma is diminished, allowing increased absorption of the electrons drifting in from the driver plasma; and
2. the additional flux of surface-produced negative ions partially goes back to the driver plasma, which reduces the electron flux drifting in from the driver plasma since fewer are needed for charge neutrality.

2.2.6 Increasing the Transverse Space-Charge Limit (TSCL) Now that it has been shown that cesium allows the negative ions to occupy virtually the entire transverse space-charge–limit budget, it remains to consider how the space-charge limit itself can be increased. The transverse space-charge limit is usually thought to depend on the geometry of the electrodes, the potentials applied, the beam current density, and the mass and charge of the ions. Actually, the transverse space-charge limit also depends on the shape of the extraction sheath, which by artificial means can be further manipulated. For example, the deliberate introduction of an additional positive charge into the pre-extraction sheath region would have the effect of changing the curvature of the sheath, effecting a *higher* space-charge limit (Whealton *et al.*, 1998). (Actually, this could be done also for positive-ion sources by the introduction of negative space charge in the presheath region.) Ionized sputtered cesium is just such a source of positive ions. There is an abundance of experimental evidence indicating the increase in space-charge limit for negative ions. The Dudnikov source, Sec. 1.2.1 (see Fig. 13), is perhaps the first source to use a collar with significant improvement (Allison 1980). Therefore, a cesium addition could increase the beam current beyond the transverse space-charge limit.

The Cs^+ space charge in the region just before extraction not only serves to increase the transverse space-charge limit by causing the extraction sheath to be more concave (Fig. 54 compared with 50), but can also reduce Bohm instabilities, through a reduction of the regions

where there is an excess of negative space charge in the pre-extraction volume.

3. APPLICATIONS

Several applications require beams of H^-. They are in the areas of material sciences, semiconductor processing, high-energy physics, nuclear physics, energy technology, and weapons.

3.1 Beam-Storage Rings—Pulsed Spallation Neutron Sources

Pulsed spallation neutron sources require proton energies of 1 GeV or so and as high a current as possible. This is usually done by storing GeV protons in an accumulator ring. To reduce the emittance of the ring current, negative-ion injections are used to avoid the consequences of Liouville's theorem. The negative ions are produced in a single-aperture source and accelerated with an rf LINAC. For a review, see Alonso (1996).

3.2 High-Energy Neutral Beam for Fusion-Plasma Heating

Neutral beams (300 keV) of hydrogen, made by stripping an H^- beam, that pass through ambient magnetic fields become ionized (positive), which puts a positive potential in the end-plug plasmas. Positive ions escaping from the mirror device are repelled by these intraplasma fields, thus enhancing plasma confinement in the mirror field.

Neutral beams of high energy, 0.5–2 MeV, are required to heat, fuel, and provide a current driver for Tokamak fusion experiments. These beams need to be neutral to get past the intense magnetic fields at the tokamak's edge. The best way to produce significant H^0 currents is to start them as negative ions and accelerate them to the required energy, then pass the beam through a gas (or plasma or perhaps a laser beam), stripping off the excess electron and making them neutral. It is far easier to remove the electron than to add an electron to a positive ion at such energies.

3.3 High-Energy Neutral Beam for the Strategic Defense Initiative

In order to fly through space unaffected by the Earth's magnetic field, neutral beams are desired. These neutral beams need to be on the order of 10% of the speed of light, and so the best way they can be produced is by generation from H^- (or D^-). These negative ions are accelerated, and then the excess electron is stripped off, leaving a neutral beam. Of course, these neutral beams need to be steered in a specific direction without significant aberrations.

3.4 Ion-Projection Lithography

Advantages of using negative ions for ion projection lithography are that the loosely bound electrons fly off as secondary-emission electrons, preventing charging (see Fig. 55), a major limitation in reliability for small feature size (Gudharay *et al.*, 1994, 1996; Ishikawa, 1994, 1996).

4. CONCLUSIONS

Negative-ion sources during the last quarter century have advanced from microampere to ampere current production. This advance has been associated with many measurements; however, the improvement has been largely empirical. A deep understanding of the beam formation mechanism has yet to be demonstrated. The half dozen or so nonlinear processes simultaneously occurring have prevented a self-consistent synthesis.

The material presented and interpreted here summarizes the major components of our understanding. Using negative-ion current as a marker, six orders of magnitude improvement

GLOSSARY

Brightness: The specific current of particles emitted by unit surface into unit solid angle.

Calutron: A powerful plasma ion source with hot cathodes, gas discharge with electron oscillation in a strong magnetic field, and transverse extraction of the ion beam, developed by E. O. Lawrence for isotope separation.

Cesium Catalysis: The significant enhancement of negative-ion formation in a gas discharge by the addition of a small admixture of cesium or other substances with low ionization potential, decreasing the electrode work function.

Child–Langmuir Law: The equation for space-charge–limited current density in a vacuum diode.

Electron Affinity: The binding energy of the additional electron in a negative ion.

Electron Cyclotron Resonance (ECR): Resonance absorption of electromagnetic radiation by electrons in a static magnetic field when the electromagnetic frequency is equal to the cyclotron frequency of the electrons. It is a most powerful method of heating electrons to a high temperature.

Emittance: A measure for the volume in phase space occupied by a beam, indicative of the reciprocal of the quality of the beam.

Ionization Potential: The smallest potential difference necessary for electron acceleration to produce atom or molecule ionization; equal to the binding energy of an electron in the atom or molecule.

Penning Discharge: A low-pressure gas discharge with oscillation of electrons along the anode tube in a magnetic field between two cathodes.

Perveance: Beam current divided by square root of the acceleration potential; used as a measure of the ratio of current to the transverse space-charge–limited current.

Secondary Emission: The emission of electrons or ions initiated by bombardment with electrons, ions, excited or fast atoms, *etc.*

Surface-Plasma Sources (SPS): Ion sources with negative-ion formation by the interaction of plasma particles with electrode surfaces in gas discharges.

Thermionic Emission: The emission of electrons or ions from a solid heated to a high temperature, taking place by the "evaporation" of the particles.

Thermionic-Emission Converter: A power supply for conversion of heat into electricity by emission of electrons from a cathode with a higher work function and collection of them by an anode with a lower work function.

Work Function: The energy difference between the vacuum energy level of an electron and the Fermi level in a solid: the evaporation energy of an electron.

SAFETY AND HEALTH IN THE PHYSICAL SCIENCE LABORATORY*

Daniel T. Crane, *Salt Lake Technical Center, Occupational Safety and Health Administration, United States Department of Labor, Salt Lake City, Utah, U.S.A.*

Introduction 189

1. **Responsibility for Safety** 190
1.1 Management Commitment 190
1.1.1 Occupational Safety and Health Act 190
1.1.2 Responsibility to Inform........ 190
1.1.3 Management Responsibility 191
1.1.4 Empowerment of Safety and Health Professional 191
1.1.5 Safety and Health Professional Responsibilities 191
1.2 Responsibility of Employees 191

2. **Planning for Safety and Health** 191
2.1 Hazard and Risk 191
2.1.1 Hazard 191
2.1.2 Risk 192
2.1.3 The Presidential/Congressional Commission on Risk Assessment and Risk Management 192
2.2 Written Safety and Health Plan 192
2.2.1 Chemical Hygiene Plan......... 192
2.2.2 Emergency Response Plan...... 192
2.3 Monitoring Safety and Health 193
2.3.1 Monitoring and Sampling 193
2.3.2 Medical Examinations for Routine Exposures 193
2.3.3 Medical Examinations After an Accident 193
2.4 Novel Hazards 193
2.4.1 Substitution 193
2.4.2 Isolation 193
2.4.3 Ventilation 194
2.4.4 Personal Protective Equipment.. 194

3. **Recognition and Remediation of Safety and Health Hazards in the Physical Laboratory** 194
3.1 Planning for Safety 194
3.1.1 Exposure Routes 194
3.1.2 Looking for Hazards 194
3.2 Common Hazards Found in the Physical Science Laboratory.... 195
3.2.1 Ergonomic Hazards 195
3.2.2 Chemical Exposure 195
3.2.3 Ignition Sources 195
3.2.4 Cryogens 195
3.2.5 Physical Hazards 196
3.2.6 Inhalation 196
3.2.7 Radiation and Radioactive Materials 196
3.2.8 Noise 196
3.2.9 Biological and Nontraditional Hazards 196
3.2.10 Heat Stress or Exposure to Temperature Extremes......... 196

4. **What To Do When an Accident Happens** 197
4.1 Emergency Response 197
4.1.1 Responsibility of the Safety and Health Professional 197
4.1.2 Injuries 197
4.2 Notification Requirements 197
4.2.1 Federal Government Notification 197
4.2.2 Local Government Notification 197
4.3 Evaluation and Remediation ... 198

5. **Conclusion** 198

Glossary 198

Further Reading 199

INTRODUCTION

Most accidents can be foreseen and avoided. Accidents usually occur either because a known hazard went unabated or because a new, unforseen hazard is encountered. Understanding the nature of common hazards

in the physical science laboratory is key to managing safety and health. The purpose of this article is to examine the role of the safety and health professional in activities and processes that may exist or occur in physical science laboratories. These professionals are known variously as industrial hygienists, safety officers, or chemical hygiene officers, or by other suitable titles. They may be certified by a professional organization.

1. RESPONSIBILITY FOR SAFETY

Safety is the responsibility of every person in a facility, beginning with top management and extending even to visitors. It is therefore important that potential hazards be communicated to all involved individuals at a facility. The control of the processes within physical science laboratories lies with the management of those facilities. While the laboratory workers perform the work directly, management ultimately has the basic responsibility to ensure that the workers have a workplace free of recognized hazards [OSHA, 1970, Section 5(a)].

1.1 Management Commitment

No program of safety and health can be effective without active support and impetus from the highest management officials. This support must be sincere and adequate. Safety and health is not the sole responsibility of the safety and health professional. All levels of management must be committed to the safety and health of all the employees whether they are researchers, graduate students, or custodial staff. The reason for this is clear. The response of employees in the work environment will follow immediately from what supervisory and management staff emphasize. Top laboratory management must actively pursue safety and health in a visible manner such that middle and first-line managers and supervisors understand that worker safety cannot be sacrificed for production or research. No influence from independent researchers must interfere with the safe operation of the facility. The safety and health professional is usually charged with the direct responsibility to provide information to laboratory personnel so that they may be aware of potential hazards and workable remediations.

1.1.1 Occupational Safety and Health Act Safety and health in the workplace is an international concern. Many nations have instituted particular regulations to limit exposure to health and physical hazards. Efforts in the United States of America are illustrative, in general, of international activities. Although the specific regulations will vary by nation, the concepts used by safety and health professionals are not tied to specific regulations. In 1970, in the United States, the Congress passed the Occupational Safety and Health Act, which states that every employer has the responsibility to provide a workplace free of recognized health or safety hazard [OSHA, 1970, Section 5(b)]. Other countries have established similar requirements (Kortsha, 1991). This article uses the United States regulations to illustrate particular concepts used by safety and health professionals.

1.1.2 Responsibility to Inform It is an important function of management, through the safety and health professional, to ensure that employees understand the hazards of the processes and materials that are present in the laboratory. The Occupational Safety and Health Administration (OSHA) has established guidelines for employee right to know (OSHA, 1997, Subpart Z, Sections 1200 and 1450). Specifically, this standard requires a number of things in the laboratory. Labels on containers of hazardous chemicals may not be removed or defaced. Material Safety Data Sheets (MSDS) received with incoming shipments of hazardous chemicals must be maintained by the laboratory and be readily accessible to laboratory personnel. Laboratory personnel must be appraised of the hazards of the chemicals and processes in the workplace through information and training at the time of their initial work assignments and whenever a new hazard is introduced into the work area. Employees must be made aware of and trained about the measures they can take to protect themselves from these safety and health hazards. This would include such measures as appropriate work practices, emergency procedures, and personal protective equipment. The safety and health officer is generally charged with making certain that such training occurs.

1.1.3 Management Responsibility Laboratory management must have an active involvement with safety. An effective means to establish and maintain a working safety and health program is to provide an empowered safety office with safety and health professionals who understand the particular issues of the physical science laboratory. The most effective safety programs are administered by joint labor and management personnel. Small operations may have a single employee serving part-time in this capacity, while in large operations the safety office or officer may have literally hundreds of employees devoted to maintaining safety in the extensive operations of the laboratory system, such as within the United States Department of Energy (Lawrence Livermore National Laboratory, 1997).

1.1.4 Empowerment of Safety and Health Professional The safety and health professional must be empowered to make administrative decisions and take immediate action regarding safety. This is why management participation is essential. He or she has the direct responsibility (with management support) to determine the content and provide the training required in each work area. Employee input is essential for determining the hazards that are present in the various work areas. Top management may be unaware of some of the hazards and must therefore be responsive to employee suggestions.

1.1.5 Safety and Health Professional Responsibilities The safety and health professional has the responsibility to provide initial training for new employees and for transferred employees before they are exposed to potential hazards. The safety office or officer has the responsibility to maintain records of all training offered and to whom it was given. The safety office or officer has the responsibility, with management, to conduct inspections to identify and correct hazards or see that the inspections are done. Effective internal safety inspections are made with a team composed of both management and labor, including employees from within the area being inspected and others who have no direct involvement so that they can take an unbiased view of the operations being inspected.

1.2 Responsibility of Employees

While management has the primary responsibility to provide a workplace free of recognized hazard, it remains with the employees of the laboratory to follow safe work practices and to work with management to abate unsafe conditions. It is not appropriate for employees purposely to put themselves at unreasonable risk to meet institutional deadlines or demands. In the course of work, employees at the work-detail level frequently are the first to become aware of new hazards. They are certainly the ones who are most often injured by not following accepted work practices. Employees must take a personal interest in using existing and appropriate personal protective equipment and engineering controls and following established safety guidelines and regulations. Employees must follow guidelines such as the wearing of safety glasses, protective clothing, or other personal protective equipment including respirators, hearing protection, face shields, *etc.*

2. PLANNING FOR SAFETY AND HEALTH

One of the best ways to avoid accident and injury is to plan ahead for foreseeable hazards. Management, along with the safety and health professional, has the first responsibility to assess the presence of potential hazards.

2.1 Hazard and Risk

To plan effectively for safety, it is necessary first to understand the difference between hazard and risk.

2.1.1 Hazard A hazard exists if a particular substance, process or situation has the potential to cause harmful effects. Given such a broad definition, there are few materials or processes which do not have some potential to cause harm. It is necessary to establish a system for determining the likelihood that a particular hazard might cause a harmful effect—that is, to determine risk (Newsom, 1996).

2.1.2 Risk Risk is defined as the probability that a substance or situation will produce harm under specified conditions. Risk is a combination of two factors: the probability that an adverse event will occur (such as a specific disease or type of injury) and the consequences of the adverse event. Risk encompasses impacts on public health and on the environment, and arises from exposure and hazard. Risk does not exist if exposure to a harmful substance or situation does not or will not occur. Hazard is determined by whether a particular substance or situation has the potential to cause harmful effects.

2.1.3 The Presidential/Congressional Commission on Risk Assessment and Risk Management This commission has published effective guidelines for determining the extent of risk. It is beyond the scope of this article to explore fully the intricacies of risk management. However, the Commission has established a six-stage framework for risk management (Newsom, 1996):

1. Define the problem and put it in context.
2. Analyze the risks associated with the problem in context.
3. Examine options for addressing the risks.
4. Make decisions about which options to implement.
5. Take actions to implement the decisions.
6. Conduct an evaluation of the actions results.

2.2 Written Safety and Health Plan

Safety and health professionals aid employers by providing written safety and health plans that are required if there is a potential for release of hazardous materials (OSHA, 1997, Subpart Z, Section 120). Such a plan assures that there is a coherent and controlled approach to the safety and health in the laboratory. A written plan provides a framework against which to build effective prevention and response.

2.2.1 Chemical Hygiene Plan The safety and health professional is instrumental in writing and maintaining the chemical hygiene plan, which is a comprehensive document that covers all aspects of safe laboratory operation. It sets forth procedures, equipment, laboratory equipment, personal protective equipment, and work practices that are capable of protecting employees from the safety and health hazards presented by hazardous chemicals and processes used in that particular workplace (OSHA, 1997, Subpart Z, Section 1450). It prescribes the proper storage and handling of chemicals, radionuclides, and physical agents. It prescribes the appropriate handling of lasers, magnetic fields, and the specific processes and hazards present in the laboratory. It is beyond the scope of this article to prescribe specific plans. However, the plan must be capable of protecting employees from safety and health hazards associated with hazardous chemicals and processes in that laboratory and capable of keeping exposures below the limits specified by OSHA or other governing national standards organization. The Chemical Hygiene Plan must also be readily available to employees, employee representatives, and, upon request, government regulators. The Chemical Hygiene Plan includes specific measures that the employer must take to ensure laboratory employee protection. These include written standard operating procedures, special engineering controls, personal protective equipment and its use, provisions for employee information and training, required medical monitoring, and emergency response procedures as well as specific instructions on how to revise the plan as needed. The safety and health professional is very familiar with all aspects of the Chemical Hygiene Plan and keeps it current and effective.

2.2.2 Emergency Response Plan The Emergency Response Plan establishes the procedures to follow in case of emergency. The plan outlines the steps to be taken following an accident. It will include who is to be notified in the laboratory organization, the local and state governments, and the national government along with required notification deadlines. It will include any specific guidelines that must be given to company or local emergency personnel in order for them to carry out their emergency response. This might include certain areas where not to fight a fire because of explosion hazard, or areas in which radiation is a concern. These instructions must be shared with the expected emergency providers before an emergency occurs to avoid any unnecessary confusion. Knowing ahead of time what hazards are present can allow professional emergency personnel to develop appropriate action plans and procedures.

2.3 Monitoring Safety and Health

It is necessary to know when and if laboratory personnel or others are affected by operations in the laboratory. For this reason, laboratory management must monitor potential exposures to hazards and then maintain for each employee an accurate record of any measurements taken to monitor employee exposures and any medical consultation and examinations, including tests or written opinions.

2.3.1 Monitoring and Sampling Generally, the safety and health official conducts or oversees monitoring or sampling to determine whether or not an employee is exposed to hazards. There are various devices for this purpose, ranging from filters to sorbent tubes to passive monitors. In some cases, there are direct-reading instruments to give an estimate of the hazard. Filters, tubes, and passive devices usually need to be analyzed by an industrial hygiene laboratory, while direct-reading instruments give an immediate indication of the exposure. Other devices are used to monitor exposures to radiation or noise. Again, some devices give an immediate reading while others such as film badges must be sent to a laboratory for interpretation. It is the responsibility to the safety and health officer to understand the proper use of these devices and techniques.

2.3.2 Medical Examinations for Routine Exposures Whenever an employee develops signs or symptoms associated with a hazardous chemical or process to which the employee may have been exposed in the laboratory, the employee must be provided an opportunity to receive an appropriate medical examination. If exposure monitoring reveals an exposure level routinely above the action level [or, in the absence of an action level, the permissible exposure limit (PEL)] for an OSHA-regulated substance for which there are exposure monitoring and medical surveillance requirements, medical surveillance must be provided for the affected employee.

2.3.3 Medical Examinations After an Accident Whenever an event takes place in the work area such as a spill, leak, explosion, or other occurrence resulting in the likelihood of a hazardous exposure, affected employees must be provided an opportunity for medical consultation.

2.4 Novel Hazards

The nature of a laboratory is generally to investigate processes that are not routine, and may be new, novel, and undocumented outside the immediate work environment. Such situations must be examined for the potential to cause harm to any exposed personnel. The safety and health professional helps researchers control hazards through the systematic use of industrial hygiene controls. Engineering controls are the first line of protection followed by good work practices, administrative controls, and, where no other mode of protection is feasible, personal protective devices. The principles of engineering control are substitution, isolation, and ventilation (Soule, 1991).

2.4.1 Substitution If a health or safety problem is presented by the use of a specific material, wavelength, or process, substitution of a more benign material, wavelength, or process should be investigated as a remediation of a hazard. For example, enclosures might be made of plastic or safety glass rather than regular glass, or cleaning chemicals might be chosen that are safer. An externally vented hood might be substituted for a stand-alone unit. Care must be taken when substituting one chemical or process for another so as not to cause further hazard.

2.4.2 Isolation The second principle of engineering control is isolation. This is frequently some barrier such as a blast shield, or may consist of remotely conducting the operation in a separate room. Also, simply putting distance between the operator and the operation can be considered isolation. In addition, compartmentalization such as is done for tank farms is a form of isolation that limits the involvement of an entire facility in the event of an accident. It may be possible to separate different procedures, isolating the most dangerous from other, more benign ones.

2.4.3 Ventilation The third principle of engineering control is ventilation. Ventilation provides control of the environment by varying the airflow. The airflow can be used to control the temperature of the space, remove a contaminant, or dilute the concentration of the contaminant to below permissible exposure levels. Control of ventilation requires a detailed knowledge of air flow and the materials or processes to be controlled. Such information is beyond the scope of this article. Information geared to industrial hygiene can be found in standard industrial hygiene references (Soule, 1991).

2.4.4 Personal Protective Equipment Personal protective equipment includes safety glasses, safety shoes, special clothing, respiratory protection, and any other device or system that is designed to be worn or used by an individual. Personal protective equipment should never be considered an acceptable alternative to a well-designed engineering approach to safety except where such is shown to be either unfeasible or more unsafe than the use of personal protective equipment. Certain pieces of personal protective equipment such as safety glasses should be used regardless of the presence of engineering controls. Where respirators are used, a respiratory protection program is required to be in place. Certain operations require specialized personal protective equipment. For example, when working with lasers, special eye protection is required. The safety and health professional must be knowledgeable as to the proper use of this type of personal protective equipment.

3. RECOGNITION AND REMEDIATION OF SAFETY AND HEALTH HAZARDS IN THE PHYSICAL SCIENCE LABORATORY

Awareness of recognized hazards is the primary tool used in recognition of the potential hazards. Management along with the safety and health professional, as well as involved workers, must review the processes used or expected to be used in the laboratory. Forethought and planning to perform the work safely knowing recognized hazards will prevent many accidents.

3.1 Planning for Safety

Looking for hazards in the physical science laboratory begins with the planning stages of a project or process by looking for recognized hazards in the processes to be used. For example, if gas cylinders are to be used, the cylinders must be properly secured and vented. If a process involves ionizing radiation, the proper safeguards, such as shielding, must be established. Laboratory personnel must continue to look for hazards after the project begins and throughout the project to remediate any significant hazard which may appear. Looking for hazards must not be limited to items which are recognized, codified into regulation, or found on a list.

3.1.1 Exposure Routes The routes of exposure to chemical and physical hazards are dermal, respiration, and ingestion.

Dermal includes any skin or eye exposure which would result in

1. direct absorption of a chemical into the skin or eye;
2. radiation exposure of the skin; or
3. temperature extreme.

Exposure through respiration is by

1. inspiration of a chemical or radiation hazard;
2. extremely hot or cold air;
3. inhalation of toxic gases;
4. exposure to atmospheres deficient in oxygen;
5. in hyperbaric conditions involving too much oxygen; or
6. the absence of air or exposure to vacuum.

Ingestion hazards are from anything that might be taken by mouth intentionally or unintentionally, by transmission from hand to mouth, or otherwise transmitted to the mouth.

3.1.2 Looking for Hazards Safety personnel, along with representatives from the work area being inspected, should look for any process, employee action, chemical storage, electrical wiring, virtually anything which might cause an accident. This inspection should not be limited to recognized hazards. Rather, the safety and health professional should look for any process or situation which *may* present a hazard. Immediately dangerous situations should be remediated as rapidly as possible. Once the team has identified potential hazards, those for which there are specific rules or regulations should be remediated. New or novel potential hazards should be evaluated for risk and remediated as appropriate.

3.2 Common Hazards Found in the Physical Science Laboratory

There are a number of common hazards to be found in the physical science laboratory. Most accidents occur as a result of slips, trips, and falls (OSHA, 1997, Subpart E, Section 38). Many other hazards are a result of environmental exposures such as extreme heat or cold (Mutchler, 1991; OSHA, 1997, Subpart D, Section 22). Confined spaces may present a hazard in breathing air quality. These spaces may be too small to contain sufficient air for the duration of the task, or a concentration of explosible gases may easily be reached when welding gases or other generated gases are being used. Certain spaces will have insufficient oxygen for breathing, concentrated toxic gases, or vacuum. (OSHA, 1997, Subpart J, Section 146).

3.2.1 Ergonomic Hazards Ergonomic hazards are generally the result of three factors: force, frequency, and posture. In the physical science laboratory, there are many tasks involving one or more of these recognized stressors that may result in repetitive motion injury, back injury, or other upper extremity cumulative trauma disorder. Back injuries can usually be limited by implementing training programs that teach employees the proper techniques for lifting and by limiting the amount of weight that individual employees are required to lift (Waters, 1993). Often, the weight involved is very little, but the frequency of repetition may reach very high levels, as in manual data input on a keyboard. Examples of this sort of stress may be seen in keyboard entry personnel and other employees in related tasks. Posture is a strong factor in cumulative trauma disorder especially when developing new tasks. Employees must not be allowed to let their dedication to the project overshadow good posture, or other good work habits. Thought must be given to service access when designing test enclosures. Proper access allows the employee to address the task with good posture. Repetitive tasks should be evaluated for good ergonomic practice, and employees must be trained in the principles of biomechanics and how good work practice will prevent ergonomic injury.

3.2.2 Chemical Exposure Much of the health hazard in the physical science laboratory comes from exposure to chemicals. Common problems arise from improper use and storage of chemicals. Incompatible chemicals should never be stored in the same cabinets. Before using any chemical in the laboratory, the employee should review the material safety data sheet, which must be available for all employees. Particular attention should be paid to the physical properties of the chemical, to ensure that the chemical will be used within safe environmental limits and stored safely and that the proper safety and spill clean-up materials are on hand. Employees handling chemicals must wear appropriate personal protective gear as necessary. This may include single or double gloves, safety glasses, respirators, or special clothing prescribed by regulation or by the producer of such chemicals.

3.2.3 Ignition Sources Generally, as part of the chemical safety requirements, the laboratory must assure that equipment used in the presence of chemicals that may form an explosible atmosphere are certified and maintained as explosion resistant (OSHA, 1997, Subpart H, Section 106 and Subpart S, Sections 304, 305 and 307).

3.2.4 Cryogens Cryogenic liquids or solids at very low temperatures pose several hazards. The first and most obvious is the low temperature itself, which is capable of freezing flesh. Appropriate personal protective equipment must be used when working with cryogens. Transfer pipes, hoses, and vessels often provide a location for condensation of air or other gas in contact with the vessel surface.

This condensate may be enriched with oxygen. As a result, such pipes and vessels should not be in contact with or suspended above asphalt surfaces or other combustible surface materials (OSHA, 1997, Subpart Z, Section 1051).

3.2.5 Physical Hazards Physical hazards may include loose objects on high ledges or shelves, improperly guarded machines, or even loose tools near large magnets. Physical hazards may also include unguarded pulleys, swinging arms, low ceilings, or stacks of unused equipment or boxes that might fall on a worker. Physical hazards might also include loose items that may fall or be thrown during an earthquake (in areas prone to earthquakes). Physical hazards might also include objects that are ejected from experimental devices, or a whole variety of electrical hazards. Some of these may include ungrounded wiring, loose cables on the floor, unshielded cables in wet areas, and too many plugs for a given circuit rating.

3.2.6 Inhalation When looking for inhalation hazards, it must be remembered that many substances when inhaled are toxic but may not necessarily present a hazard otherwise. Any dust that can be inhaled must be controlled to acceptable levels, preferably by the use of engineering controls such as fume hoods, local exhaust, barriers, or remote operation (OSHA, 1997, Subpart Z, Section 1000). Protection from exposure to gases to prevent toxic exposure or suffocation must be provided. Again, engineering controls are preferred to personal protective devices such as respirators. Survey the materials being used and check for any applicable standards such as OSHA standards, HSE standards, ISO standards, EPA standards where appropriate, DOE standards, DOT regulations where appropriate, or special industry standards. In certain emergency situations, as specified in OSHA standards, respirators may be used when

1. they meet use criteria;
2. there is a respirator program in place to assure safe use of the respirator; and
3. the safe capacity of the particular respirator meets or exceeds the expected concentration of contaminant.

Other criteria may apply and the laboratory should consult current OSHA requirements on this issue (OSHA, 1997, Subpart I, Sections 132–136).

3.2.7 Radiation and Radioactive Materials Most generally, radiation is divided into two classes, ionizing and nonionizing. Ionizing radiation includes particulate, beta, alpha, and gamma radiation. Nonionizing radiation generally includes ultraviolet (UV), infrared (IR), radio frequency (rf), extremely low-frequency (ELF), and sonic energy. The distinction between the two classes is generally made by considering whether or not a particular type of radiation can cause ionization in human skin. This energy level is often taken to be 10 eV. Further specific information on appropriate levels of exposure will be found in several of the references given in the Further Reading section. See also Wilkening (1991); OSHA (1997), Subpart G, Section 97.

3.2.8 Noise Noise exposures may come from a variety of sources including equipment, tools, radios, and explosions. Care must be taken to assure that exposures to noise are not excessive. Ear damage due to noise exposure is generally permanent. OSHA has established permissible exposure levels based upon the A-weighted scale of a standard noise meter (OSHA, 1997, Subpart G, Section 95).

3.2.9 Biological and Nontraditional Hazards Physical science laboratories are becoming more interdisciplinary in nature, with equipment being developed for medical diagnostics and other nontraditional markets. It is therefore necessary to be aware of and follow requirements for safe handling of biological materials. It is possible that biological samples such as microorganisms, including viruses, may be present in the physical laboratory. Laboratory animals or pathogenic tissue samples may be found in some laboratories. OSHA regulates the handling of biological materials primarily through the bloodborne pathogens regulations, which are aimed at HIV and HIB (OSHA, 1997, Subpart Z, Section 1030).

3.2.10 Heat Stress or Exposure to Temperature Extremes Precautions must be taken to ensure that employees do not suffer either hyperthermia (high temperature) or hypothermia (low temperature). Hyperthermia is generally considered to exist when the body core temperature exceeds 38 °C and there is no underlying physical condition to cause the high temperature. Hypothermia is generally considered to exist when the core body temperature falls below about 32 °C.

4. WHAT TO DO WHEN AN ACCIDENT HAPPENS

The definition of an accident includes incidents involving spills of hazardous materials, bomb threats, civil disturbance, explosion, fire, natural disaster such as an earthquake, terrorism, or any other act or happenstance that could put laboratory personnel or the community at risk. Specific requirements vary by locality and nation. Many community governments and most national governments can provide contacts and specific information necessary to meet legal requirements in their respective venues.

4.1 Emergency Response

It is beyond the scope of this article to describe procedures for every possible accident. A laboratory chemical response plan such as that required by OSHA will establish the levels of response based upon the relative severity of the accident. It includes whom to call for particular events, what to do, and whom to inform. All employees in a facility must be trained in the contents of this plan and how to respond if an accident occurs.

4.1.1 Responsibility of the Safety and Health Professional Depending upon the size of the facility, the safety and health professional and one or more employees may be specially trained to respond to medical emergencies, chemical spills, radiation releases, or other hazards. When such employees or teams are used, they must be appropriately trained according to applicable local and federal regulations.

4.1.2 Injuries When an injury occurs, immediate notification of in-laboratory first aid responders or local emergency medical providers is imperative. For other emergencies such as fire or other large incidents, an automatic call system may be used to contact emergency responders. Such procedures will be set out clearly in the written safety and health plan for the laboratory. Generally, a good relationship should be established between the laboratory and the local emergency responders. Where there are security areas or special hazards, it is important for the local emergency responders and laboratory management to work out agreeable procedures for emergency response. The safety and health official is usually the point of contact with local service providers in setting up such procedures.

4.2 Notification Requirements

Every incident will be reported to immediate supervisors, while more severe incidents will be required to be reported to local, state, and national agencies.

4.2.1 National Government Notification In the United States, OSHA requires employers to maintain a log of injury and illness that is occupationally related. This is kept on the OSHA 200 log (OSHA, 1997, Subpart F, Section 67). Moreover, OSHA must be notified within 8 h of any fatal accident or any work-related incident requiring the hospitalization of three or more employees (OSHA, 1997, Subpart Z, Section 8). The Environmental Protection Agency requires notification of spills through the Resource Conservation and Recovery Act (RCRA) (EPA, 1976a), Toxic Substances Control Act (TSCA) (EPA, 1976b), Comprehensive Environmental Response Compensation and Liability Act (CERCLA) (EPA, 1977), and Superfund Amendments and Recovery Act (SARA) (EPA, 1986). This response is required within 24 h of the incident to the closest EPA office. Other nations may require differing levels of reporting. The safety and health professional will be familiar with all requirements for reporting.

4.2.2 Local Government Notification Many local governments have regulations requiring notification in the event of an accident. As it is a good practice to involve local service providers in safety planning, these same local providers should prove to be valuable sources for specific local reporting requirements. Along with these providers the local air-quality board or its equivalent, the waste-management authority, the EPA, and the OSHA office or their equivalents are excellent sources of specific and current information.

4.3 Evaluation and Remediation

Once an incident has occurred, it is important to evaluate the causes and ramifications of the incident to avert further incidents. Management, along with the safety team and the principal investigators, should evaluate all pertinent information to establish appropriate remediations in whatever form necessary to assure safe working conditions for laboratory personnel, visitors, and the community in which the laboratory is located.

5. CONCLUSION

Safety and health in the physical science laboratory is the responsibility of everyone in the facility. The safety and health professional acts as an integral part of the laboratory to help each employee to understand his or her role in managing safety in the laboratory. There may be specific requirements to be followed by the laboratory imposed by national or local government as well as by contracting authorities. No element of a sound safety plan can be abrogated by the pressure of project completion deadlines or cavalier attitudes of investigators. It is the responsibility of management to assure that laboratory employees and invited investigators adhere to established procedures and that where new processes are being developed, appropriate planning and care is taken to evaluate potential hazards and risk for those processes. Because of the intricacy of the processes and governmental requirements, it is suggested that competent professional safety and health consultants be retained either on an as-needed basis or on staff. In addition, all the regulatory agencies provide help for specific processes and can be very helpful in setting up and maintaining effective safety and health programs.

GLOSSARY

Accident: Any unexpected happening that interrupts the work sequence or process and that may result in injury, illness, or property damage to the extent that it causes loss.

Ergonomics: The science of fitting the job to the worker in a manner so as to lessen the risk of injury from operations involving repetitious, forceful or awkward postures.

Hazard: A situation or process that has the potential to cause harm.

MSDS: Material safety data sheet. A document that communicates the physical and chemical hazards of chemicals to the employee using or handling the chemical. The MSDS contains detailed information about handling, storage and use of a chemical and how to control unexpected events.

OSHA: Occupational Safety and Health Administration.

PEL: Permissible exposure limit. An exposure level to a chemical or other hazard, established by OSHA, above which employees may not be exposed.

PPE: Personal protective equipment. Items such as safety glasses, gloves, respirators, or similar apparel that are used by individuals as protection from hazard.

Risk: The likelihood that a particular hazard will result in an accident.

INTRODUCTION

Silicon forms a wide variety of compounds with metals; these compounds are called silicides. Silicides have a number of useful properties including high thermal stability, high mechanical hardness, and low resistivity. Silicides are used in a wide variety of applications. In microelectronics, silicides are used as Ohmic contacts, Schottky contacts, and interconnects. In these applications, the high thermal stability of the silicides and the low resistivity provide an advantage compared with other conductors, such as Al, which has much lower thermal stability, or polycrystalline silicon, which has much higher resistivity. Silicides are often used as furnace elements, on account of their thermal stability in oxidizing ambients. Because of their high strength, silicides are also being considered for use as high-temperature structural materials, in aircraft engines for example. For these applications, silicides have an advantage of higher thermal stability and lower density compared with Ni-based super-

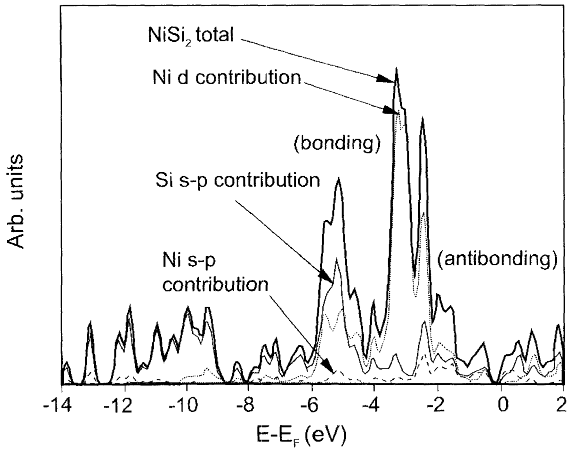

FIG. 1. Theoretical density of states and partial density of states for $NiSi_2$ (Bisi and Calandra, 1981).

alloys, and higher ductility and lower cost compared with Si-based ceramics. Other applications where silicides are being considered include thermoelectric devices, magnets and superconductors.

This article surveys the properties, processing, and applications of transition-metal silicides. The first section focuses on the properties of silicides, including the electronic and atomic structure, reactions and stability, and the mechanical, optical, electrical, and magnetic properties of these materials. The second section describes processes for forming silicides, such as the salicide process, the polycide process, physical vapor deposition, chemical vapor deposition, ion implantation, melt growth, sintering, and plasma-spray deposition. The final section discusses applications of silicides, including microelectronics, structural materials, coatings, thermoelectric materials, magnetic materials, and optical materials. Silicides formed from alkali metals, alkaline-earth metals, and rare-earth metals (Samsanov and Vinitskii, 1980) are not discussed in detail here, because there are very few potential applications for these materials at present.

1. PROPERTIES

1.1 Structure

1.1.1 Electronic Structure

1.1.1.1 Bulk Electronic Structure Many of the useful properties of silicides, such as high melting point and high mechanical hardness, arise from the formation of strong covalent bonds. Despite these strong covalent bonds, in most silicides there is a continuous density of states across the Fermi level, which provides high conductivity. Knowledge of the electronic structure of silicides is also useful for understanding properties such as Schottky-barrier heights (see Sec. 1.1.1.2) and chemical bonds and compound stability (see Sec. 1.1.2.1).

The main factor in determining the electronic structure of transition-metal silicides is the formation of hybrid orbitals between d states in the transition metal and 3p states in Si, resulting in strongly covalent metal d–Si p bonds (Lange, 1996; Bisi and Calandra, 1981; Speier *et al.*, 1989; Mattheiss, 1992; Reader *et al.*, 1992). These bonds produce bonding and antibonding states above and below the Fermi level (Fig. 1). In addition, there are some nonbonding d states with energies close to those of the pure metals, but of reduced width as a result of the greater separation between metal atoms in the silicides compared with the pure metal. The Si s states are only weakly involved in chemical bonding and form a relatively broad band several electronvolts below the Fermi level. The sequence of these levels with increasing energy is as follows: Si s, Si p/metal d bonding, metal d nonbonding, and Si p/metal d antibonding. The Fermi level is generally between the nonbonding and the antibonding states; hence the nonbonding states are usually occupied while the antibonding states are usually empty (Derrien, 1995).

Some trends in the band structure of silicides are observed with increasing atomic

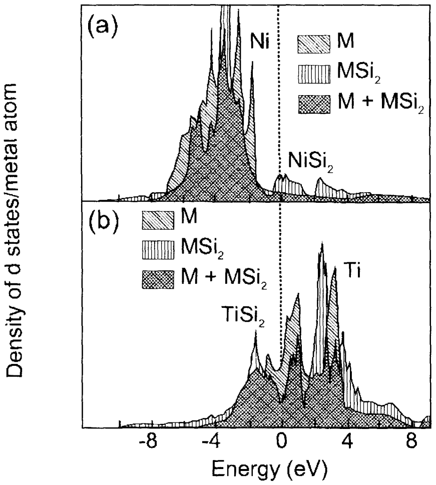

FIG. 2. Comparison of the calculated metal d-state densities in the pure metal and the disilicides for (a) Ni and (b) Ti. The pure metal bands have been shifted so that the centroids of the d band match those of the disilicides. (Reprinted from Weijs *et al.*, 1990, with permission from Springer-Verlag. Copyright 1990.)

number, moving through a series in the periodic table (Derrien, 1995; Reader *et al.*, 1992). First, the metal d states move through the Fermi level with increasing atomic number. In addition, the shape of the d states varies within a series, starting as a broad band of mostly empty states and finishing as a narrow band of mostly filled states. These trends are apparent when one compares the band structures of $NiSi_2$ and $TiSi_2$ (Weijs *et al.*, 1990; Reader *et al.*, 1992) (Fig. 2). The reduction in band width of the nonbonding metal d states compared with the elemental metal is greater for $NiSi_2$ than for $TiSi_2$, because of a stronger interaction with the Si p states in the case of $TiSi_2$. In addition, compared with $TiSi_2$, the Ni d character in the band structure of $NiSi_2$ is relatively weak in the bonding–antibonding regions above and below the metal d bands. The difference is due to the smaller radial extent of the Ni 3d wave function compared with that in Ti, which results in less mixing of the Si p and metal d states.

In most of the transition-metal silicides, there is a continuous density of states across the Fermi level, resulting in a metallic conduction. However, some silicides are semiconductors (see Sec. 1.3.3.1), with the minimum in the density of states at the Fermi level opening up into an energy gap. For a given metal, the density of states at the Fermi level increases as one goes from the Si-rich phases to the metal-rich phases, as a result of an increasingly strong interaction between metal d states (Speier *et al.*, 1989).

1.1.1.2 Interfacial Electronic Structure

One of the major applications for silicides is as contacts to semiconductors (see Sec. 3.1). The electronic structure of interfaces is also of interest for determining the adhesion strength of metal–silicide interfaces in structural materials (Hong *et al.*, 1993).

The electrical properties of the contacts are determined by the electrical barrier that forms at the metal–silicon interface. The height and width of the barrier determine the ease of electron transport across the interface, and hence determine whether the contact is Ohmic or rectifying, and whether it has high or low resistance. The barrier height depends on the work-function difference between the metal and semiconductor, the interface state density, the atomic structure at the interface, and the doping level in the semiconductor.

The mechanism of Schottky-barrier formation in covalent semiconductors is still not well understood, despite years of study. The barrier height ϕ_b is determined by the requirement that in equilibrium, the Fermi levels of the metal and semiconductor must be equal. This is achieved by creation of an electric dipole at the interface. In the absence of interface states, the charge at the interface is related to the difference in Fermi levels between the metal and the semiconductor, and is given by

$$\Phi_b = \varphi_m - \chi_s, \qquad (1)$$

where φ_m is the metal work function and χ_s is the electron affinity of the semiconductor. This model works fairly well for ionic semiconductors, where the interface state densities are low, and the barrier height does in fact show a strong dependence on the electronegativity of the metal (which is related to the work function of the metal; see Louie *et al.*, 1977; Schluter, 1977; Kurtin *et al.*, 1969). However, for covalent semiconductors, there is much less dependence of the barrier height on the electronegativity of the metal, as a result of the presence of interface states that pin the

Fermi level (Cowley and Sze, 1965; Heine, 1965). For covalent semiconductors, an extra term is added to Eq. (1), corresponding to the electrostatic interface dipole, that is determined by the electron distribution at the interface (Flores and Ortega, 1992). In fact, interface states associated with the silicide have been postulated from recent band-structure calculations of the silicide–Si interface (Fujitani and Asano, 1994). Some of these interface states have energies within the Si band gap and spatially extend a few atomic layers into the Si.

Recently it has been shown that Schottky-barrier heights depend on the local atomic structure of the interface (Tung, 1992). For example, the barrier height of epitaxial $NiSi_2$ on *n*-type Si can range from 0.40 eV [on (100) Si] to 0.79 eV [for type B $NiSi_2$ on (111) Si] (Tung, 1993). (For the type A interface, the silicide has the same orientation as the substrate, whereas for the type B interface, the silicide also has a ⟨111⟩ orientation, but is rotated by 180° about the ⟨111⟩ surface normal with respect to the substrate.) Fujitani and Asano (1994) have proposed that the atomic-structure dependence of the barrier height is due to bond bending at the interface, though more studies are required to determine if this hypothesis is correct.

Most of the Schottky-barrier heights on Si reported in the literature have been measured on polycrystalline silicides (Table 1). However, the different orientations in the polycrystalline silicide are likely to have different barrier heights, so that the contacts are electrically nonhomogeneous. The Schottky-barrier heights measured from polycrystalline silicides will be determined by the silicide grains with the lowest barrier heights (Tung, 1992).

The Schottky-barrier heights of silicides have been characterized on a number of compound semiconductors (Liu *et al.*, 1997; Shih *et al.*, 1988, Yokoyama *et al.*, 1986; Porter *et al.*, 1995a,b,c) including SiC, GaAs and GaN (Table 2). GaN and SiC have a greater degree of ionic bonding than Si or GaAs; hence, the barrier heights are expected to show a greater dependence on the type of metal or silicide.

1.1.2 Atomic Structure

1.1.2.1 Crystal Structure The crystallographic structures of transition-metal silicides are varied and complex (Fig. 3). Some structures form over significant regions; an MSi compound with the FeSi prototype is formed for nine different transition metals. Typically, an identical or related structure is found for silicides of the same composition and group (Murarka, 1983), though this is not without

Table 2. Schottky-barrier heights for various silicides on n-type compound semiconductors. In all cases, the silicide is polycrystalline.

exception (for example, V_3Si and $CrSi_2$; see Fig. 3 and Table 3). Further details on crystal structure are available in standard references (Pearson, 1972).

The $MoSi_2/CrSi_2/TiSi_2$ prototypes are closely related and are just variations in stacking sequences of close-packed triangular layers (Fig. 4). The tetragonal $MoSi_2$ structure results from a twofold repeat, the hexagonal $CrSi_2$ structure results from a threefold repeat, and the orthorhombic $TiSi_2$ results from a fourfold repeat. The $ZrSi_2$ structure is also related to these structures. The structural differences correlate with d-band filling, with C40 being more stable than C54, and $C11_b$ being more stable than C40, as the number of d electrons in the transition metal increases. This suggests that the structural energies of transition metal disilicides are mainly determined by electronic band effects rather than atomic size effects (Carlsson and Meschter, 1991).

1.1.2.2 Interfacial Atomic Structure: Epitaxial Silicide–Silicon Interface In Sec. 1.1.1.2, it was noted that the Schottky-barrier height depends on the atomic structure of the silicide–silicon interface. In addition, novel device structures are made possible by growing silicides epitaxially on Si (see Sec. 3.1.4). Hence, there has been much interest in the atomic structure of epitaxial silicide–Si interfaces.

Factors that affect epitaxial growth are the lattice mismatch between the two materials and the chemical bonding at the interface (Chen and Tu, 1991; van den Hoek *et al.*, 1988; Zur *et al.*, 1985). Epitaxial growth is often observed in systems where the two lattices have identical or quasi-identical forms and have similar lattice spacings. The interfacial chemistry also plays an important role in epitaxial growth; epitaxial growth can occur if the interfacial energy is sufficiently low, even if the lattice mismatch is relatively high (an example is C54-$TiSi_2$ on Si).

Recently, the differences in interface structure between epitaxial $CoSi_2$ and epitaxial $NiSi_2$ on (111) Si have been explained in terms of the interfacial bonds (van den Hoek *et al.*, 1988). For $NiSi_2$, the metal atoms closest to the interface are seven-fold coordinated (seven nearest-neighbor Si atoms), and the Si atoms of the silicide form bonds to the Si substrate, whereas for $CoSi_2$, the metal atoms closest to the interface are eight-fold coordinated (eight nearest neighbor Si atoms) and form bonds to the Si substrate. The most energetically favorable structure depends on the number of electrons in bonding orbitals. In $CoSi_2/(111)$, only

the metal–Si bonding orbitals are filled with electrons; the Si–Si bonding orbitals have no electrons, and hence are energetically unfavorable. For $NiSi_2$/(111), the extra d electron from Ni occupies the Si–Si bonding orbital; this is energetically more favorable than metal–Si bonding orbitals with two electrons, because of the large overlap of the Si–Si bonds (Fig. 5).

1.1.2.3 Phonons There have been relatively few studies on phonon spectra (atomic vibrations) in silicides. Most of the studies have focused on semiconducting silicides, where the phonon spectra can be used to analyze phases and crystalline quality (Fenske *et al.*, 1996). A number of studies have also been made of specific heat and low temperature resistivity of silicides, which are related to phonons (Nava *et al.*, 1993). Infrared spectroscopy or Raman scattering has been used to study phonons in PtSi, $TiSi_2$, WSi_2, $CoSi_2$, $NiSi_2$, and β-$FeSi_2$ (Miglio and Meregalli, 1996; Guizetti and Marabelli, 1995).

The phonon spectra of semiconducting silicides show high complexity (Fig. 6), due to the

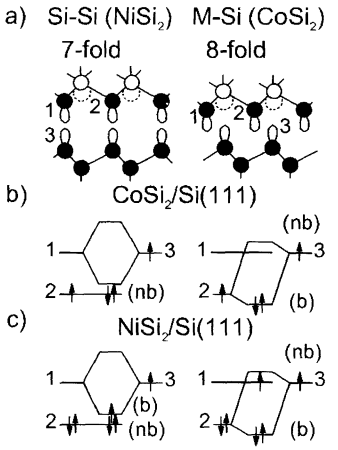

FIG. 5. Energy-level diagrams of interface bonds for (a) seven-fold (left) and eight-fold (right) structures, showing a comparison between (b) $CoSi_2$/Si (111) and (c) $NiSi_2$/Si (111). (Reprinted with permission from van den Hoek *et al.*, 1998. Copyright 1988 by the American Physical Society.)

large number of atoms per unit cell (Miglio and Meregalli, 1996). The phonon spectra for these silicides show a high absorption coefficient, which is a typical feature of ionic bonding, despite the fact the these silicides have strong covalent bonds. A possible explanation is that dynamical charges arise when the atoms vibrate on account of their large polarizability.

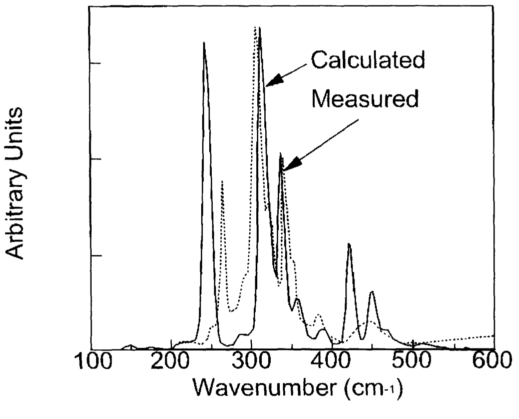

FIG. 6. Comparison between simulation (solid line) and experiment (dotted line) for infrared spectra of β-$FeSi_2$. The peaks in the spectra are probably related to lattice vibrations in the orthorhombic CaF_2 structure. (Reprinted with permission from Miglio and Meregalli, 1996.)

In addition, the phonon spectra for the semiconducting silicides are in nearly the same frequency interval, despite the large mass differences between the metals (for example, Fe and Ir). This suggests that the spectra are mainly determined by the bonding properties, which are similar in these silicides (Fenske *et al.*, 1996; Lange, 1996). Finally, phonons may be responsible for the low mobilities observed in semiconducting silicides (Christensen, 1990).

For silicides with cubic CaF_2 structures, such as $NiSi_2$ and $CoSi_2$, two phonon modes are expected, one Raman-active and the other (at higher frequency) IR-active (Bocelli *et al.*, 1995). The Raman-active mode consists of counterphase motion of the Si atoms along the ⟨111⟩ direction, while the metal atom is at rest (*i.e.*, only the Si atoms move), whereas for the IR-active mode, there is counterphase motion of the Si atoms with respect to the metal along the ⟨111⟩ direction (*i.e.*, both Si and metal atoms move) (Malegori and Miglio, 1993).

1.2 Reactions and Stability

1.2.1 Metal–Si Reactions One of the most common methods to form silicides is by reacting a thin film of metal with Si. This approach is used in microelectronics manufacturing to form silicides on polycrystalline Si gates or single crystal Si contacts (see Sec. 3.1). Reactions between metals and Si are also used in diffusion bonding of Si-based ceramics to metals (see Sec. 3.3). In addition, metal–Si reactions are of scientific interest and have revealed much information on mechanisms of thin-film reactions.

1.2.1.1 Silicide Phases In general, when Si comes in contact with a metal it is not thermodynamically stable and will react to form silicides, with the reaction depending on the annealing temperature, the metal–Si phase diagram, and kinetics (Gas and d'Heurle, 1993; Zhang and d'Heurle, 1994). For transition metals, a series of intermediate silicide phases will form. In principle, all the stable intermediate phases in the phase diagram at the annealing temperature should form. However, often for thin-film reactions some stable phases are not observed on account of kinetics factors (see below).

A number of general observations can be made about the binary phase diagrams of

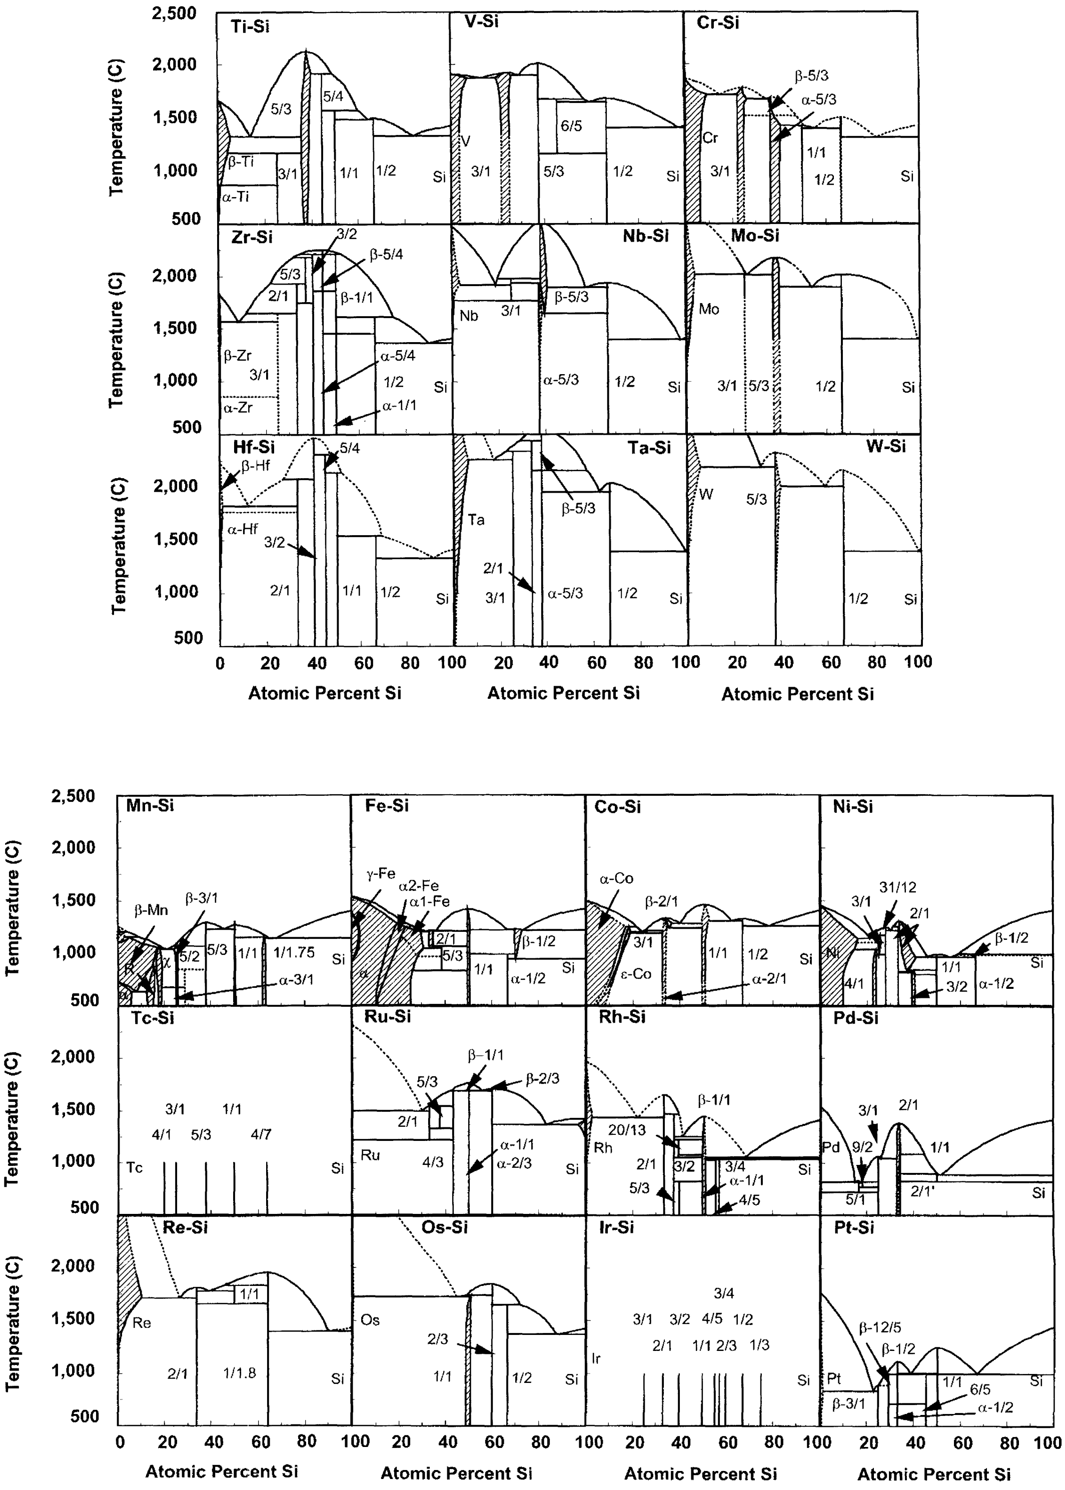

FIG. 7. Phase diagrams of transition-metal silicides (from Massalski, 1990).

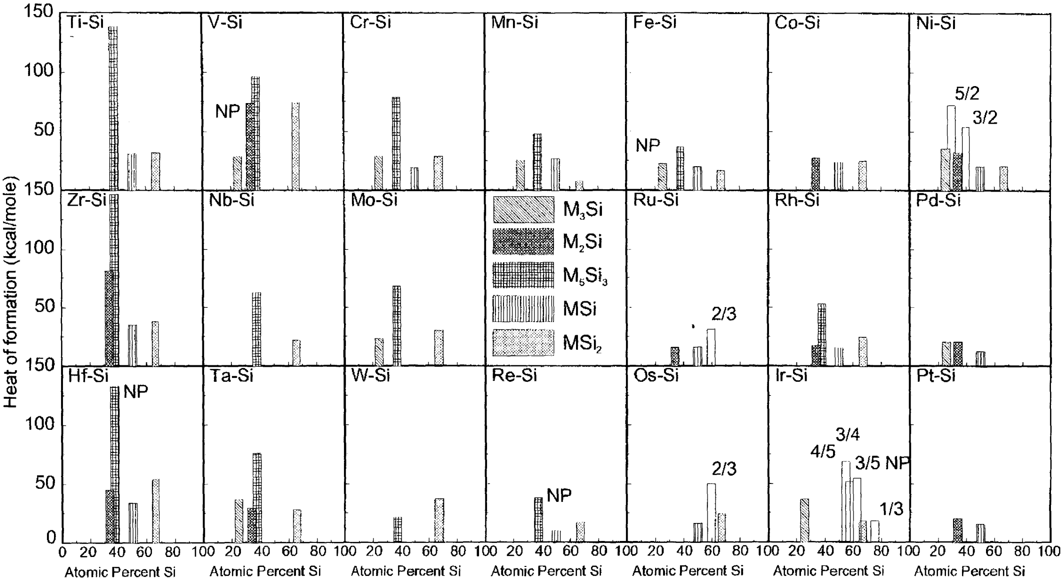

FIG. 8. Heats of formation for transition metal silicides. The M/Si composition is indicated by shading for common stoichiometries or by text. The NP designation is for compositions not present in the equilibrium phase diagram (from Mann and Clevenger, 1995).

transition-metal silicides (Massalski, 1990) (Fig. 7). As noted above, the Si-rich phase is typically MSi_2 except in the case of Ir where a more Si-rich phase, $IrSi_3$, is formed. The most metal-rich phase is generally M_4Si or M_3Si with a number of exceptions. Typically, about five silicide phases are formed for each element, with a minimum of two for W–Si or a maximum of almost ten for Ni, Rh, or Ir. There is significant Si solubility for the first row of transition metals (Ti to Ni), about 3–20 at.% Si, and for Nb, Mo, Ta, W, and Re in the second and third rows, about 3–10 at.% Si. In general, silicides have very limited composition ranges. Significant deviations from stoichiometry are found in Ti_5Si_3, Nb_5Si_3, Cr_5Si_3, Mo_5Si_3, W_5Si_3 (W_5Si_3 and Mn_5Si_3 are prototype structures; see Fig. 3), V_3Si, Cr_3Si (Cr_3Si prototype), FeSi, OsSi, CoSi (FeSi prototype), and a number of other silicides.

Typical values of the transition-metal silicide heats of formation are arranged according to the periodic table (Fig. 8) (Mann and Clevenger, 1995). The heat of formation is related to the d-band occupancy of the silicide. In refractory-metal silicides, only the bonding orbitals are occupied, so that the heat of formation directly reflects the bonding energy. However, in near-noble–metal silicides, nonbonding and antibonding orbitals are occupied, which reduces the bonding energy. Hence, the heat of formation is lower for near-noble–metal silicides compared with refractory-metal silicides (Hara and Ohdomari, 1988).

1.2.1.2 Kinetics Silicides formed by reacting a metal with Si require nucleation and growth of the new phase. If the growth rate is faster than the nucleation rate, then the silicide formation is nucleation controlled. If the nucleation rate is faster than the growth rate, then the silicide formation is either diffusion limited or interface reaction-rate limited (Mayer and Lau, 1989).

Diffusion-limited reactions generally exhibit laterally uniform growth with well-defined kinetics, whereas nucleation-limited reactions exhibit laterally nonuniform growth and a critical temperature dependence (no reaction below the critical temperature and extremely rapid reaction above the critical temperature). In most applications (and especially for integrated circuits), a uniform reaction is required; hence diffusion-limited kinetics are preferred.

Nucleation effects are often observed during formation of new phases in thin films (d'Heurle, 1988). Nucleation-limited reactions are expected when a new phase is forming at an interface and the free-energy change for the transformation is small with respect to the increase in surface energy. Nucleation is generally not rate limiting in reactions between transition metals and Si, because the free-energy change is usually large. Nucleation-limited reactions are often observed during the formation of the Si-rich silicide phases or when the transition results in only a small change in composition or structure (for example, the transformation of C49-$\mathrm{TiSi_2}$ to C54-$\mathrm{TiSi_2}$). The films produced from nucleation-limited reactions are often rough; the film nucleates in isolated regions, then grows rapidly both laterally and vertically.

After nucleation, growth of the new phase is limited either by the interface reaction or by diffusion (Gas and d'Heurle, 1993). As the thickness increases, the growth of the new phase becomes limited by the flux of atoms through the new phase to the growing interface(s). The growth of the new phase will be diffusion limited and will increase with the square root of time,

$$L(t)^2 = K_{\mathrm{d}}t \tag{2}$$

where K_{d} is related to the diffusivity of the dominant moving species through the new phase. The analysis is much more complicated if two or more phases grow simultaneously (Zhang and d'Heurle, 1994).

For thin-film reactions such as those used in CMOS processes (*i.e.*, formation of NiSi from $\mathrm{Ni_2Si}$ and Si), it is generally observed that the silicide phases form sequentially rather than simultaneously. The new phase (NiSi) only begins to grow after the most metal-rich phase (Ni) is completely consumed. In contrast, in bulk diffusion couples the $\mathrm{Ni_2Si}$ phase can reach the critical thickness such that $\mathrm{Ni_2Si}$ and NiSi (as well as other phases) can exist simultaneously. Of course, if the diffusion of reactants is altered (by impurities in the films, for example) then multiple silicide phases may be observed simultaneously even in the thin-film case.

1.2.1.3 Results on Metal–Si Reactions Diffusion-limited kinetics have been observed for both bulk and thin-film reactions between metals and Si (Lien *et al.*, 1986; d'Heurle and Gas, 1986; Mayer and Lau, 1989; Gas and d'Heurle, 1997) (Table 4). The reaction kinetics are similar for bulk and thin-film couples. However, the diffusivities are higher in the thin-film case as a result of the contribution from grain-boundary diffusion (Barge *et al.*, 1995). The kinetics can be analyzed by plotting the square of thickness versus time for different annealing temperatures. For diffusion-limited kinetics and assuming that only one phase forms at a time, a series of straight lines is ob-

Table 4. Silicide phase sequence for thin metal films on single-crystal Si. The silicides are listed in the order of their appearance from the top down. The diffusing species during silicide formation is italicized. Where known, the reaction kinetics, t or $\sqrt{t}$, are indicated. (Reprinted from Colgan *et al.*, 1996, copyright 1996, with permission from Elsevier Science.)

Ti[a] $\mathrm{Ti_5Si_3}$ (?) $\mathrm{Ti}\mathit{Si}$ $\mathrm{Ti}\mathit{Si}_2$ t, $\sqrt{t}$(?)	**V** $\mathrm{V}\mathit{Si}_2$ t, $\sqrt{t}$	**Cr** $\mathrm{Cr}\mathit{Si}_2$ t

[a] Whether $\mathrm{Ti_5Si_3}$ and TiSi form before $\mathrm{TiSi_2}$ in a clean system is not clear. The growth kinetics of $\mathrm{TiSi_2}$ are linear on single crystal Si and $\sqrt{t}$ on α-Si.

[b] Silicide formation occurs in a laterally nonuniform manner.

[c] The diffusing species during $\mathrm{Pd}_2\mathit{Si}$ formation is probably both Pd and Si.

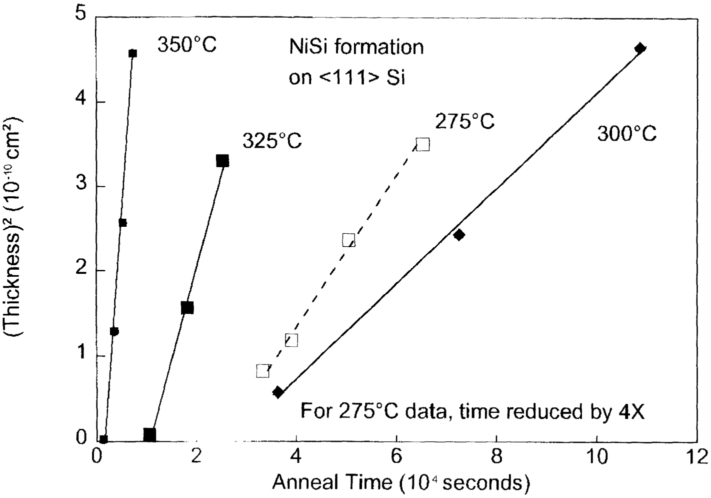

FIG. 9. The thickness of NiSi squared as a function of time, showing diffusion-limited kinetics. (Reprinted with permission from d' Heurle *et al.*, 1984. Copyright 1984 American Institute of Physics.)

tained (d'Heurle *et al.*, 1984) (Fig. 9). The slopes of the lines are related to the diffusivity of the dominant diffusing species, while an Arrenhius plot of the slopes is related to the activation energy for diffusion.

In most cases (Co in Co_2Si, Ni in Ni_2Si, Si in $TiSi_2$), the majority atoms in the silicide are the most mobile (d'Heurle and Gas, 1986). In general, these atoms are next-nearest neighbors to one another, so that a vacancy can propagate along the network of majority atoms with only small perturbations of the lattice. In contrast, the motion of minority atoms requires the coexistence of either two vacancies (minority and majority) or local destruction of the lattice, resulting in a high activation energy.

Nucleation-limited reactions have been observed in a number of silicides where the free energy of formation is small (d'Heurle, 1988). These nucleation effects are eliminated when these phases are formed on amorphous Si, because of the additional free energy in the system associated with crystallization of amorphous Si. Similarly, there is evidence that grain boundaries and grain-boundary triple points are preferred sites for the nucleation of both $CoSi_2$ (Applebaum *et al.*, 1985) and C54-$TiSi_2$ (Ma and Allen, 1994), presumably because of the additional gain in free energy produced by eliminating grain boundaries. The nucleation of C54-$TiSi_2$ is an important problem in microelectronics processing (see Sec. 3.1).

Metal–Si reactions can also be affected by impurities, which generally inhibit silicide formation. The impurities can be films at the metal–Si interface, such as native oxides or surface contamination, contaminants in the metal film from either the metal deposition or the anneal ambient, or dopants in the Si substrate. The most common contaminants during processing of silicides for integrated circuits are oxygen and nitrogen, as well as dopants such as As, P, and B (Gambino and Colgan, 1998).

1.2.2 Results on Metal Reactions with Si-Based Compounds

Metals can react with a number of Si-based compounds to form silicides, including SiO_2, Si_3N_4, SiC, and SiGe. For Si integrated-circuit processing, SiO_2 and Si_3N_4 are used as insulators and often react with transition metals used for contacts and interconnects, such as Ti or Co. These reactions can be beneficial, for example by providing good adhesion between the metal and the insulator, or they can be detrimental, for example by leaving conducting filaments on insulating regions. For structural materials, SiO_2, Si_3N_4, or SiC is used either as reinforcing fibers or as the matrix in composites, and often reacts with transition metals that are in the composites. These reactions are usually beneficial, providing strong adhesion between the different components of the composites. Reactions between metals and ceramics are also used to join structural metal alloys to structural ceramics, by diffusion bonding. Finally, SiC or SiGe is used in novel microelectronic devices, and reacts with metals in contacts to form Ohmic or Schottky contacts.

1.2.2.1 Metal–SiGe Reactions There are many studies of reactions of metals with SiGe alloys, including Ti, Zr, W, Co, Ni, Fe, Cr, Mn, Pd, and Pt (Aldrich *et al.*, 1996; Aldrich *et al.*, 1995; Hong and Mayer, 1990; Luo *et al.*, 1997; Carmondy *et al.*, 1996; Boutarek and Madar, 1993). Si and Ge are very similar chemically; hence many of the silicide phases observed in metal–Si reactions are also observed in metal reactions with SiGe alloys. However, there are a number of notable differences, including formation of metal–Ge compounds or metal–SiGe solid solutions, and segregation of Ge.

A number of general trends are observed during reactions of metals with SiGe alloys. Silicide formation is favored over germanide formation, because of the higher heat of formation for silicides (Aldrich *et al.*, 1996). For the same reason, the silicide formation temperatures are higher on SiGe alloys compared with pure Si (Aldrich *et al.*, 1995; Luo *et al.*, 1997). The phase sequence is silicide-like for Si-rich SiGe alloys and germanide-like for Ge-rich SiGe alloys (Aldrich *et al.*, 1995). The dominant diffusing species is usually the same as during silicide formation (*i.e.*, generally metal for near-noble metals and Si/Ge for refractory metals).

The phases that form depend on the miscibility of the silicides and germanides of a given metal (Boutarek and Madar, 1993). For Ti (and Zr), the C54 phases of $TiSi_2$ and $TiGe_2$ have the same structure and very similar unit cell dimensions, and therefore are completely miscible, forming a $Ti(Si_{1-y}Ge_y)_2$ solid solution. Metals where the silicides and germanides are partially miscible, such as V, form solid solutions over a limited range of SiGe alloy compositions. Finally, metals for which the silicides and germanides are immiscible, such as Fe, Cr, and Mn, form separate silicide and germanide phases (Fig. 10). For some metals both types of behavior are observed, depending on the phase that forms; CoSi and CoGe form solid solutions whereas $CoSi_2$ and $CoGe_2$ do not.

1.2.2.2 Metal–SiO_2 Reactions The transition metals exhibit a wide range of reactivities with SiO_2. Titanium and Ta will reduce SiO_2, forming metal oxide and silicide compounds, whereas Co, Mo, and W do not react significantly with SiO_2. These differences can be

FIG. 11. Ternary phase diagrams for (a) Ti–Si–O, (b) Co–Si–O, (c) W–Si–O, (d) Mo–Si–O and (e) Ta–Si–O. [Parts (a) and (c)–(e) reprinted with permission from Bayers, 1984. Copyright 1984 American Institute of Physics. Part (b) from Maex, 1993, with permission from Elsevier Science.]

understood in terms of the M–Si–O phase diagrams (Fig. 11) (Beyers, 1984; Maex 1993); no reaction will occur between the metal and SiO_2 if there is a tie line between the metal and SiO_2.

Titanium is a good example of a metal that reacts with SiO_2. Reactions between Ti thin films and SiO_2 result in the formation of Ti_5Si_3 at the interface and TiO at the surface (Wang and Mayer, 1990). Oxygen from the consumed SiO_2 is pushed into the unreacted Ti and eventually forms TiO on top of the Ti_5Si_3. A metal-rich silicide (Ti_5Si_3) forms rather than a Si-rich silicide ($TiSi_2$) because the supply of Si is limited (since it is bonded to SiO_2) whereas the supply of Ti is relatively large. Similarly, a Ti-rich oxide is formed (TiO) rather than an oxygen-rich oxide (TiO_2), because the supply of oxygen is limited. Cobalt is a good example of a metal that is relatively unreactive with SiO_2. In fact, no reaction is observed at temperatures below 700 °C (Nguyen *et al.*, 1996).

1.2.2.3 Metal–Si_3N_4 Reactions There have been relatively few studies of metal reactions with Si_3N_4. However, the results are expected to be qualitatively similar to metal reactions with SiO_2: metals that react with SiO_2 will generally also react with Si_3N_4. Reactions between Ti and Si_3N_4 have been studied in detail. The ternary phase diagram (Fig. 12) shows that reactions are expected between Ti and Si_3N_4 (Sambasivan and Petuskey, 1994). At low temperatures (500 °C), the reaction between Ti and Si_3N_4 results in Ti_5Si_3 at the interface, with N dissolving into the unreacted Ti, analogous to the case of Ti on SiO_2. However, at higher temperatures (800 °C), $TiSi_2$ forms at the interface and TiN

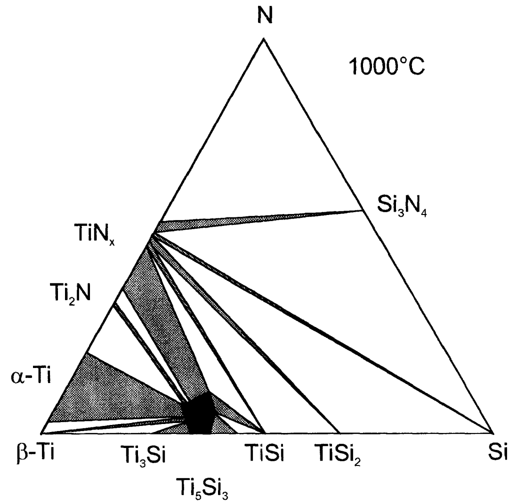

FIG. 12. Ternary phase diagrams for Ti–Si–N (reprinted with permission from Sambasivan and Petuskey, 1994, Fig. 2).

forms on the surface (Barbour *et al.*, 1987), presumably because the reaction is no longer limited by the supply of Si.

1.2.2.4 Metal–SiC Reactions There are many studies of reactions of metals with SiC, including Ti, Hf, Mo, Co, Ni, and Pt. At low temperatures (<750 °C) the results are qualitatively similar to studies on metal reactions with SiO_2 or Si_3N_4. The Ti–Si–C phase diagram (Fig. 13) shows that reactions are expected between Ti and SiC (Taubenblatt and Helms, 1986). Experiments show the Ti_5Si_3 forms at the interface and TiC forms at the surface (Porter *et al.*, 1995a,b). No reactions are observed between Pt, Ni, or Co and SiC at low temperatures. However, at high temperatures (>900 °C), extensive reactions are observed associated with interfacial melting between the metal and SiC. The most likely mechanism is formation of a thin molten silicide layer at the interface (*i.e.*, if the anneal temperature is above the eutectic temperature of the silicide), followed by decomposition of the SiC, with the decomposition of SiC expected to be the rate-limiting step. Because of the limited supply of Si, the reacted layer generally consists of a metal-rich silicide, such as Pt_2Si, Co_2Si, or Ni_3Si (Chou *et al.*, 1991; Porter *et al.*, 1995a,b), though Si-rich silicides are sometimes observed at the highest reaction temperatures. Carbon is also observed, rather than metal carbides, probably in consequence of the low heats of formation for these metal carbides.

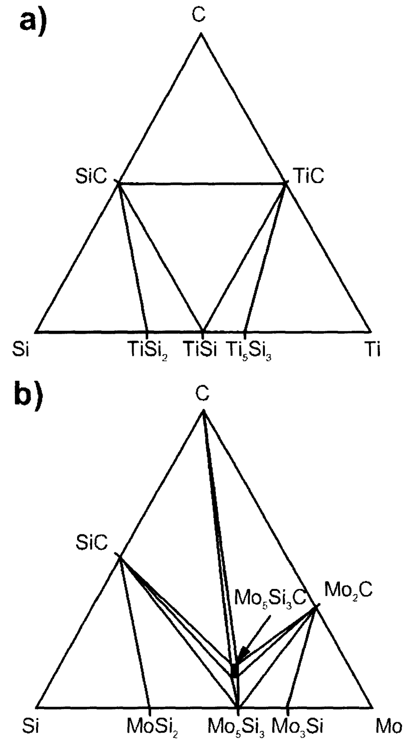

FIG. 13. Ternary phase diagrams for (a) Ti–Si–C (reprinted with permission from Taubenblatt and Helms, 1986. Copyright 1986 American Institute of Physics) and (b) Mo–Si–C (from van Loo *et al.*, 1982, Fig. 2, reproduced with permission).

1.2.3 Thermal Stability The thermal stability of silicides is one of the main reasons that they are used in so many different applications. In microelectronics, the silicide must be stable with respect to the underlying semiconductor during annealing steps used in integrated-circuit manufacturing (such as glass reflow). In structural materials, the silicide must be stable in high-temperature environments, such as the turbines in jet engines.

1.2.3.1 Melting Point Using the traditional definition of "refractory" (stable at >1538 °C, the melting point of Fe), the majority of transition-metal silicides are refractory compounds (Fig. 7). The melting points of the transition metals range from 1246 °C for Mn to 3422 °C for W (Massalski, 1990) and

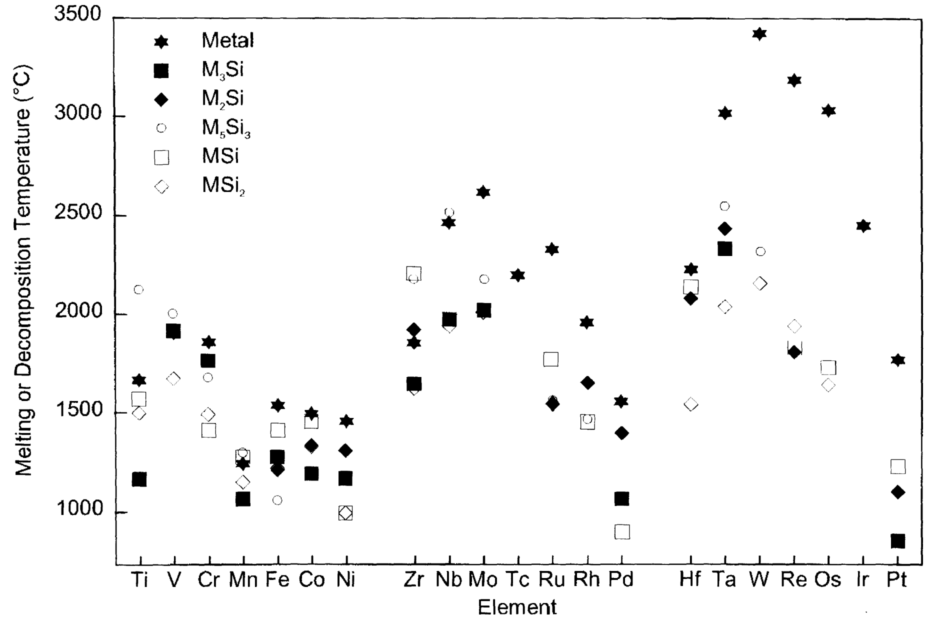

FIG. 14. Melting or decomposition temperature for transition metals and some transition metal silicides by period and group in the periodic table (from Massalski, 1990).

the decomposition temperature of the most stable transition-metal silicides range from 1229 °C for PtSi to 2550 °C for Ta_5Si_3. For comparison, the melting temperature of Si is 1414 °C. The melting or decomposition temperatures increase with the period number (Fig. 14), reaching their maximum values for groups V or VI (V, Cr, Nb, Mo, Ta and W), and are at their minimum values for the near-noble metals (Ni, Pd and Pd). Interestingly, there are silicide phases that have higher melting points than that of the parent metal for Ti, Zr, Hf, V, Nb, and Mn (Figs. 7 and 14). The thermal stability of the near-noble–metal silicide thin films on silicon is also limited by the presence of low-temperature (< 1000 °C) Si-rich eutectics (Fig. 7). The metal melting point and the melting point of the most stable silicide are somewhat correlated (Fig. 15).

1.2.3.2 Stability of Thin Films The stability of silicide thin films is of interest in microelectronics applications. In Si integrated circuits, silicides must be stable on both single-crystal Si and polycrystalline Si. High-temperature annealing can cause agglomeration of silicides on either single-crystal or polycrystalline Si, and can cause silicide-enhanced grain growth in polycrystalline Si (Colgan *et al.*, 1996a).

Agglomeration of silicides on single-crystal Si is often observed after high-temperature annealing, especially for near-noble–metal silicides. There have been many studies of the agglomeration of silicide thin films on Si, including $TiSi_2$, $CoSi_2$, and $NiSi_2$ (Colgan *et al.*, 1996a,b). Agglomeration starts with grain-boundary grooving in the silicide, followed by grain separation and finally the formation of silicide islands. The driving force for grain-boundary grooving is the reduction of grain-boundary energy in the system (Nolan *et al.*, 1992; Mullins, 1957; see also GRAIN BOUNDARIES).

Agglomeration depends on a number of factors, including film thickness, grain size, grain-boundary energy, surface energy (of the film and the substrate), and interface energy (of the film–substrate interface). Agglomeration will increase as the groove depth increases; hence, agglomeration increases with decreasing film thickness, increasing grain size, and increasing grain-boundary energy. Agglomeration is probably limited by the slowest-diffusing species, because there must be transport of

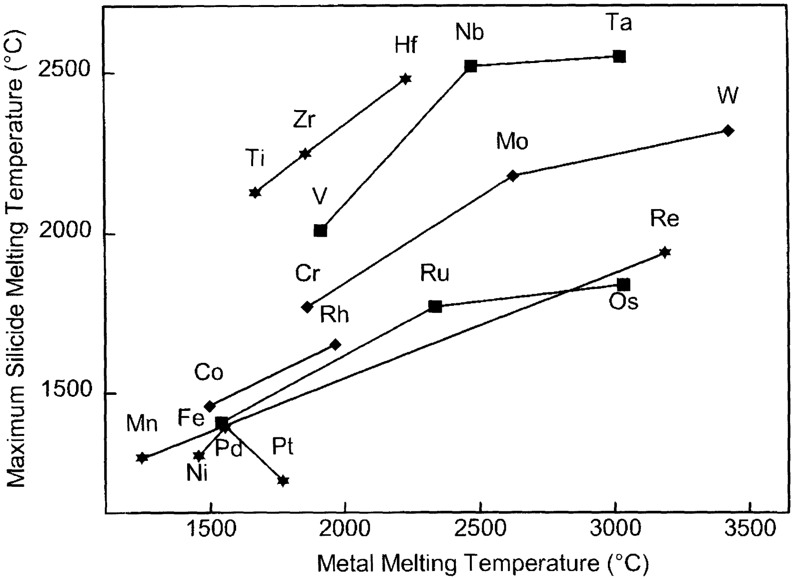

FIG. 15. Maximum silicide melting temperature *versus* parent metal melting temperature. Elements in the same group are connected by lines (Massalski, 1990).

both Si and the metal. Hence, it is expected that the agglomeration temperature for a given silicide will scale with the melting point of the silicide.

Silicide thin films are less stable on polycrystalline Si than on single-crystal Si, because there is an additional driving force for morphological changes: the grain-boundary energy of the polycrystalline Si. Grain growth in the polycrystalline Si is enhanced by the silicide, which provides a fast diffusion path for transport of material. The grain growth in the polycrystalline Si can cause severe roughening of the silicide–polycrystalline Si interface, and is undesirable in integrated circuits (Colgan *et al.*, 1996a; Gambino *et al.*, 1998). On the other hand, similar silicide-enhanced grain growth has been used to form large-grain Si films, which are desirable for thin-film transistors (Lee *et al.*, 1996). The temperature at which silicide-enhanced grain growth occurs for a given silicide scales with the deformation temperature of the silicide (Fig. 16). The growing Si grains protrude into the silicide; the growth

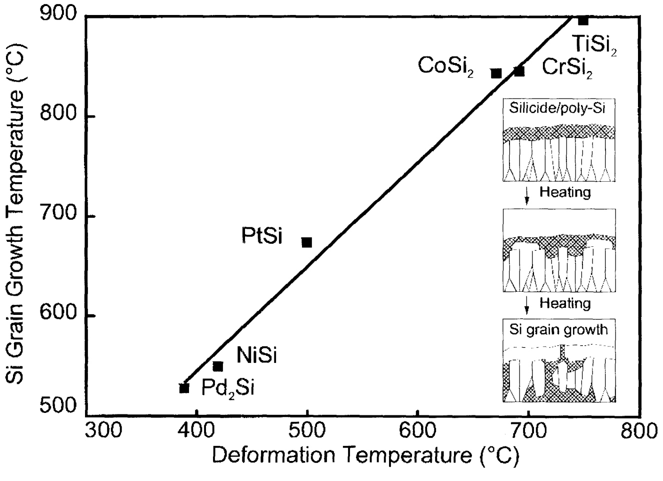

FIG. 16. Silicide degradation temperature as a function of silicide deformation temperature for various silicides (from Hong *et al.*, 1994).

of the grains will be constrained if the silicide is difficult to deform (Hong *et al.*, 1994).

1.2.4 Chemical Stability The chemical stability of silicides is important in a number of applications. In structural materials, it is desirable that the silicides withstand corrosive environments such as high-temperature oxidation. The oxidation resistance of silicides is also of interest in microelectronics applications, where silicides are exposed to high-temperature oxidations used to fabricate devices. However, during integrated-circuit fabrication it is also necessary to pattern silicides; in this case etching of the silicides is necessary and desirable.

1.2.4.1 Oxidation The oxidation of silicides has been widely studied for both microelectronics applications and structural materials. Oxidation can result in either SiO_2 formation or metal oxides, depending on the availability of Si at the oxide–silicide interface. In general, it is preferred to form SiO_2 rather than metal oxides, because SiO_2 is a stable oxide that grows relatively slowly without affecting the integrity of the underlying silicide. In contrast, many metal oxides (such as W oxides and Mo oxides) are volatile and can produce cracks or blisters in the oxide film.

Metal-free oxides can be formed on most of the silicides (including WSi_2, $MoSi_2$, $CoSi_2$, $TiSi_2$, $NiSi_2$ and PtSi) if there is an adequate supply of Si. This can be seen from the ternary phase diagrams (Fig. 11); metal oxides will not form if the system stays in the MSi_2–SiO_2–Si triangle (Beyers *et al.*, 1984). The supply of Si at the oxide–silicide interface can be analyzed in terms of the activity of Si at the interface, which is related to the chemical potential (Zhang and d'Heurle, 1992; Lee, 1992). If the silicide is saturated with Si, the activity of Si at the oxide–silicide interface approaches unity and SiO_2 is formed. However, if the supply of Si is limited, the activity at the oxide–silicide interface will decrease, and may become low enough to allow oxidation of metals to occur.

For refractory-metal silicides (such as $TiSi_2$, $MoSi_2$, and WSi_2), Si diffusion through the silicide provides the excess Si required for SiO_2 formation. The excess Si must be supplied from the underlying Si (in the case of a thin silicide film) or from excess Si in the bulk of the silicide. In either case, the diffusion of Si to the oxide–silicide interface must be unhindered, to ensure that there is an adequate supply for SiO_2 formation. Because the activation energy for Si diffusion throught the silicide is higher than that for the growth of SiO_2, high oxidation temperatures (800 °C or above) are required to form SiO_2. At low temperatures, the supply of Si will be limited and metal oxides will form (Zhang and d'Heurle, 1992).

For near-noble–metal silicides (such as $NiSi_2$, $CoSi_2$, and PtSi), the metal diffusivity is high and oxidation occurs by a different mechanism. During oxidation, the silicide decomposes at the oxide–silicide interface, providing Si for oxidation. The free metal then diffuses to the underlying Si, forming more silicide. During oxidation of $NiSi_2$ and $CoSi_2$, there is also diffusion of excess Si away from the oxide–silicide interface, due to the volume increase (and hence compressive stress) associated with SiO_2 formation (d'Heurle *et al.*, 1987). In either case, the diffusivity of the metal must be high enough to ensure an adequate supply of Si at the oxide–silicide interface.

The formation of SiO_2 on silicides and on Si occur by similar mechanisms (Zhang and d'Heurle, 1992). During the initial stages of the reaction, oxidation is limited by the interfacial reaction between Si and oxygen, and oxide growth will be linear with time. As the oxide grows, the reaction will eventually be limited by diffusion of oxidizing species through the SiO_2, and the oxide thickness will increase with the square root of time. For dry oxidations, the diffusing species is molecular oxygen, whereas for wet oxidations (*i.e.*, steam), the diffusing species is H_2O (Irene, 1988). Although the kinetic processes are similar, the oxidation rates of silicides are generally higher than that of Si, with near-noble–metal silicides usually having higher oxidation rates than refractory metal silicides (Frampton *et al.*, 1987) (Fig. 17).

The oxidation of WSi_2 and $MoSi_2$ can result in the formation of volatile metal oxides (such as WO_3 and MoO_3) if there is insufficient Si at the surface. The formation of these volatile metal oxides causes volume expansion and blistering of the protective SiO_2 films, resulting in futher oxidation of the silicide. The formation of metal oxides can cause peeling of silicide thin films (Yoo *et al.*, 1990) and can cause disintegration of bulk silicides; this is

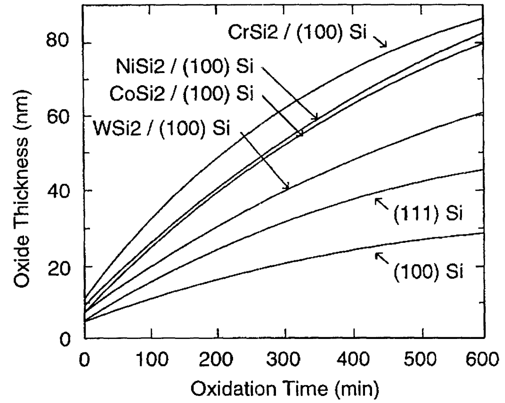

FIG. 17. The kinetics of SiO_2 formation for several silicides at 800°C in nominally dry O_2 (reprinted with permission from d'Heurle *et al.*, 1987, and Taylor & Francis, Ltd.).

often referred to as a "pest" reaction (Fig. 18) (Grabke and Meier, 1995; Chou and Nieh, 1993).

A number of methods have been investigated for preventing metal oxidation. For thin films used in microelectronics, a Si-rich silicide is used to ensure that there is an adequate supply of Si at the surface during oxidation. For bulk $MoSi_2$ structural materials, one approach that has been used is to alloy the silicide with Ge. Germanium forms a glass (GeO_2) at lower temperatures than SiO_2; the GeO_2 glass protects the silicide at low temperatures. The GeO_2 also lowers the viscosity of SiO_2 at high temperatures, making it easier to seal cracks if they form. In addition, GeO_2 increases the coefficient of thermal expansion, which reduces the expansion mismatch between the $MoSi_2$ and the protective SiO_2 layer (Mueller *et al.*, 1992).

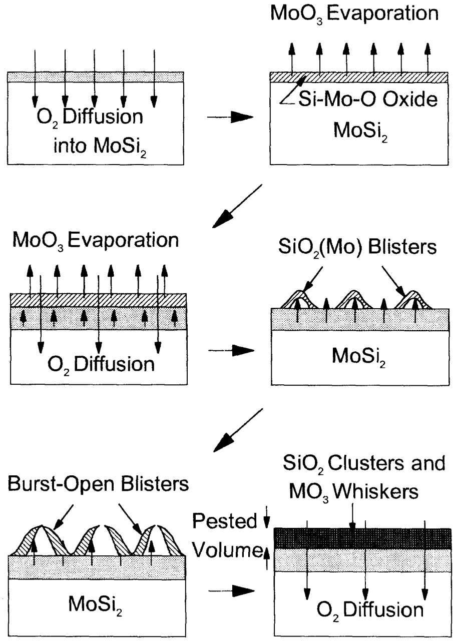

FIG. 18. Schematic of pest reaction in single crystal $MoSi_2$ (reprinted with permission from Chou and Nieh, 1993, Fig. 17).

1.2.4.2 Silicide Reactions with Dopants (As, P, B) In microelectronics applications, silicides are often in contact with heavily doped Si (*i.e.*, Si doped with As, P, or B). For these applications, it is desirable to maximize the active dopant concentration in the Si. Hence, the thermodynamic and kinetic stability of the silicide on doped Si is important. Diffusion of dopants into the silicide can lower the dopant concentration in the Si, causing a higher contact resistance for contacts to diffusions and a threshold-voltage shift for contacts to gates. At the same time, dopant diffusion from the silicide can be beneficial, making it possible to form shallow junctions. Interactions between dopants and silicides are also relevant for structural materials; B doping in Ni_3Si improves the ductility of the alloy (Takasugi and Yoshida, 1991). Hence, an understanding of the interactions between silicides and dopants is required, including compound formation, solubility, diffusivity, and segregation (Maex *et al.*, 1989; Lien and Nicolet, 1984; Murarka and Williams, 1987).

There have been relatively few studies on the solubility of dopants in silicides (Shone *et al.*, 1986; Jahnel *et al.*, 1982); most of the data on solubilities are from studies on dopant diffusion in polycrystalline silicides. In most cases, the solubilities were estimated on the basis of the average dopant concentration in the silicide. It is expected that dopants segregate to grain boundaries in many cases, and so the actual solubility (*i.e.*, in the grains) will be less than that estimated from measurements on polycrystalline thin films.

Silicides can react with dopants to form metal–dopant compounds. Most silicides are

FIG. 19. Ternary phase diagrams for metal–Si–dopant phases: (a) Co–Si–P, (b) Co–Si–As, (c) Co–Si–B, (d) Ti–Si–P, (e) Ti–Si–As and (f) Ti–Si–B (reprinted with permission from Madar, 1995).

expected to form binary or ternary compounds with dopants at sufficiently high dopant concentrations (Fig. 19, from Madar, 1995). However, these compounds are often not observed in microelectronics applications (Maex, 1993), perhaps because dopant concentrations are below the solubility limit in the silicide. In contrast, binary and ternary dopant compounds are often observed in structural silicides (Briant and Taub, 1988).

There have been many studies on dopant diffusion in polycrystalline silicides (Gas *et al.*, 1995). With the exception of a few studies where silicides with large grain sizes were used, diffusivities measured in most studies are probably dominated by grain-boundary diffusion. This is directly relevant for microelectronics applications, where the silicides are polycrystalline thin films. A comparison of dopant diffusion studies (Fig. 20) indicates that grain-boundary diffusion greatly enhances dopant transport in silicides with small grains

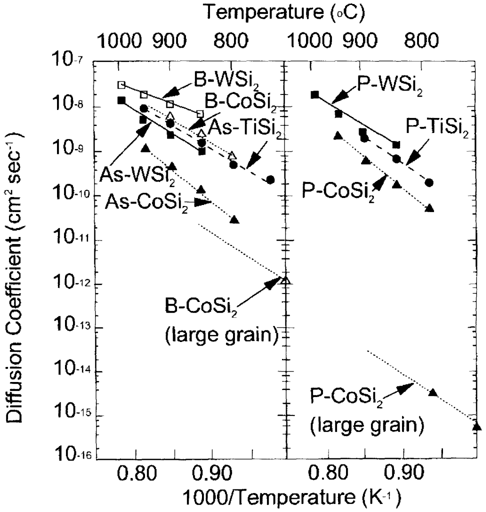

FIG. 20. Diffusion coefficients of B, As and P in various silicides (reprinted from Gambino and Colgan, 1998, with permission from Elsevier Science).

(Chu *et al.*, 1992) compared with silicides with large grains (Thomas *et al.*, 1988b; Zaring *et al.*, 1990). In most cases, the diffusion coefficients of the dopants in silicides are higher than those in Si. The activation energies for volume diffusion are typically 2–3 eV, and are similar to those for silicide self-diffusion, suggesting a substitutional diffusion mechanism (Gas *et al.*, 1995).

1.2.4.3 Chemical Reactivity The chemical reactivity of silicides is important in microelectronics applications. When silicides are patterned by dry etching methods a high reactivity is required. However, during subsequent wet or dry etch steps, a low reactivity is required. Low reactivity is also required for silicides used for coatings in corrosive environments.

Vijh (1994) has studied the hydrogen evolution reaction ($H_2O \rightarrow H_2 + \frac{1}{2}O_2$) in a number of silicides; the hydrogen-evolution reaction is of relevance for corrosion and electrolysis reactions. In general, silicides show high chemical and electrochemical stability in electrolyte solutions, especially at cathodic potentials. At anodic potentials, some oxide growth and dissolution of the silicide can occur. In addition, a variety of electrode reactions, including the hydrogen-evolution reaction, can be sustained at high rates on silicide electrode materials. Silicides formed from a catalytic metal (such as PtSi) show higher rates for the hydrogen-evolution reaction in acidic solutions compared with alkaline solutions; the reverse is true for silicides formed from noncatalytic metals (such as Zr).

In microelectronics applications, silicides must withstand a number of wet etches used for cleaning the substrates or for removing excess metal (see Sec. 2.1), including HF, $H_2O_2 + H_2SO_4$, $H_2O_2 + NH_4OH + H_2O$ (SC-1 solution), and $H_2O_2 + HCl + H_2O$ (SC-2 solution). Most commonly used silicides etch slowly if at all in $H_2O_2 + H_2SO_4$ cleans and SC-1 or SC-2 cleans. One exception is $TiSi_2$, which can be etched in $H_2O_2 + NH_4OH + H_2O$ solutions. Another exception is As-doped $CoSi_2$, which can be etched and oxidized in $H_2O_2 + HCl + H_2O$ solutions (Gambino *et al.*, 1990). Most silicides etch to some degree in HF. A common method for patterning silicide thin films formed by metal-Si reactions is to use a wet etch that attacks the nonsilicided metal over the insulator regions, but does not attack the silicide that forms in the contacts (*i.e.*, salicide process; see Sec. 2.1). A number of etches have been developed for $TiSi_2$, $CoSi_2$, NiSi, and PtSi (Gambino and Colgan, 1998).

Reactive ion etching (RIE) is commonly used for patterning codeposited silicide thin films for microelectronics applications (*i.e.*, polycide process, see Sec. 2.2) (Flamm *et al.*, 1984). Anisotropic etching is achieved by using ion bombardment to accelerate the etch reactions. Reactive ion etching can occur if the material to be etched forms volatile compounds with the etch gases. Tungsten, Ti, and Si all form relatively volatile fluorides, chlorides, and bromides, and therefore can be etched with either F-, Cl-, or Br-based chemistries (Chow *et al.*, 1984). In contrast, Ni, Pt, and Co fluorides, chlorides and bromides have high boiling points; hence $NiSi_2$, $CoSi_2$, and PtSi are difficult to pattern by RIE.

1.3 Properties

1.3.1 Mechanical Properties The mechanical properties of silicides, such as creep rate, hardness, yield strength, and brittle–ductile transition temperature, are obviously relevant for structural materials. Because of this, there have been many studies on the mechanical properties of bulk silicides (Kumar, 1994). Mechanical properties are also important for microelectronics applications, where high stresses can be detrimental to underlying devices.

A high value of hardness is required for applications such as coatings, and is also a measure of strength. In general, hardness increases with increasing melting point of the material (Fig. 21), and so most silicides have high values of hardness (Fleischer, 1994; Ostling and Zaring, 1995). The hardness and fracture toughness of silicides can often be increased by alloying (Fig. 22) (Maloy *et al.*, 1991).

The yield strength of a material is the minimum stress that must be applied to induce plastic deformation of the material, and is usually proportional to the elastic modulus (Young's modulus) of the material (Barrett *et al.*, 1973). The yield strengths and elastic moduli for silicides are generally high compared with other materials (Fig. 23) (Shah *et al.*, 1992), Ostling and Zaring, 1995).

All rights reserved.)

The yield strength and ductility of a material are related to the slip systems that are available in the structure for dislocation motion. Slip is difficult in most silicides, because of complicated crystal structures and covalent bonding. The mobility of dislocations increases as the ratio of the lattice spacing to the Burgers-vector length (*i.e.*, the width of the dislocation) decreases. In silicides, the lattice spacing for the slip planes is often large, on account of the complicated crystal structures. In addition, the Burgers vectors are often small, as a result of dissociation of dislocations caused by the highly directional covalent bonds. Hence, dislocations in silicides generally have low mobility. As a result, silicides have high yield strength but low ductility. Silicides are generally brittle at low temperatures, which is a disadvantage for structural materials, because they are weak against fracture. Slip becomes easier as temperature increases, because dislocation motion, which requires an atom at the core of the dislocation to jump a distance on the order of the Burgers vector length, increases with temperature (Hertzberg, 1976).

The temperature of the brittle-to-ductile transition generally increases with increasing

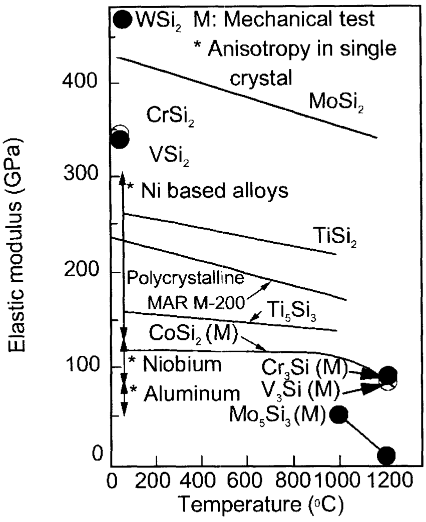

FIG. 23. Comparison of average elastic modulus as a function of temperature (reprinted from Shah *et al.*, 1992, copyright 1992, with permission from Elsevier Science).

melting point of the material (Fig. 24) (Fleishcher, 1994). Because of their low temperature brittleness, silicides by themselves cannot be used as structural materials. However, this problem can be overcome by forming a composite, adding a second phase to the silicide that improves the low temperature ductility. The fracture toughness is a measure of the work expended at a crack tip during crack propagation, and gives a measure of brittleness (*i.e.*, brittle materials have low fracture toughness). The fracture toughness of silicide composites is much greater than that of the silicide alone (Vasudevan and Petrovic, 1992).

The high-temperature (>900 °C) yield strength of MoSi$_2$ is anisotropic (Fig. 25) and is much higher at orientations near [001] compared with other orientations (Umakoshi *et al.*, 1990; Kimura *et al.*, 1990). The dominant high-temperature slip planes in MoSi$_2$ (and also WSi$_2$, which has the same structure) are the {110} and {013} planes, with the {110}

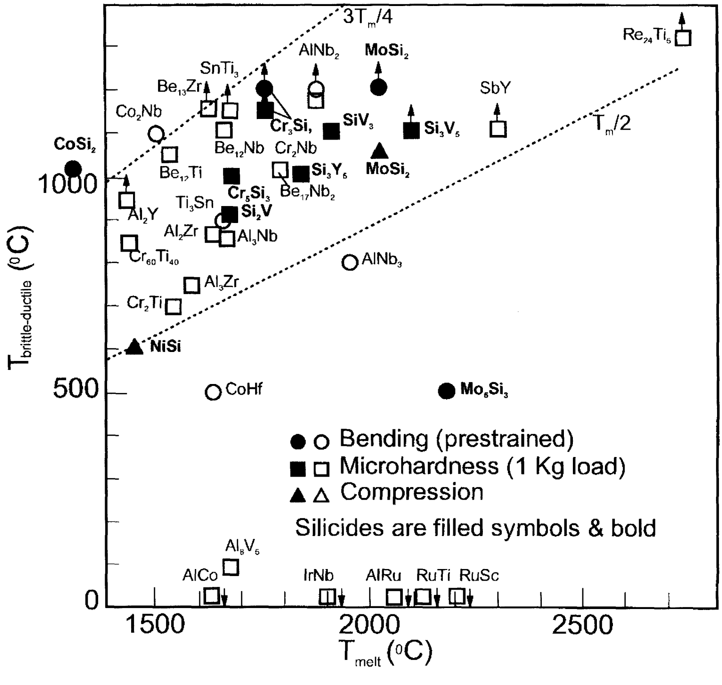

FIG. 24. Brittle-to-ductile transistion temperatures as a function of melting points of the material. Data are from bending, microhardness, and compression experiments. (From Fleischer, 1994. Copyright John Wiley & Sons Limited. Reproduced with permission.)

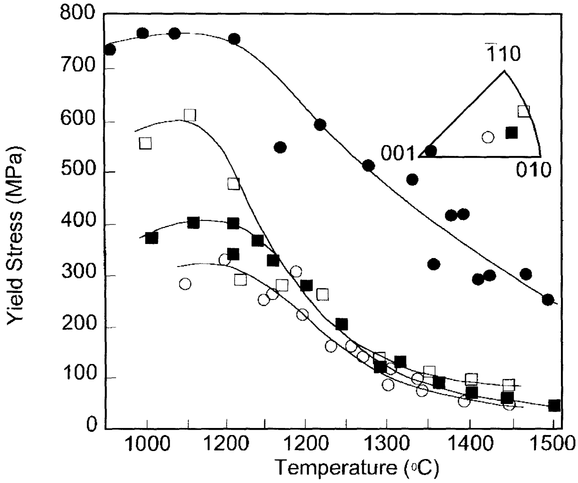

FIG. 25. Temperature dependence of yield strength for several orientations of $MoSi_2$ single crystals (from Umakoshi *et al.*, 1990, copyright 1990, with permission from Elsevier Science).

planes being dominant; the slip direction is ⟨331⟩ in both cases. For $MoSi_2$, the critical resolved shear stress for {013} planes is higher than that for {110} planes, perhaps because the cores of dislocations on {013} planes are nonplanar and spread onto several planes (the {110} planes have a simple ABAB stacking sequence, whereas the {013} planes have a long-period stacking sequence). Orientations near [001] will deform on the [013] slip system, and hence will have a higher yield strength. In contrast, for WSi_2, the critical resolved shear stress for {110} planes is higher than that for {013} planes, perhaps due to a large number of stacking faults on {110} planes.

$CoSi_2$ is more ductile than $MoSi_2$, on account of a more active slip system. $CoSi_2$ has the fluorite structure, and has an fcc crystal symmetry (compared with the more complicated tetragonal $C11_b$ structure of $MoSi_2$). Possible slip systems include {110}, {111}, and {001} planes, all in the ⟨110⟩ direction, as well as {001} planes in the ⟨100⟩ direction. The {111} planes are probably the dominant slip planes at high temperatures (>800 °C), as in fcc metals (Takeuchi *et al.*, 1992). However, at room temperature the {001} planes are the dominant slip planes, in the ⟨100⟩ direction (Ito *et al.*, 1992). Orientations near [100] will deform on the [110] slip system, and hence will have a higher yield strength.

The yield strength of $MoSi_2$ decreases abruptly at high temperatures (between 1100 and 1200 °C, see Fig. 25), indicating an increase in ductility (Umakoshi *et al.*, 1990). The improvement in ductility is due to activation of the {110} and {013} slip systems. At these temperatures, most dislocations have ⟨331⟩ Burgers vectors. At higher tempertures (above 1300 °C), ⟨100⟩ and ⟨110⟩ dislocations are activated, and the ductility is greatly improved.

At high temperatures (greater than half the melting point), the plastic deformation of a material under an applied stress varies with time, independent of whether the applied stress is greater than or less than the yield strength. This deformation is called creep. Many silicides have low creep rates, which are desirable in structural materials (Fig. 26) (Shah *et al.*, 1992). The creep rates of $MoSi_2$ can be further improved by forming composites (Bose, 1992). The activation energy for creep in $MoSi_2$ is high in comparison with lattice diffusion (4.48 eV compared with 2.4 eV for Si diffusion and 3.6 eV for Mo diffusion in $MoSi_2$). Possible creep mechanisms include grain-boundary sliding and dislocation climb at higher applied stresses, and grain-boundary sliding at lower applied stresses (Vasudevan and Petrovic, 1992; Sadananda *et al.*, 1992). Dislocation climb is expected to be limited by diffusion of Mo, which is the slower diffusing species.

1.3.2 Optical Properties The optical reflectivity of metallic silicides can be used to examine the electronic structure such as the

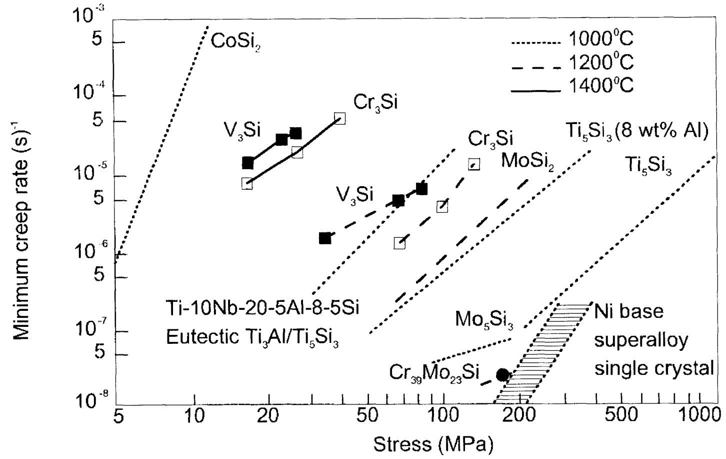

FIG. 26. Comparison of minimum creep rates in compression *versus* stress for several silicides and alloys (reprinted from Shah *et al.*, 1992, copyright 1992, with permission from Elsevier Science).

density of states and character of the bands through the complex dielectric function. The complex dielectric function, $e(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega)$, is related to the complex refractive index, $n = n + ik$ so that $\varepsilon_1 = n^2 + k^2$ and $\varepsilon_2 = 2nk$ and can be calculated from reflectance or other optical data. A recent review (Guizetti and Marabelli, 1995) summarizes information on the complex refractive index for silicides. Examples of the interpretation of the optical response of metallic silicides in terms of the electronic structure can be found in the work of Nava *et al.* (1993). Following Nava *et al.*, for the free-electron region at low photon energies, the classical Drude model (Ashcroft and Mermin, 1976) can be used to determine the plasma frequency (ω_p) and the relaxation time (τ) from the complex refractive index:

$$\varepsilon_1(\omega) = 1 - \omega_p{}^2/[\omega^2 - (1/\tau)^2] \tag{3}$$

$$\varepsilon_2(\omega) = 1 - (\omega_p{}^2/\tau)/\omega[\omega^2 - (1/\tau)^2] \tag{4}$$

The optical resistance at zero frequency, $\rho_{\mathrm{opt}} = 4\pi/\omega_p{}^2\tau$, was also calculated and compared well with the dc resistance measurements. The optical reflectivity and dielectric functions for VSi$_2$, NbSi$_2$, and TaSi$_2$ thin films are shown in Fig. 27 (Nava *et al.*, 1993). At low photon energy, the reflectivity is very high and rapidly decreases for energies around 1 eV. The value of ε_2 drops from a large free-elec-

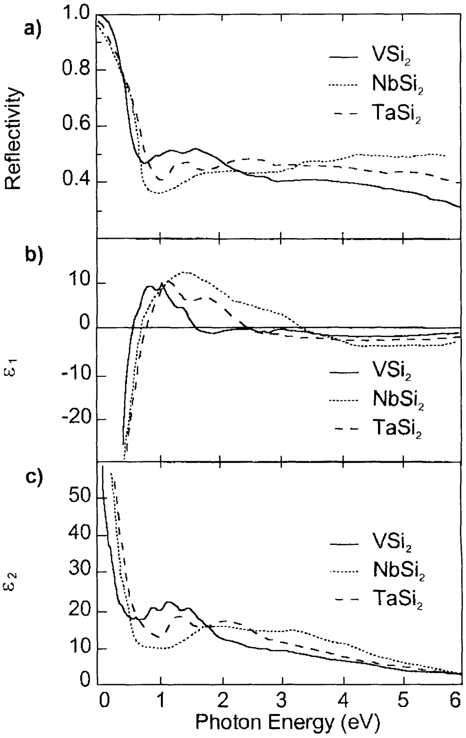

FIG. 27. (a) Optical reflectivity, (b) real part of the dielectric constant, and (c) imaginary part of the dielectric constants for VSi$_2$, NbSi$_2$ and TaSi$_2$ (reprinted from Nava *et al.*, 1993, copyright 1993, with permission from Elsevier Science).

tron value at low photon energy and passes through a minimum around 1 eV.

The optical properties of semiconducting silicides can be used to determine the band gap and whether the transition is direct or indirect. The absorption coeffient, $\alpha = 4\pi k/\lambda$, is calculated from k, the extinction coefficient, where λ is the wavelength. For an indirect transition,

$$\alpha = 0 \quad \text{for } h\nu < E_g - E_p, \tag{5}$$

$$\alpha = A(h\nu - E_g + E_p)^2 \quad \text{for} \quad E_g + E_p > h\nu > E_g - E_p, \tag{6}$$

$$\alpha = A(h\nu - E_g + E_p)^2 + B(h\nu - E_g - E_p)^2 \quad \text{for } h\nu > E_g + E_p, \tag{7}$$

where E_g is the energy gap, E_p is the phonon energy, h is Planck's constant, ν is the frequency of the absorbed light, and A and B are constants. For a direct transition,

$$\alpha = 0 \quad \text{for } h\nu < E_d, \tag{8}$$

$$\alpha = C(h\nu - E_d)^{1/2} \quad \text{for } h\nu > E_d, \tag{9}$$

where E_d is the energy of the direct transition and C is a constant. A good example of a semiconducting silicide with a direct energy gap is β-FeSi$_2$, with a direct band-gap energy of 0.89 eV (Fig. 28) (Bost and Mahan, 1988; Guizetti and Marbelli, 1995).

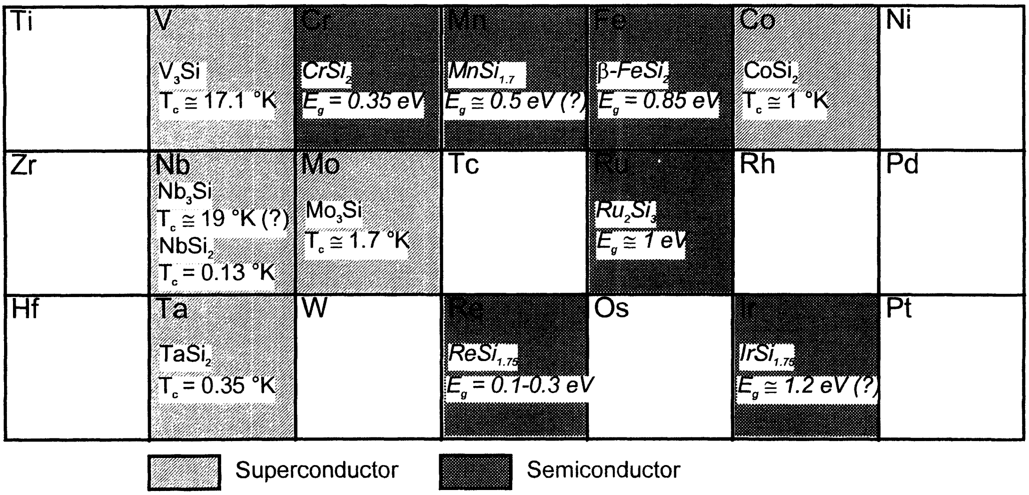
1.3.3 Electrical Properties The electrical properities of silicides have been studied extensively, since the resistivity is of critical importance for many applications (Nava *et al.*, 1993; Gottlieb *et al.*, 1995). The electrical transport properties of silicide–semiconductor interfaces have also been widely studied.

1.3.3.1 Resistivity In general, silicides are metallic conductors with room-temperature resistivities on the order of 10^{-6}–10^{-3} Ωcm, but a number of silicides are superconducting or semiconducting (Fig. 29). For the metallic silicides, the resistivity increases with temperature and can be approximated by Matthiessen's rule (Kittel, 1976), where the temperature-dependent resistivity is equal to an electron-impurity scattering component that is temperature independent plus temperature-dependent terms that include electron–phonon scattering, electron–electron scattering, and other temperature-dependent effects. The temperature dependence of the resistivity for a number of silicide single crystals has been modeled by Nava *et al.* (1993), and it was found that in several cases there were well defined temperature ranges in which a specific electron–phonon scattering mechanism dominated.

The resistivity of noncubic single crystals exhibits anisotropy due to the shape of the Fermi surface (Fig. 30 and Table 5) (Nava *et al.*, 1993). The room-temperature anisotropy is nearly 2 for the hexagonal silicides (VSi$_2$, NbSi$_2$, TaSi$_2$ and Pd$_2$Si) and almost undetectable for the higher-symmetry orthorhombic TiSi$_2$.

The semiconducting silicides (Fig. 29) are generally formed from the middle groups of transition metals. As mentioned in Sec. 1.1.1.1, for the semiconducting silicides, a minimum in the density of states at the Fermi level opens into a gap. In moving from NiSi$_2$ to TiSi$_2$, the density of states due to the metal d electrons moves to lower energy, passing through the Fermi level, with increasing atomic number (see Fig. 2). The shift of the minimum in the density of states relative to the Fermi level changes the conduction in the disilicide. The conduction in NiSi$_2$ and CoSi$_2$ is metallic, but the majority carriers are holes (Nicolet and Lau, 1983). The next silicides, CrSi$_2$, MnSi$_{1.7}$,



Ti	V V_3Si $T_c \cong 17.1$ °K	Cr $CrSi_2$ $E_g = 0.35$ eV	Mn $MnSi_{1.7}$ $E_g \cong 0.5$ eV (?)	Fe β-$FeSi_2$ $E_g = 0.85$ eV	Co $CoSi_2$ $T_c \cong 1$ °K	Ni

and b-$FeSi_2$, are semiconductors. Finally, $TiSi_2$ is a metallic conductor with electrons as the majority carriers (the carrier type for VSi_2 has not been reported). "Undoped" semiconducting silicides (*i.e.*, no intentional dopants) usually have holes as the majority carriers. They can be made *n*-type by the addition of transition metals with a larger number of d electrons (Co, Ni, Pd, or Pt has been used with b-$FeSi_2$), or *p*-type by the addition of transition metals with a smaller number of d electrons (Mn, Cr, V, or Ti has been used with b-$FeSi_2$), than the metal atom they replace (Lange, 1996). The activation energies for most dopants vary between about 0.08 and 0.14 eV.

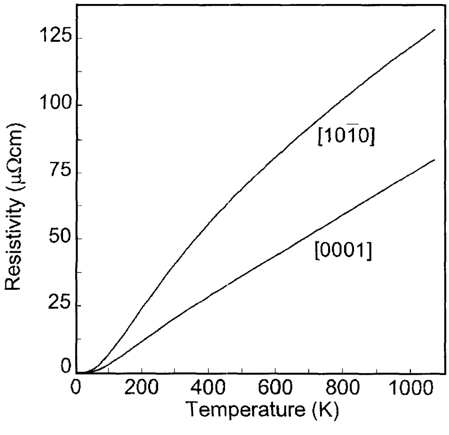

FIG. 30. Temperature dependence of single-crystal $TaSi_2$ resistivity with the current parallel to the [0001] and [10$\bar{1}$0] crystallographic directions (reprinted from Nava *et al.*, 1993, copyright 1993, with permission from Elsevier Science).

There have been relatively few studies on the superconducting properties of silicides, probably because the critical temperature (T_c) is low for most superconducting silicides (see Fig. 29). One exception is V_3Si, which has a relatively high critical temperature (≈ 17 K) compared with other intermetallic superconductors. However, all of the intermetallic superconductors have much lower critical temperatures than oxide superconductors (Bednorz and Müller, 1986), and therefore have been less studied in recent years.

V_3Si, like other intermetallic superconductors with high T_c, has the A15 crystal structure. The Si atoms are arranged on a body-centered cubic (bcc) lattice, and the V atoms are in pairs that straddle the center of a face of the cube. This results in orthogonal chains of closely spaced V atoms running through the crystal structure. It is believed that these chains lead to the good superconducting properties of these materials (Stekly and Gregory, 1994).

1.3.3.2 Ohmic, Rectifying, and Gate Contacts

Metal contacts on lightly doped Si form rectifying contacts (*i.e.*, nonlinear current–voltage

Table 5. Electrical properties of some transition-metal silicides (from Nava *et al.*, 1993).

characteristics, with high current in one polarity and low current for the opposite polarity), which are used to make Schottky diodes. For Schottky diodes, the most important property is the barrier height, which depends on the properties of the metal and the semiconductor surface. Metal contacts on heavily doped Si can be Ohmic (*i.e.*, linear current–voltage characteristics) and are used to make contacts to diffusions. The most relevant parameter for Ohmic contacts is the contact resistance, which depends on the metal and the doping in the Si. For gate contacts to metal–oxide–semiconductor (MOS) transistors, the most relevant parameter is the threshold voltage, which determines when the device "turns on" (*i.e.*, when the MOS transistor conducts current). Silicide or metal contacts on top of polycrystalline Si in polycide structures (see Sec. 2.2) do not directly affect the threshold voltage of the device. However, the silicide can indirectly affect the threshold voltage by depleting dopant from the underlying polycrystalline Si.

The current–voltage characteristics of Schottky diodes are determined by the barrier height at the metal–semiconductor interface. For lightly doped Si at room temperature, the current transport across the interface is dominated by thermionic emission of majority carriers over the barrier (Sze, 1981).

For heavily doped Si, the potential barrier at the metal–Si interface becomes very narrow, and tunneling of electrons from the conduction band of the Si into the metal is the dominant transport mechanism. A critical parameter for characterizing Ohmic contacts is the specific contact resistance, which depends strongly on the both the barrier height and the active dopant concentration (Sze, 1981).

Most Ohmic contacts in microelectronics applications are made with Ti or $TiSi_2$. The barrier height of Ti on Si is between 0.5 and 0.6 eV, depending on the annealing temperature after metal deposition (Aboelfotoh and Tu, 1986). Hence, the resistance for these contacts is mainly dependent on the doping level. In order to minimize contact resistance, the contacts are often doped to above the solubility limit. A lower contact resistance is expected for *n*-type contacts than *p*-type contacts, because the *n*-type dopants such as As and P have a higher solubility than *p*-type dopants such as B (Nobili, 1990). In fact, data on $TiSi_2$ contacts (Hui *et al.*, 1985) show a 2× higher contact resistance for *p*-type contacts compared with *n*-type contacts (Fig. 31).

1.3.4 Magnetic Properties The magnetic properties of some silicides are of interest for permanent magnets (Buschow, 1991). There are very few reports on the magnetic properties of silicides. All the studies on the magnetic properties of silicides involve ferromagnetic compounds, where Si is combined with Fe, Co, or rare earths. One type of ferromagnetic material consists of ternary Fe–Al–Si alloys, which exhibit high magnetic permeability (Kumar, 1994). More recent studies have focused on the magnetic properties of ternary

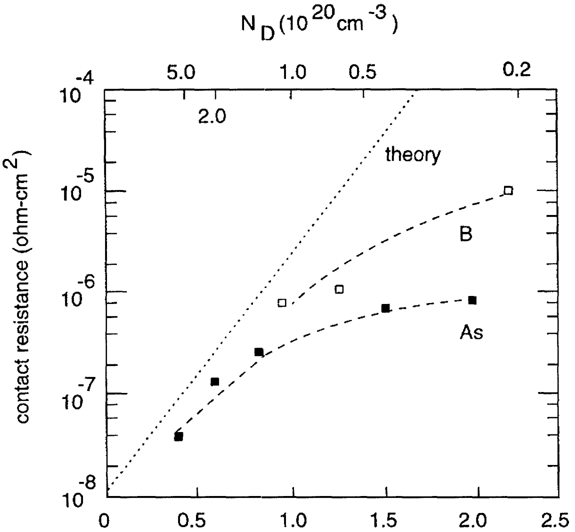

FIG. 31. Specific contact resistance *versus* dopant concentration for $TiSi_2$ on B-doped or As-doped Si (from Hui *et al.*, 1985). Theoretical curve is from Sze (1981), assuming a barrier height of 0.6 eV. (Reprinted from Gambino and Colgan, 1998, copyright 1998, with permission from Elsevier Science.)

silicides with the tetragonal $ThMn_{12}$- or $ThCr_2Si$-type structures (Buschow, 1991). The tetragonal structures provide magnetic anisotropy, which is desirable for permanent magnets. The $ThMn_{12}$ structures also possess high Curie temperatures.

The $ThMn_{12}$ compounds have a composition $RFe_{12-x}Si_x$, where R is a rare-earth element, such as Y, Nd, or Sm (note that other elements can be used instead of Si, including Al, Ti, V, Cr, Mo, and W). The role of the Si is to stabilize the structure, while the rare earths and the Fe provide the permanent magnetic moment. The magnetic properties can be described by combining the $Fe_{12-x}Si_x$ sublattice magnetization with the R sublattice magnetization. For light rare-earth elements, there is a ferromagnetic coupling between the two sublattices, whereas for heavy rare-earth elements there is an antiferromagnetic coupling (Buschow, 1991; Matar *et al.*, 1994).

2. FABRICATION

2.1 Salicide Process

Silicides in Si integrated ciruits are often formed by a solid-state reaction between the metal and Si (Fig. 32). The metal is deposited by physical vapor deposition (see Sec. 2.3) over a patterned wafer, where the pattern consists of insulators (used for isolating de-

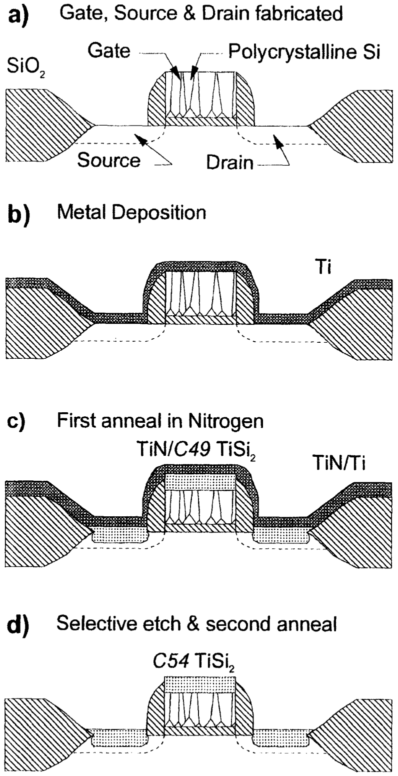

FIG. 32. Schematic of salicide process on an MOS transistor to form $TiSi_2$: (a) starting structure, (b) Ti deposition, (c) first anneal in N_2 to form C49 $TiSi_2$ (and TiN), (d) selective wet etch to remove Ti/TiN and second anneal to form C54-$TiSi_2$. (Reprinted from Gambino and Colgan, 1998, copyright 1998, with permission from Elsevier Science.)

vices) and exposed Si regions (where junctions or gates are to be formed). The wafers are then annealed, with the metal only forming silicide in regions where the Si or polycrystalline Si is exposed. For the appropriate anneal conditions (*i.e.*, sufficiently low temperatures) there is no significant silicide formed in regions where there are insulators, such as Si_3N_4 or SiO_2, since metals react much more slowly with these materials compared with Si. Hence, the silicide is self-aligned to the contacts and gates of the device. The nonsilicided metal is then removed by a wet etch, which etches the metal much faster than the silicide (see Sec. 1.2.4.3). This process is often called a self-aligned silicide or salicide process (Colgan *et al.*, 1996a).

There are a number of advantages to using the salicide process compared with other metallizations. Silicides formed by solid-state reactions often consume contamination and defects at the original metal–Si interface, resulting in low contact resistance for Ohmic contacts and reproducible rectifying behavior for Schottky diodes. Relatively planar metal–Si reactions allow metallization of shallow junctions without degradation of the junction electrical properties (*i.e*, without metal penetrating the junctions and causing high leakage currents). Finally, the self-aligned formation allows a smaller spacing between conductors or contacts than can be achieved with lithography, resulting in higher circuit densities.

There are also problems associated with the salicide process. Lateral silicide formation can result in shorting of contacts (Fig. 33); hence, the anneal temperature and time must be minimized to limit lateral silicide formation. Excessive surface contamination or doping can inhibit silicide formation, resulting in nonuniform silicide thickness and high sheet resistance (see Sec. 1.2.1.3). Nonplanar silicide formation or silicide agglomeration (see Sec. 1.2.3.2) during high-temperature annealing can result in silicide protrusions, junction leakage or high sheet resistance. For silicides on polycrystalline Si, silicide-enhanced grain growth can also occur during high-temperature annealing (see Sec. 1.2.1.3), resulting in threshold-voltage shifts or gate oxide leakage (Fig. 33). Finally, phase transformations (such as C54-$TiSi_2$) can be inhibited on narrow lines, resulting in high sheet resistance (Fig. 34).

Bridging
Junction leakage

FIG. 33. Schematic showing advantages and disadvantages of salicide structure. (Reprinted from Gambino and Colgan, 1998, copyright 1998, with permission from Elsevier Science.)

A number of techniques have been used to avoid the problems described above, including integrated processing, capping layers, preamorphization, ion-beam mixing, epitaxial growth and nucleation enhancement. Integrated processing combines a number of steps, such as the preclean, metal deposition, and silicide formation anneal, in one cluster tool (Nulman, 1990; Aoki *et al.*, 1994). This minimizes the exposure of the Si surface and metal films to air, thereby improving silicide formation. Another approach to prevent oxygen contamination of the metal used in the salicide process (*i.e.*, during exposure to air or the anneal ambient) is to use capping layers such as TiN or Si on top of the metal film (Kaplan *et al.*, 1992; Berti and Bolkhovsky, 1992). For nucleation-limited reactions, such as $TiSi_2$ or $CoSi_2$ formation, amorphization of the substrate can enhance the nucleation of the new phase (Mogami *et al.*, 1994; Kuwano *et al.*, 1990). The free energy of the system is increased, resulting in an increased driving force for the reaction. Amorphization is usually achieved by implantation of Si, Ge, or As prior to metal deposition. Another approach to improve nucleation is ion-beam mixing (Mayer *et al.*, 1981; Maex *et al.*, 1986). In this

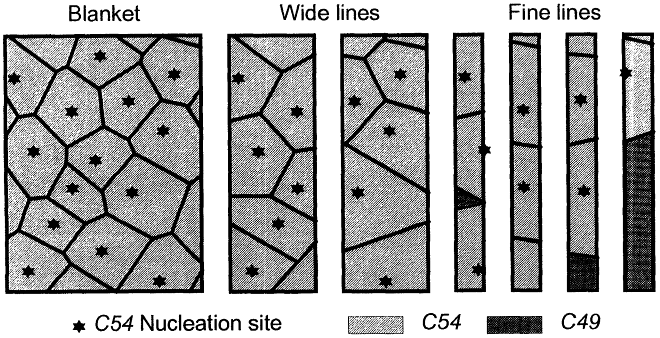

FIG. 34. Schematic of nucleation of C54-$TiSi_2$ as a function of linewidth. For narrow lines, the average distance between nuclei will increase compared with that for blanket films as a result of geometric effects. (Reprinted from Gambino and Colgan, 1998, copyright 1998, with permission from Elsevier Science.)

case, ion implantation is performed after metal deposition, to intermix the metal and Si atoms at the interface. A third approach to improve nucleation is to add impurities that aid in the nucleation of the new phase. This method has been used to improve the nucleation of C54-$TiSi_2$ (Clevenger *et al.*, 1996). The formation of epitaxial silicides has been studied as a method to improve the uniformity of the silicide–Si interface (Hsia *et al.*, 1991; Ogawa *et al.*, 1994; Tung, 1997). Epitaxial growth can be achieved in a salicide process by depositing a thin diffusion barrier (SiO_2 or a refractory metal, such as Ti, Ta, Zr, W) between the metal to be reacted (such as Co) and the Si substrate. If the diffusion barrier is sufficiently thin, the overlying metal can diffuse through it and react with the substrate to form a silicide. The reaction is slowed down, allowing the silicide to grow epitaxially.

2.2 Polycide Process

Silicides in integrated circuits are often formed by codeposition of the silicide, followed by reactive ion etching (RIE) to pattern it (Fig. 35). This process is often used to fabricate MOS transistors (see Sec. 3.1.1) and is referred to as a polycide process. In the polycide process, the polycrystalline Si for the gate is deposited and doped; doping can occur *in situ* during the deposition of the polycrystalline Si or can be done after the deposition by ion implantation (Colgan et al., 1996a). The silicide is then deposited by PVD or CVD (see Secs. 2.3 and 2.4), followed by deposition of an insulator such as SiO_2 or Si_3N_4. The gate stack

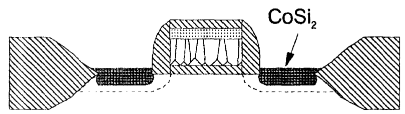

FIG. 35. Schematic of polycide process on an MOS transistor to form $TiSi_2$ on gates: (a) deposit polycrystalline Si, $TiSi_2$, and SiO_2, then pattern using lithography and reactive ion etching, (b) thermally oxidize sidewalls and form sidewall spacers using conformal deposition of an insulator and RIE, (c) form junctions by ion implantation and annealing, and (d) form $CoSi_2$ on the junctions using a salicide process. (Reprinted from Gambino and Colgan, 1998, copyright 1998, with permission from Elsevier Science.)

(*i.e.*, insulator, silicide, polycrystalline Si, and gate oxide) is patterned by lithography and RIE. Next, the structure is exposed to a brief thermal oxidation to remove etch damage at the perimeter of the gate oxide. Insulating sidewalls are formed by conformally depositing an insulator (by CVD), then removing the insulator on horizontal surfaces using RIE. Finally, junctions are formed by ion implantation and annealing. The silicide patterning is a self-aligned process because the silicide is aligned to the polycrystalline Si using no additional masks (Colgan *et al.*, 1996a).

There are a number of advantages to using codeposited silcides compared with other metalizations. Silicon-rich silicides are thermodynamically stable on Si at high temperatures (800–1000 °C) (see Sec. 1.2.1.1), and therefore are compatible with high-temperature processes such as junction anneals and glass-reflow anneals. Silicides are also generally stable during thermal oxidation (see Sec. 1.2.4.1), which is useful during the sidewall oxidation of gates in MOS transistors. The silicide–Si interface is more planar than that resulting from solid state metal–Si reactions, and no Si is consumed. Hence, the formation of silicide protrusions into the polycrystalline Si is reduced.

There are also problems associated with the polycide process. Patterning of some silicides (such as $CoSi_2$, $NiSi_2$, and PtSi) by RIE is difficult because of the relatively low volatility of the metal chlorides and bromides, resulting in incomplete removal of the silicide (see Sec. 1.2.4.3). In addition, the silicide must be defined by lithography; this is not a problem for gate conductors, but is a problem for junctions, where the silicide must be as closely aligned to the Si as possible to avoid problems with leakage or high series resistance. High-temperature annealing can lead to enhanced grain growth in the polycrystalline Si (see Sec. 1.2.3.2), resulting in threshold-voltage shifts or gate-oxide leakage. High-temperature annealing can also lead to dopant diffusion into the silicide and, hence, dopant depletion from the underlying Si, resulting in high contact resistance or threshold-voltage shifts. Finally, oxidation of the silicide can lead to localized consumption and thinning of the polycrystalline Si or oxidation of the metal in the silicide (see Sec. 1.2.4.1).

2.3 Physical Vapor Deposition

Physical vapor deposition (PVD) techniques include evaporation and sputtering, where material is removed from a target by vaporization or ion bombardment and deposited on a substrate. Sputtering (*q.v.*) is often used in integrated-circuit fabrication for depositing elemental metals for silicide reactions or for codepositing the metal and Si, because it is a simple and relatively low-cost method (Table 6). For integrated circuits, sputtering is preferred over evaporation because it is easier to obtain uniform films on large (200-mm diameter) wafers and because the deposition is more conformal over topography on the wafers. The one application where evaporation is used (at least for research) is the epitaxial growth of silicides on Si by molecular-beam epitaxy (MBE). For MBE of silicides (Table 6), metal and Si atoms are evaporated under ultrahigh vacuum on a clean Si surface at high temperatures (von Känel, 1992). PVD methods are also used to make coatings in structural materials (Mashayekhi *et al.*, 1992; Arps, 1996).

In advanced integrated circuits (sub-0.25-µm feature sizes), the metals are often deposited into features with high aspect ratios, such as contact holes. The sputtering process

must be modified to ensure that there is adequate step coverage at the bottom of the hole. One approach is to use a collimator in between the target and the wafers (*i.e.*, collimated sputtering), so that only sputtered atoms with nearly normal incidence reach the substrate. Another approach is to ionize the sputtered atoms (*i.e.*, ionized PVD), so that highly directional deposition of the metal ions can be achieved (Rossnagel, 1995).

2.4 Chemical Vapor Deposition

Chemical vapor deposition (CVD) (*q.v.*) is often used to form WSi_2 in integrated circuits, providing improved step coverage and lower resistivity compared to PVD films (Domenicucci *et al.*, 1997). Recently, there has also been interest in selective CVD of $TiSi_2$ for contacts to Si devices (Maury *et al.*, 1997). Silicides formed by the selective CVD process potentially have lower resistivity and lower Si consumption compared with silicides formed by metal–Si reactions. Another advantage of CVD processes is that the as-deposited silicide is polycrystalline with a relatively large grain size, as opposed to codeposited PVD films which are an amorphous mixture of the metal and Si. CVD has also been used to form silicide coatings on structural materials, by depositing Si or silicides on metal alloys at high temperatures (Singheiser *et al.*, 1982; Nicoll *et al.*, 1979; Southwell *et al.*, 1987).

For CVD of silicides, a metal precursor (WF_6, $TaCl_5$, $MoCl_4$, or $TiCl_4$) is reacted with a Si precursor (SiH_4, Si_2H_6, or SiH_2Cl_2) at elevated temperatures (Table 7). There have been few detailed studies on the kinetics of silicide formation by CVD. Kinetics studies on CVD of WSi_2 and $TiSi_2$ suggest that there are at least two competing reactions that are depositing the metals and/or silicon (Srinivas *et al.*, 1990; Southwell and Seebauer, 1997). In both cases, Si deposition occurs by dissociation of an Si precursor, such as SiH_4, on the Si surface. During CVD of $TiSi_2$, Ti is deposited by adsorption and dissociation of $TiCl_4$. During CVD of WSi_2, W is probably deposited by adsorption and dissociation of WF_6 on the surface of the substrate, analogous to the case of W CVD (Kobayashi *et al.*, 1991; Colgan and Chapple-Sokol, 1992; Hsieh, 1993). In the case of $TiSi_2$ CVD, the rate-limiting step is believed to be the arrival of $TiCl_4$ at the surface, whereas for WSi_2 CVD, the rate-limiting step may be related to the dissociation of SiH_4 at the surface. The byproducts of these reactions are F- and Cl-based species that can etch Si. These byproducts should be minimized to avoid damaging underlying Si devices.

2.5 Ion Implantation

Ion implantation is the introduction of ionized atoms into a substrate with enough energy to penetrate beyond the surface (Seidel, 1983). The technique is widely used for doping semiconductors, but can also be used to form buried polycrystalline or epitaxial silicide layers in Si (Mantl, 1992). Formation of silicides in Si requires implanting a high dose of metal ($>10^{17}\,cm^{-3}$) followed by a high-temperature anneal (>600 °C). Ion implantation has been used to form a variety of thin silicide films, including $CoSi_2$, $TiSi_2$, $NiSi_2$, $CaSi_2$, $CrSi_2$, and $FeSi_2$ (Mantl, 1992; Audet *et al.*, 1992; Omura *et al.*, 1991). Although the technique has been widely studied, it has not been used in manufacturing on account of high cost and residual implant damage in the substrate.

Some unique mechanisms occur when silicides are formed by reacting Si with implanted metals, rather than deposited metals (Mantl, 1992). Silicide precipitates form in the Si during ion implantation. During the early stages of thermal annealing, there is competive growth of the precipitates, with larger precipitates growing at the expense of smaller precipitates (*i.e.*, Ostwald ripening). In order for a continuous silicide layer to form, there must be an interconnected network of precipitates; otherwise, the Ostwald ripening will result in large isolated grains. The coalescence of adjacent silicide precipitates is driven by a reduction of interface energy, and results in planarization of the silicide–Si interface (Mantl, 1992).

2.6 Melt Growth

Growth by solidification of a molten alloy is often used to form structural materials, including silicides. Growth from a melt is also used to form single-crystal silicides for experimental studies, using Czochralski or float zone techniques.

Bulk polycrystalline silicides can be formed by traditional metallurgy techniques such as arc melting and casting (Shah *et al.*, 1992). Novel composites can be fabricated by solidification of melt near the eutectic composition. This technique has been used to fabricate Nb/Nb_5Si_3 composites (Nb_5Si_3 matrix) and SiC/$MoSi_2$ composites ($MoSi_2$ matrix) (Mendiratta *et al.*, 1991; Tilly *et al.*, 1992).

Single crystals of silicides have been grown by either Czochralski or floating-zone techniques (Nava *et al.*, 1993). In both techniques, single crystals are grown on seed crystals from a melt. In the Czochralski method, a single crystal is pulled from a melt of the appropriate material, whereas in the float-zone method, a small region in a rod of polycrystalline material is melted, then resolidified (Ghandi, 1983). A problem with applying these methods to refractory-metal silicides is that Si has a high vapor pressure at the melting point of the silicide, resulting in loss of Si and the formation of metal-rich silicide phases (Lograsso, 1992). Crystal growth is performed in an inert ambient to minimize the concentration of oxygen or nitrogen impurities in the melt. A problem with applying the Czochralski technique to silicides is that there is no crucible material that can contain liquid metal silicides without contaminating them. This problem can be overcome by using an rf-levitated melt, and has been used to grow single crystals of $TiSi_2$, VSi_2, $CrSi_2$, $NbSi_2$, $MoSi_2$, $TaSi_2$, WSi_2, and Pd_2Si (Nava *et al.*, 1993). The floating-zone technique produces purer crystals than the Czochralski technique because no crucible is required, and has been used to grow single crystals of of $TiSi_2$, VSi_2, $CrSi_2$, $CoSi_2$, $MoSi_2$, α-$FeSi_2$, and V_3Si (Nava *et al.*, 1993).

2.7 Sintering

Sintering is often used to form high-temperature structural materials, including silicides and silicide composites (Table 8). Sintering is generally used when melt growth is not practical, because of the high melting point of the materials, or for composites, where a two- (or more-) phase structure is desired. Sintering is a process where particles are pressed into a die that has the shape of the desired part. The compact is then heated at a high enough temperature so that the particles bond together, with the driving force being the reduction in surface energy of the particles (Barrett *et al.*, 1973; Kingery *et al.*, 1976). Although most of the porosity of the original powder is eliminated, some porosity often remains. Some special types of sintering that have been applied to silicides include hot pressing or hot isostatic pressing, where the compact is sintered under high pressure and high temperature, and reaction sintering, where reactive powders (such as a metal and SiC) are mixed and then annealed.

Oxygen contamination must be minimized during the sintering of $MoSi_2$, because the presence of an SiO_2 phase at grain boundaries in the silicide reduces the high-temperature strength (see Sec. 1.3.1). Hence, sintering must

Table 8. Formation of structural silicides. The table includes the powders used, the method (HIP = hot isostatic pressing), the maximum annealing temperature, the density (% of theoretical density), and the reference.

take place in an oxygen-free ambient, such as Ar. In addition, the starting powders must be free of oxygen contamination. This can be achieved by mixing powders in an oxygen-free environment (Schwarz *et al.*, 1992).

Reaction sintering (also referred to as solid-state displacement reactions) uses diffusional phase transformations to react two or more elements or compounds to form new compounds that are more thermodynamically stable (Hanager *et al.*, 1992). Interwoven or dispersed microstructures can be fabricated with this method, making it especially useful for making composites.

2.8 Plasma Spray Deposition

Plasma spray deposition can be used to deposit large thicknesses of materials (>30 μm) on a substrate, and has been used to form silicides and silicide composites for structural materials (Table 8). Plasma spray deposition uses a thermal plasma (plasma flame) formed by an electric arc. A powder of the material to be deposited is fed into the flame in a carrier gas (typically Ar). The injected powder accelerates, melts, and is carried to the substrate, where it solidifies rapidly, forming a thick coating (Herman, 1988). Some of the advantages of using plasma spraying for silicides include dense, oxide-free deposits, small grain size, and the possibility of making laminated composites (Tiwari *et al.*, 1992; Castro *et al.*, 1992; Alman *et al.*, 1992).

3. APPLICATIONS

3.1 Microelectronics

3.1.1 MOS Technology Most Si integrated circuits are fabricated by use of complementary metal–oxide–semiconductor (CMOS) technology. The advantages of CMOS technology compared with bipolar technology are lower power consumption, higher circuit densities, and lower manufacturing costs (Ning, 1992; Masaki, 1992).

Silicides are often used on the gates and diffusions of MOS transistors to reduce the series resistance of the device, and hence increase the circuit speed. In memory chips such as dynamic random-access memories (DRAMs), silicides are mainly used on the word lines (gates) and bit lines (first interconnect level) (Fig. 36) (Winnerl, 1994). For these devices, there is little performance gained by using silicides on diffusions since the series resistance of the device is usually dominated by the contact to the storage node. In addition, silicides on the diffusions increase cost and potentially

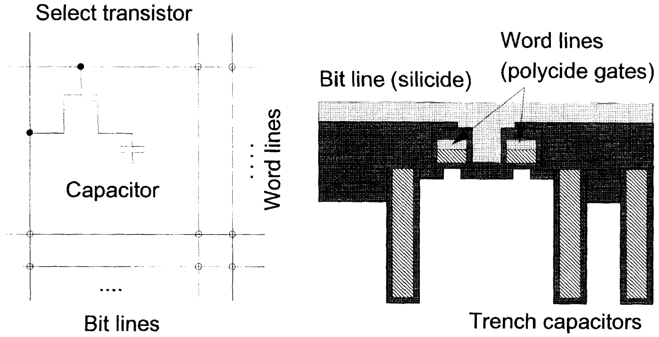

FIG. 36. Schematic of DRAM with silicide on word lines and bit lines (reprinted from Gambino and Colgan, 1998, copyright 1998, with permission from Elsevier Science.)

could decrease yield (through junction leakage associated with metal contamination). Polycides are generally used on the gates because there is a large gain in performance (gates run along the length of the array and so low resistance is required to minimize the *RC* delay) and there is less extra processing compared with a salicide process. In addition, polycide structures can be easily capped with an insulator such as Si_3N_4, which is useful for fabricating borderless contacts (a 30–40% increase in density can be achieved by using contacts that are borderless to gates and isolation; see Gambino *et al.*, 1995). Polycides are often used for bit lines as well, with the polycrystalline Si underlayer serving to act as a contact to diffusions. If lower resistance is required, a W bit line could be used instead of a polycide, with either polycrystalline Si or W studs as contacts to gates and diffusions. The most commonly used silicide in polycide structures is WSi_2, because it has good high temperature stability, is relatively easy to pattern by RIE, and can be deposited by either PVD or CVD.

In logic chips, silicides are often used on source/drain junctions as well as gates and local interconnects (Fig. 37). The improvement in performance is great enough to justify the extra cost and yield loss. In addition, contacts that are borderless to gates are seldom used in logic devices, and so insulator-capped polycide structures are not required. Silicided local interconnects can be fabricated at the same time as the gate and source/drain silicides. Alternatively, W local interconnects can be fabricated along with W studs for contacts. For logic applications, the silicide is usually formed by a salicide process using $TiSi_2$. $TiSi_2$ has a number of advantages compared with other silicides, including low resistivity, relatively high thermal stability, and relatively low sensitivity to interfacial contamination (because Ti reduces native oxides).

As with DRAMs, the switching speed of the device is increased by lowering the resistance of the gates (Fig. 38). The silicide on the source/drain junctions increases the drive current of the MOS transistor (Fig. 39). The silicide reduces the voltage drop at the source end of the device, which increases the effective applied gate potential. The reduced voltage drop is mainly the result of a reduction in the effective contact resistance, due to an increase in the contact area (Ng and Lynch, 1987). The low sheet resistance of the silicide is important for devices that have long lengths of diffusions and for wide devices that have a low channel resistance (Osburn *et al.*, 1991). Silicides can

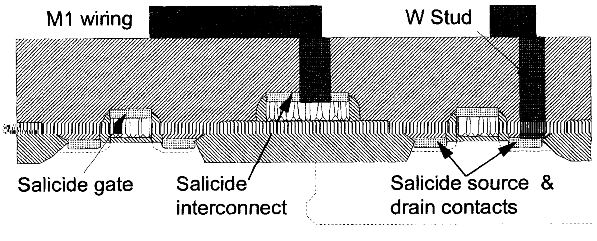

FIG. 37. Schematic of logic device showing silicides on gates and diffusions (reprinted from Gambino and Colgan, 1998, copyright 1998, with permission from Elsevier Science.)

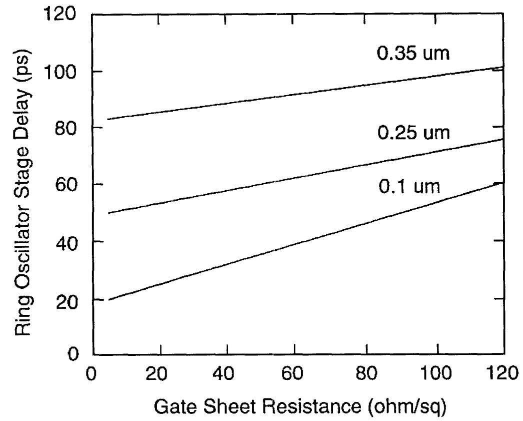

FIG. 38. Performance of ring oscillator as a function of gate resistance (reprinted with permission from Mann *et al.*, 1995).

also be used to increase the packing density of devices. For example, butting n^+ and p^+ diffusions can be connected by a silicide rather than the first metal level. The area of the diffusions can be reduced, since an extra contact hole can be eliminated.

Although silicides can enhance device performance, they can also degrade yield. Junction leakage can be increased (Osburn, 1990; Maex, 1993; Nauka *et al.*, 1986), and gate-oxide breakdown voltage decreased (Koburger *et al.*, 1982; Gambino *et al.*, 1992; Tanielian *et al.*, 1985), if too much Si or polycrystalline Si is consumed in the junctions or the gates, respectively. Interface state densities can be increased by rapid thermal anneals (Hsieh *et al.*, 1993; Liu *et al.*, 1995) used to form silicides or due to gettering of hydrogen (Chang and Chiu, 1989; Hirade *et al.*, 1995) by Ti during post-metallization anneals. Dopant depletion or counterdoping can occur during high-temperature anneals after silicide formation, resulting in high contact resistance (Scott *et al.*, 1987; Chittipeddi *et al.*, 1993) or threshold-voltage shifts (Matsuoka *et al.*, 1994; Hillenius *et al.*, 1986). Finally, excessive lateral silicide formation in a salicide process can cause leakage between junctions and gates.

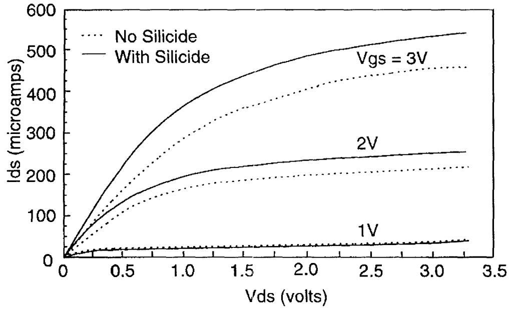

FIG. 39. Device characteristics with and without silicide on source/drain junctions (reprinted from Osburn *et al.*, 1991, copyright 1991, with permission from Elsevier Science).

3.1.2 Bipolar Technology The main use of silicides in bipolar transistors is as Schottky diodes. There have also been proposals to use silicides on base contacts (Fig. 40) or collector contacts, but these processes are not currently used in manufacturing (Shiba *et al.*, 1996; Yallup *et al.*, 1995).

Schottky diodes are used as clamping diodes between the base and collector to prevent excess minority-carrier charge storage that would limit switching speed (Sze, 1981; Tada and Laraya, 1967). PtSi is the most commonly used silicide for bipolar transistors (Li *et al.*, 1987), on account of a high barrier height and ease of patterning by a salicide process. Some problems associated with PtSi formation on bipolar transistors are incomplete silicide formation (Moy *et al.*, 1988), because Pt does not reduce native oxides, and nonuniform reactions between Pt and polycrystalline Si, which can cause junction leakage (Gambino *et al.*, 1989).

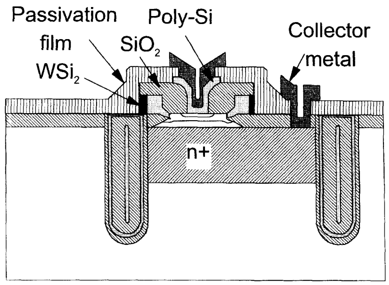

FIG. 40. Schematic of bipolar transistor with silicide on base contact to reduce series resistance (reprinted with permission from Shiba *et al.*, 1996, © 1996 IEEE).

3.1.3 Infrared Detectors Another application for silicide Schottky diodes is as infrared detectors (Kimata and Tubouchi, 1995). Schottky diodes have a number of advantages compared with other infrared detectors, including monolithic construction using standard Si processing and high uniformity. The silicides for Schottky diodes are formed by a salicide process.

The operation of Schottky-diode photodetectors is based on internal photoemission (Kimata and Toubouchi, 1995; Jimenez, 1996). In the first step (Fig. 41), incident photons are absorbed in the silicide and generate electron–hole pairs. Some of the photoexcited holes are then emitted over the Schottky barrier, becoming detected carriers. Hence, the Schottky barrier height defines a minimum energy or cutoff wavelength for detection. Because the energy of infrared radiation in the atmospheric window is in the range of 0.1–0.4 eV, a low Schottky-barrier height is required; this can be most easily achieved on p-type Si.

The quantum efficiency of Schottky-diode infrared detectors depends on the photon energy, because of the strong dependence of photoemission on the energy of the excited holes (Kimata and Tubouchi, 1995). The quantum efficiency η is given by

$$\eta = C_1(h\nu - \phi_B)^2/h\nu \tag{10}$$

where C_1 is the quantum efficiency coefficient, h is Planck's constant, ν is the wavelength of the incident radiation, and ϕ_B is the barrier height. Hence, the Schottky-barrier detector has no response to photons with energy lower than the barrier height.

There are five silicides used for Schottky-barrier infrared detectors: Pd_2Si, PtSi, IrSi, Co_2Si, and NiSi (Table 9 and Fig. 42). PtSi on *p*-type Si is most commonly used, on account of a spectral response to radiation in the range 3–5 μm. IrSi on *p*-type Si is expected to have the lowest barrier height, and therefore should be able to detect radiation at the longest wavelengths (8.2 μm).

Table 9. Properties of silicides used in infrared detectors (from Kimata and Tubouchi, 1995).

Silicide	Silicon	Barrier height (eV)	Cutoff wavelength (μm)
Pd_2Si	*n*-type	0.6	1–2
$CoSi_2$	*p*-type	0.44	2.8
NiSi	*p*-type	0.40	3.1
Pd_2Si	*p*-type	0.34	3.5
PtSi	*p*-type	0.22	6
IrSi	*p*-type	0.152	8.2

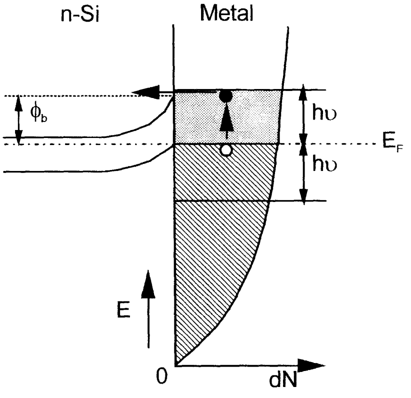

FIG. 41. Schematic of internal photoemission in a Schottky-barrier infrared detector (used with permission from Kimata and Tubouchi, 1995).

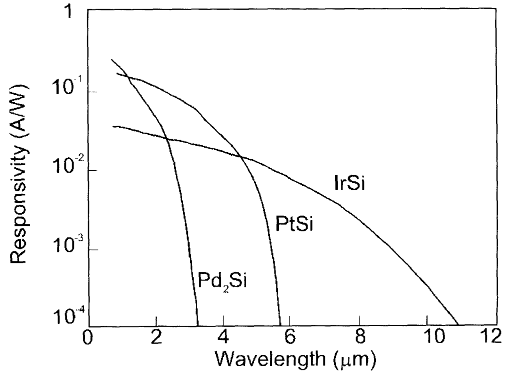

FIG. 42. Plot of $(\eta h\nu)^{1/2}$ *versus* $h\nu$ for a Schottky-barrier infrared detector. The gradient of the plot gives the square root of the quantum efficiency while the intersection with the *x* axis gives the barrier height (used with permission from Kimata and Tubouchi, 1995).

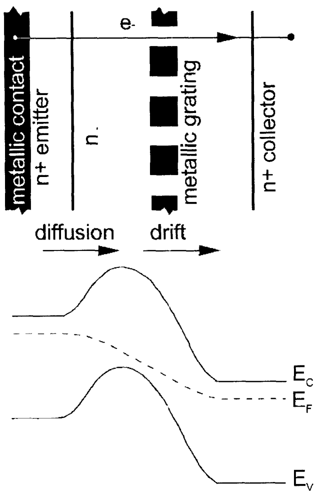

FIG. 43. Schematic cross section of permeable-base transistor with corresponding energy diagram (from Reader *et al.*, 1992).

3.1.4 Permeable-Base Transistors In permeable-base transistors (Reader *et al.*, 1992), a metal grid is used to modulate current flow from an emitter to a collector (Fig. 43). The metal grid is embedded in an n region, resulting in a Schottky diode and a depletion layer around the metal. The extension of the Schottky diode is controlled by the voltage on the metal grid, which in turn controls the flow of carriers through the grid.

There are a number of advantages of permeable-base transistors compared with bipolar or MOS transistors. The main advantage is that the width of the control electrode is determined by the thickness of the metal layer, rather than by lithography (as is the case in MOS transistors), so that the transit time for charge carriers can be very fast, resulting in high switching speeds. The main problem with this device is the difficulty of fabricating buried silicide layers in defect-free Si. Defects in the Si associated with the buried silicide can cause high leakage currents. Because of these problems, permeable-base transistors are still in the development stage and are not being manufactured.

3.2 Structural Materials

Silicides are being considered for a number of applications as structural materials in the aerospace and automotive industries. Aerospace applications include aircraft-engine turbine components, such as blades, vanes, combustors, nozzles, and seals. Automotive applications include turbocharger rotors, valves, glow plugs, and advanced turbine engine parts (Petrovic, 1993).

Structural materials can be broadly classified into two groups of applications, depending on the use temperature. For applications in the range of 800–1000 °C, nickel-based superalloys are being used. Above 1000 °C, silicon-based ceramics are being considered, because of their excellent oxidation resistance and low density. However, these materials are brittle over the entire temperature range, and the cost of fabrication is high. Hence alternative materials are being investigated for high-temperature structural materials, including silicides (Vasudevan and Petrovic, 1992). The use of high-temperature materials can provide a number of advantages, including minimized air cooling, fewer engine parts, and higher operating temperatures (which can improve fuel efficiency).

Silicides have a number of advantages compared with other structural materials, including higher melting points and lower densities compared with other intermetallics, and lower costs and greater ductility (at high tempertures) compared with Si-based ceramics. In addition, silicides can be alloyed with other materials such as SiC or other silicides, to improve their properties. This is important because the mechanical properties of the silicides by themselves are inadequate for these applications; improvements are required in the high-temperature strength and creep resistance, and in the low-temperature fracture toughness. Composite reinforcement of a silicide matrix can significantly improve these mechanical properties (see Figs. 19–21). These composites can be fabricated using a wide variety of techniques (Table 8), including melt casting and sintering.

Composites are classified into the following categories based on the morphologies, orientations, and distributions of the strengthening or toughening components in the intermetallic (silicide) matrix: discontinuous reinforcements, continuous reinforcements, and hybrids (Miracle and Mendiratta, 1994). In discontinuous composites, an intermetallic matrix contains particulates, whiskers, or chopped fibers, such as SiC whiskers, in an $MoSi_2$ matrix. At high temperatures, where there is significant plasticity of the silicide matrix, the morphology and aspect ratio of the discontinuous reinforcements strongly influences the strength and creep resistance of the composite; needle-like reinforcements with a high aspect ratio provide the greatest strengthening and toughening. Continuous composites contain continuous fibers or filaments, typically distributed in a uniaxial direction in a silicide matrix. Fibers with high strength and stiffness enhance the strength and creep resistance of the silicide. Since the mechanical properties are highly anisotropic, applications as structural materials are limited to components where transverse properties are not critical (*e.g.*, turbine blades, ring components, and structural rods). Both refractory-metal and ceramic fibers have been used to reinforce $MoSi_2$ (Maloney and Hecht, 1992). The refractory-metal fibers are ductile, and therefore increase the damage tolerance of the brittle silicide matrix. Although the ceramic fibers are brittle, the composite can have improved fracture toughness if there is a weak fiber–matrix interface; a weak interface when present in the path of a crack will debond locally and blunt the crack (Shaw *et al.*, 1995). Hybrid composites incorporate multiple types of reinforcement, designed to enhance specific mechanical properties. For example, continuous uniaxial fibers may primarily enhance high-temperature strength and creep resistance, whereas a dispersion of whiskers in the matrix may enhance toughness and transverse mechanical properties.

There are a number of other considerations in the fabrication of composites (Maloney and Hecht, 1992). The thermal expansion coefficient must be closely matched between the fiber and the matrix, in order to minimize thermal stress. For $MoSi_2$, sapphire fibers are closest in terms of thermal expansion coefficient, whereas SiC is significantly lower. This problem can be alleviated by adding a phase with a low thermal expansion coefficient to the silicide matrix (such as SiC platelets or particles). Another consideration when using refractory metal fibers is the reactivity of the metal with the silicide. Minimal reactivity is desirable, so that the refractory metal remains a metal, rather than being converted into a (brittle) silicide. For $MoSi_2$, Ta exhibits the lowest reactivity compared with other refractory metals.

3.3 Oxidation-Resistant Coatings

Silicides have been used as oxidation-resistant coatings on a number of materials, including Ni-based alloys, steels, and refractory metals and alloys (Kumar, 1994). The SiO_2 layers that grow on silicides in oxygen ambients show a low permeation rate to oxygen compared with other materials, especially above 1500 °C. The SiO_2 layers are also stable in the alkaline sulfates that are often found in gas turbines. More recently, silicides have been examined as coatings to protect Ni-based superalloys from carburization in high-temperature reactors (Singheiser *et al.*, 1982).

Silicides that are used as coatings must be "matched" to the underlying substrate, to prevent degradation by cracking, spalling, or interdiffusion. The brittleness of silicides and the thermal expansion mismatch between the coating and the substrate can lead to cracking and spalling during thermal cycling. Alloying can be used to adjust the thermal expansion mismatch of the protective SiO_2 layer, and hence reduce cracking. B_2O_3 or GeO_2 additions to the coating not only decrease the thermal expansion mismatch but also decrease the viscosity of the SiO_2 layer, making it more resistant to cracking. Interdiffusion between the substrate and the coating can alter the protective properties of the coating, by depleting Si from the silicide. Metal-rich silicides generally oxidize much faster than silicon-rich silicides, resulting in a less effective coating (Kircher and Courtright, 1992). Interdiffusion can be controlled by using an appropriate diffusion barrier between the substrate and the coating; for example, a TiC diffusion barrier can be used between a graphite substrate and an $MoSi_2$ coating (Grunling and Bauer, 1982).

Most of the applications for silicide coatings involve protecting the underlying material from oxidation. Some examples include Ni–Cr silicide coatings on Ni-based superalloys, Cr–Ti silicide coatings on Nb-based alloys, and $MoSi_2$ coatings on refractory metals. Silicide coatings have been fabricated with a wide variety of methods, including PVD, CVD, plasma spray deposition, or diffusion reactions (pack coating) (Nicholls and Stephenson, 1994).

3.4 Thermoelectric Materials

One of the earliest applications for silicides was as heating elements in high-temperature furnaces (Kumar, 1994). More recently, semiconducting silicides have been investigated as thermoelectric devices, for converting heat into electricity (Verdnikov, 1994).

Furnace elements made from silicides consist of $MoSi_2$ with about 20 vol% of a glassy phase. $MoSi_2$ has a number of advantages as a heating element compared with other materials. First, the resistivity of $MoSi_2$ increases with temperature; if a new batch of material is introduced into the furnace (causing the temperature to drop), the power output of the heating elements rises rapidly and automatically compensates. In addition, the heating elements will accept high power loads so that large amounts of power can be concentrated in a small area. Finally, a protective SiO_2 coating forms on the silicide, resulting in a long life span for the heating elements, even in oxidizing ambients.

Thermoelectric devices convert heat into electricity, and are often used in deep-space vehicles with a radioactive heat source. At present, these devices are made from SiGe alloys. However, several semiconducting silicides are promising as thermoelectric devices. The themoelectric figure of merit for $MnSi_{1.7}$ is comparable to that for SiGe alloys, and calculations suggest that the figure of merit for Ru_2Si_3 may be higher than that for SiGe alloys (Vedernikov, 1994; Vining, 1992).

3.5 Magnetic Materials

There have been two different approaches to using silicides as magnetic materials. One approach is to add Si to an Fe-based alloy to improve the wear resistance and corrosion resistance of the alloy. Ternary Fe-Al-Si alloys are an example of this approach, and have been used in magnetic heads (Kumar, 1994). The other approach is to use Si-stabilized Fe-based compounds for permanent magnets (see Sec. 1.3.4). These materials have not yet been used commercially.

3.6 Optical Materials

Silicides have been used as optical materials in attenuated phase-shift masks. Phase-shift masks are used to improve the resolution of optical lithography during fabrication of integrated circuits. An attenuated phase-shift mask allows some transmission of light through the "opaque" regions of the mask, thereby changing the phase and improving the resolution of the image (Hashimoto *et al.*, 1994). Recently, MoSi alloys have been used as the "opaque" material in attentuated phase-shift masks, instead of Cr. The MoSi alloys are easier to pattern than Cr, thus making it easier to fabricate defect-free masks (Jonckheere *et al.*, 1994).

4. SUMMARY

This article has reviewed the properties, processing, and applications of silicides. The combination of high thermal stability, high mechanical hardness, and low electrical resistivity has made the use of silicides attractive for a wide range of applications. Already, there is widespread use of silicides in the microelectronics industry. With continued studies on these materials, it is likely that silicides will also be used in other applications such as structural materials.

There are many areas of study that could be useful in terms of improving these materials. A better understanding of the atomic and electronic structures of interfaces between silicides and semiconductors could be useful for microelectronics applications. Much has been learned about metal–Si reactions, but further work is required to understand the effects of nucleation, impurities, and grain boundaries on these reactions. More work is needed to understand reactions between metals and Si compounds, for both microelectronics and structural materials applications. More details on the surface and interface energies would be useful in understanding the thermal stability of silicide thin films. Information on the effect of defects on oxidation of silicides could be used to improve the properties of silicide coatings. Detailed studies of the phase equilibria between dopants and silicides could be useful for creating new structural materials. Much information is still needed to understand the etching and passivation reactions for silicides in aqueous solutions. Additional studies are needed on the basic mechanical properties of silicides, as well as processes for improving these properties. More work is also needed to improve the electrical properties of silicide thin films used in microelectronics applications. The initial work on the optical and magnetic properties of silicides shows that there may be new opportunities to use silicides for these applications.

Because of the many potential applications, there are likely to be many new studies on silicides in the coming years.

ACKNOWLEDGEMENT

The authors thank F. M. d'Heurle and J. M. E. Harper for helpful discussions.

GLOSSARY

Agglomeration: The breaking up of a thin film on a substrate into islands, due to a reduction in surface and interface energies.

Burgers Vector: The unit slip distance for the dislocation, parallel to the direction of slip.

Composite: A polyphase material with a large fraction of a minor phase (generally at least 10%).

CVD: Chemical vapor deposition.

DRAM: Dynamic random-access memory.

Electron Affinity: The energy released when an electron is attached to an atom or molecule.

Epitaxy: Growth of a thin layer of material with the same orientation and crystal structure as the underlying single crystal substrate.

Eutectic: A solid solution of two or more components (eutectic composition), having the lowest freezing point (eutectic temperature) of all possible mixtures of the components.

Ferromagnetic: Materials that have a permanent magnetic field even in the absence of an applied field.

Fracture Toughness: Work expended at a crack tip during crack propagation.

Fermi Level: The energy at which the probability of finding an electron in an energy band in a solid is 1/2.

MBE: Molecular beam epitaxy.

MOS Transistor: Metal–oxide–semiconductor transistor.

Nucleation: The initial formation of a new phase within a material or at an interface or surface.

Phase: A homogeneous, physically distinct, and mechanically separable portion of a material with a given chemical composition and structure.

Phase Diagram: A phase equlibria diagram between two or more components (binary = two components, ternary = three components) at a constant pressure, with temperature and composition as variables.

Phonons: Lattice vibrations in a crystal.

Photoemission: Emission of electrons as a result of bombardment by photons.

Polycide: A self-aligned silicide process used in microelectronics applications, where the silicide is deposited on a polycrystalline Si gate stack and patterned by RIE.

PVD: Physical vapor deposition, such as evaporation or sputtering.

Raman Scattering: A scattering effect where the scattered light differs in wavelength from the incident light.

Refractory Materials: Materials that have a high melting point (>1538 °C, the melting point of iron).

RIE: Reactive ion etching; a directional dry etching method used in microelectronics processes.

Salicide: A self-aligned silicide process used in microelectronics applications, where the silicide is formed selectively on Si using a metal–Si reaction and a selective etch.

Schottky Barrier: Potential barrier for electronic carriers at a metal–semiconductor or metal–insulator interface.

Sintering: Compression of particles into a solid body using heat and pressure, at a temperature below the melting point of the solid.

Slip Plane: The plane on which a dislocation moves. A slip system describes all the different slip planes in a given crystal structure.

Thermoelectric Effect: The generation of electrical currents in a material due to a temperature gradient in the material. Also, the production or absorption of heat when electronic carriers are forced across a temperature gradient in a material.

Threshold Voltage: The voltage that must be applied to the gate of an MOS transistor to "turn on" the transistor.

Transition Metals: The metals between II and III in the periodic table; the subgroups starting with Sc and ending with Zn.

Work Function: The difference in energy between the Fermi level of a solid and the vacuum energy.

Yield Strength: The minimum stress that must be applied to induce plastic deformation in a material.

INTRODUCTION

Silicon is the second most abundant element in the Earth's crust. One can argue that in fact it is the second most important element in today's technological world, just after carbon, which is the essential ingredient of life. This is because microelectronics relies almost exclusively on silicon to make the chips that are the soul of every microprocessor and intelligent system. Silicon has taken such a leadership position in high technology and consumer electronics alike for two main reasons: it is cheap and abundant, and its oxide can be prepared with excellent properties.

The wafers that are used in microelectronics are made of bulk, crystalline silicon (c-Si). The properties of this form of silicon have been extensively investigated for more than 40 years and, as a result, are well known. But there are many other forms of silicon. Polycrystalline and microcrystalline silicon films are made of crystalline silicon grains with sizes ranging from ≈1 μm to a few nanometers. They are routinely prepared by a variety of techniques such as chemical vapor deposition or laser recrystallization of yet another form of silicon, called amorphous silicon. The boundaries between the grains, which act as a source of traps and scattering centers, control many of the electrical properties. Amorphous silicon is a form of silicon that lacks long-range order but maintains the local tetrahedral coordination. Amorphous silicon itself is useless as an electronic material because it contains a huge density of traps, called dangling bonds. These dangling bonds can be passivated by hydrogen, which removes them from the band-gap region. Thus alloying amorphous silicon with several atomic percent of hydrogen makes it useful for photovoltaics, for example. Silicon is also present in a large variety of polymeric and organic compounds.

unique properties, distinct from those of crystalline, microcrystalline, or amorphous silicon. It was first prepared in 1956, but its true nature was not understood until more than one decade later. The most common preparation procedure consists of etching a silicon wafer in an electrochemical cell in the presence of HF. Under the appropriate conditions, a large density of pores is produced on the surface of the wafer, which is used as the anode. These pores, which can vary in size from ≈ 1 nm to >1 μm, can run straight perpendicular to the wafer surface or form a complex mesh of interconnected pores. They can penetrate tens of micrometers below the wafer surface. The silicon material left between the pores usually retains its crystalline nature and is made of structures whose sizes can vary from ≈ 1 nm to >1 μm.

It is clear that porous silicon can be prepared with a wide range of properties, which makes it a very versatile material. All forms of porous silicon share a very large internal surface area, which can be as large as an Olympic stadium per gram of material. Thus, most properties of porous silicon are affected not only by its crystalline core but also by its surface properties. In addition, the properties of the crystalline core may differ from those of bulk c-Si when the size of the silicon structures drops below 10 nm, a size regime in which quantum mechanical effects modify its electronic states.

Although porous silicon has been studied and used for more than 40 years, it is only starting in 1990 that it attracted a lot of attention. This interest was triggered by the discovery that appropriately prepared porous silicon can emit bright visible light that can be tuned from the near infrared throughout most of the visible spectrum. Since bulk crystalline Si has an indirect band gap near 1.1 eV (or 1.1 μm), both the brightness and the color range were unexpected. For the first time, silicon light emitters appeared possible. Since then, we have learned much about the properties of this unusual form of silicon. This article reviews our understanding of many of its properties. It starts with a discussion of the preparation conditions and the post-preparation treatments that stabilize its properties. The article then moves to a review of many of its properties. Its optical properties are highlighted, since they are responsible for most of the interest in porous silicon since 1990. Finally, several applications of porous silicon are discussed, in the areas of light-emitting devices, solar cells, integrated optics, sensors, micromachining, and biomedicine.

1. PREPARATION/MATERIALS SCIENCE

1.1 Electrochemistry: Electropolishing and Porous-Silicon Formation

Porous silicon (PSi) is a form of silicon that is produced chemically or electrochemically. The electrochemical route is more flexible, in the sense that it leads to a wider range of porosities, thicknesses, *etc.* PSi is prepared by anodic etching of silicon in a solution containing HF. It was first made in 1956 (Uhlir, 1956) and later recognized as etched silicon, as opposed to a deposit on the silicon wafer. In the electrochemical cell, the anode is the silicon wafer and the cathode is a platinum wire. When a constant current is passed between the electrodes, one can distinguish three regions in the curve of current (I) *versus* polarity (V) (Fig. 1). In reverse bias, I is zero and the dissolution rate of the silicon wafer is very slow. In forward bias, at low I, the I-V curve is reminiscent of a diode; this is the region where PSi is formed. As V is increased further, a region of instability is entered, beyond which the increase of I with V becomes minimal; this is the regime of electropolishing. In this regime, the Si is dissolved layer by layer, whereas in the PSi regime, pores of different sizes, depending on several parameters, are produced (Smith and Collins, 1992). There is a

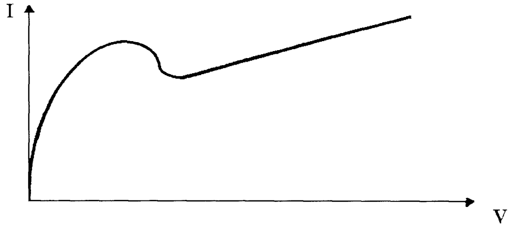

FIG. 1. Current–voltage relationship corresponding to the anodic oxidation of a p-type Si wafer in HF.

critical current density below which PSi is formed and above which electropolishing takes place. This demarcation exists because the formation of pores requires that the transport of holes from the bulk to the surface be the limiting step.

It is also possible to produce PSi starting from an *n*-type Si wafer. In this case, there are two interesting regimes in the *I*-*V* curve. In forward bias, *I* increases as in a diode and PSi can be formed. In reverse bias, no current flows except when the liquid/semiconductor interface is flooded by light. In this case, the *I*-*V* curve resembles that for *p*-type Si, except with an offset near 0 V. Note that porous silicon can also be prepared starting from polycrystalline, microcrystalline, or even heavily doped amorphous silicon. In addition, several other semiconductors have been made porous electrochemically.

The pore morphology and achievable porosities are strongly dependent on the current density, the HF concentration, the use of light during anodization, and the substrate type and doping density. Additionally, they are influenced by the *p*H of the solution, the use of alcohol in the solution, and other parameters such as the temperature. As the porosity increases,

1. the pores lose their directionality and the structure acquires a spongy character, and
2. the average size of the silicon skeleton decreases to a few nanometers.

The terminology used to described PSi has traditionally focused on the pore size (Table 1). This classification is convenient when the pores are of interest, but less useful for studies of the properties of electrons and holes in the silicon material left between the pores (Fauchet, 1997). Since Canham's work in 1990 (Canham, 1990), most of the interest in PSi has come from its strong, visible luminescence. Luminescence has been associated with the presence of silicon wires or nanocrystallites with typical dimensions in the nanometer size. Thus, a new term has been introduced, nanoporous silicon. Here, the prefix nano is used to describe the size of the Si objects. The porosity and the nanocrystallite size can be correlated for various types of samples. Because PSi is a very complex material, which can contain either Si wires or Si dots or even both types of structure simultaneously, the words nanocrystallites, dots, wires, and columns will be considered interchangeable. In a given section, one word will be preferred if this choice helps conveys the concept under examination.

Table 1. Traditional porous silicon classification.

Classification	Diameter of pores (nm)	Surface area ($m^2\,cm^{-3}$)
Macro	>50	10–100
Meso	2–50	100–300
Micro	≤ 2	300–800

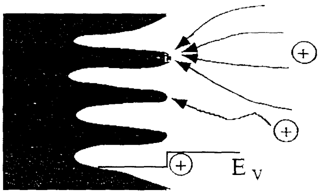

FIG. 2. Three mechanisms promote the formation of pores. From top to bottom, they are the concentration of the electric field lines at the pore's tip; random walk, which makes it easier for the holes to reach the pore's tip; and the potential barrier to hole transport from the bulk to the Si column's tip due to quantum confinement.

The pore initiation and growth mechanisms are qualitatively understood. Pore growth can be explained by several models, each one of which is more relevant for a specific regime of porosity and pore size (Smith and Collins, 1992). Assume first that shortly after anodic etching has started, the silicon/electrolyte interface has become irregular (Fig. 2). The key question is whether the fluctuations of the Si/electrolyte interface will grow (PSi formation) or disappear (electropolishing). Si etching requires the injection of holes from the substrate. A depletion region is formed in the thin PSi layer itself and also in a region of the Si wafer near the PSi/c-Si interface. In forward bias, the holes can still reach the Si/electrolyte interface by one of two mechanisms. First, the electric field lines are focused at the pore's tip. Thus, holes will preferentially reach the Si/electrolyte interface deep in the pores, where etching will proceed rapidly. In contrast, no holes will reach the end of the Si rods, effectively stopping the etching there. Second, if this electrostatic effect is not strong enough, random walk of the holes toward the Si/electrolyte interface makes it more likely that they reach it at or near the pore's tip, resulting in an effect similar to the electrostatic one. Another important mechanism becomes predominant if the Si rods are narrow enough (typically less than 10 nm). In this size regime, the electronic states start to differ from those of bulk silicon. When the motion of carriers is restricted in one or more dimensions, their minimum energy can no longer be zero. As a result of this effect, which is called quantum confinement, the holes in the valence band of the Si rods are pushed to lower energy, which produces a potential barrier to hole transport from the wafer to the Si rods. The holes can no longer drift or diffuse into the Si rods and further etching stops (Lehmann *et al.*, 1992).

When the top layer of the wafer is amorphized—for example, by ion implantation at high doses—hole transport is suppressed and porous-silicon formation is inhibited. In contrast, when the wafer surface is lightly damaged—for example, by a light ion milling—a higher density of larger nanopits or nano-irregularities is produced on the surface, the electric field lines are redistributed, and porous silicon is produced at a much increased rate (Duttagupta *et al.*, 1995). When light of increasing photon energy is used during anodization, the resulting peak luminescence energy also increases. This result can be explained as follows: In the dark, the etching of the Si rods stops when their valence-band edge drops by an amount that is sufficient to present an insurmountable barrier to hole transport from the Si wafer. With light, holes continue to be generated by absorption of the incoming photons, resulting in further etching and thinning of the Si rods. The valence-band edge continues to drop and the conduction-band edge continues to increase. The band-gap energy of the Si rods, which is given by the sum of the band-gap energy of bulk Si, the drop in the valence-band edge, and the increase in the conduction-band edge, increases further. This increase in the band-gap energy should be reflected by an increase of the luminescence energy. Similar experiments performed in the electrolyte in the open-circuit configuration just after the end of anodization yield similar result and thus confirm the interpretation (Koyama and Koshida, 1993).

1.2 Other Techniques to Produce Nanocrystalline Silicon

Since the discovery that PSi can emit light efficiently in the visible range, there has been a renewed interest in the manufacture of silicon quantum dots and wires. Spark erosion (Hummel *et al.*, 1993) consists of producing an electric discharge between a silicon wafer and an electrode, either in vacuum or in the presence of a gas. The resulting Si surface is covered by pits and hills of various sizes in the micrometer to nanometer scale. Spark-processed silicon is found to be highly luminescent in the visible range. Its color depends on the processing conditions, ranging from the red to the blue.

Lithographic techniques have also been used produce nanometer-size Si pillars or wires. Optical or electron-beam lithography is first used to produce submicron features. The Si stuctures are then thinned—for example, by an anisotropic etch in KOH and/or by oxidation—until the remaining Si nanostructure is on the order of 10 nm or less. Vertical Si pillars (Nassiopoulos *et al.*, 1995) and horizontal Si wires (Zaidi *et al.*, 1995) with dimensions below 10 nm have been fabricated. In many cases, luminescence has been reported with these structures, including at least one report of electroluminescence. However, the density of the Si nanostructures is low, which severely limits the brightness.

Another interesting method to produce Si nanocrystals that emit light is to start with a microcrystalline film and then to oxidize the film such that the diameter of the Si crystallites decreases to the appropriate size (less than 5 nm) and the surface of each nanocrystallite is passivated by silicon dioxide (Tamura *et al.*, 1994). This procedure has been shown to produce films with easily detectable visible luminescence. The advantages of this technique are that it is simple and compatible with Si microelectronic technology. The highest reported efficiency to date remains more than one order of magnitude below that of a typical PSi film. In addition, the crystallite size distribution is not well controlled.

Theory predicts that it should be possible to achieve visible luminescence even if the carriers are confined in only one direction, in Si slabs. These Si slabs are very similar to the familiar quantum wells grown by molecular-beam epitaxy (MBE) or chemical vapor deposition (CVD). Si/CaF_2 films grown by MBE exhibit visible luminescence when the Si layer thickness drops below 2 nm (Vervoot *et al.*, 1995). However, the Si films are microcrystalline because the large lattice mismatch and difference in thermal expansion coefficient between Si and CaF_2 make it impossible to grow epitaxial films free of dislocations. Thus, quantum confinement probably takes place in three directions, not just one, which triples the increase in the band-gap energy. It has also been shown that amorphous silicon layers sandwiched between silicon dioxide barriers luminesce in the visible range (Lu *et al.*, 1995). Once again, there is a critical thickness of the a-Si layers above which no luminescence is detected. The maximum luminescence efficiency of these structures remains at least one order of magnitude below that of a good-quality PSi film.

Another promising technique for the production of highly luminescent Si nanostructures involves the recrystallization of an amorphous Si/SiO_2 superlattice, made of many alternating layers of amorphous Si and SiO_2 (Tsybeskov *et al.*, 1998). These recrystallized Si layers are made of identical Si crystallites whose diameter is determined by the thickness of the original Si layer. These films exhibit an external photoluminescence quantum efficiency between 0.1 and 1% and a luminescence spectrum including all the well-known phonon replicas, which coincides with that of bulk c-Si for diameters in excess of 10 nm.

Si quantum dots can be prepared by several other techniques. One example consists of implanting SiO_2 with Si and then annealing the film to form Si clusters that then recrystallize. The luminescence of these structures can be tuned throughout the visible part of the spectrum by controlling the processing steps (Petrova-Koch *et al.*, 1996). However, the control on the size of the crystallites and the crystallite packing density is limited. Another example consists of preparing clusters or crystallites in the gas phase, which are then collected on a glass plate or in a matrix (Littau *et al.*, 1993). Gas-phase synthesis of Si quantum dots, followed by gas-phase oxidation and size selection, has produced the most luminescent material to date (quantum efficiency of 50% at low temperatures). Unfortunately, the production rate of these crystallites is too low to make them technologically useful.

1.3 Post-Preparation Treatments

1.3.1 Supercritical Drying One of the major problems in the manufacture of PSi involves the removal of the etching solution from the pores after anodization. The most straightforward technique consists of letting the solution evaporate in air. This procedure can lead to the collapse of the Si rods in highly porous samples. This collapse is a consequence of the large capillary-induced tensile stresses encountered during evaporation at the vapor–liquid interface in the pores. To avoid this problem, various methods have been proposed, including the use of low–surface-tension fluids such as pentane, freeze drying, and supercritical drying, a technique well known from silica aerogels. The use of supercritical fluids as drying agents has led to the best results (Canham *et al.*, 1994). Their application requires knowledge of the phase boundary and critical point of the confined fluid in the porous material, which are usually estimated from bulk fluid properties. The phase-coexistence boundary and critical point of a confined fluid can, however, be significantly different from its bulk values.

Figure 3 shows a typical trajectory followed during supercritical drying and contrasts it to a trajectory corresponding to normal drying in air. Trajectory 1–2–3 illustrates the supercritical drying of PSi with carbon dioxide (bulk phase $T_c = 31.1\,°C$, $P_c = 73.8\,bar$). The ethanol is first replaced by liquid CO_2 for 3 h at point 1. This is followed by the conversion of liquid CO_2 into a supercritical state by raising its temperature to 40 °C during the step 1–2. Finally, the CO_2 is vented at 40 °C for a period of 3 h during step 3. Similar results are obtained if another fluid is used (for example, C_2H_4). Whereas most samples prepared without supercritical drying often break for porosities greater than 80%, PSi films of porosities greater than 95% survive intact if they are prepared by supercritical drying. This is the case even for free-standing films lifted off the Si substrate (von Behren *et al.*, 1997).

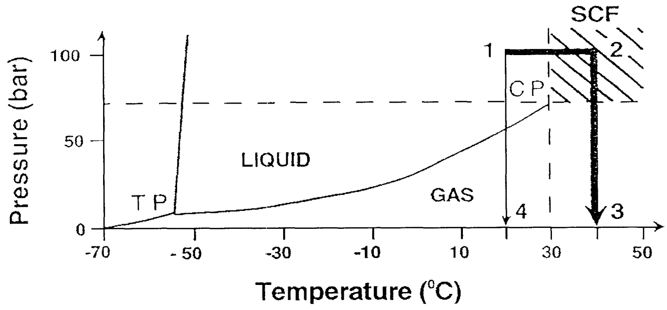

FIG. 3. Pressure–temperature diagram of bulk CO_2. Supercritical drying (trajectory 1–2–3) avoids the liquid–gas interface by converting liquid CO_2 into a supercritical fluid (SCF). Conventional drying is shown by trajectory 1–4.

1.3.2 Chemical Quenching Because of its very large internal surface, PSi is an ideal laboratory for the study of the chemistry of silicon surfaces. The surface of PSi, which is passivated by Si–H_n bonds, can be modified by chemical reactions (Sailor and Lee, 1997). The chemical compounds or molecules that become attached to the PSi surface can act as surface-state traps or sites for interfacial energy transfer and charge transfer, resulting in the quenching of the photoluminescence (PL). Reaction of PSi with iodine completely quenches the PL, on account of the production of Si–I surface traps that act as nonradiative recombination centers. This type of reaction is not fully reversible. In contrast, exposure to liquid or vapor methanol also quenches the PL, but this quenching is reversible because no net chemical reaction has taken place. Exposure to electron acceptor or donor components can also quench the PL reversibly (Rehm *et al.*, 1996), as in the case of a toluene solution of anthracene. However, if the electron acceptor (donor) state has a higher (lower) energy than the conduction- (valence-) band edge of PSi, electron (hole) transfer from PSi to the component is energetically forbidden and the PL is not quenched (*e.g.*, naphthalene). The quenching ability of a chemical species is also a function of the initial PSi surface termination. For example, reversible quenching is observed when Si–H–passivated PSi is exposed to liquid methanol. When SiO_2-passivated PSi is exposed to the same solution, no quenching is observed (Rehm *et al.*, 1995).

1.3.3 Aging and Oxidation After anodization, the internal surface of PSi is covered by silicon hydride bonds that remove any surface dangling-bond states from the band gap and thus provide excellent surface passivation. Excellent passivation is a requirement for achieving a high luminescence efficiency, since the radiative lifetime of PSi is in the microsecond to millisecond time domain because of the indirect gap of porous silicon, which is ample time for trapping in any nonradiative recombination center. Experimentally, it is observed that the PL efficiency is decreased by many factors (Collins *et al.*, 1992), including illumination with short-wavelength light, heating, exposure to various gases and liquids, and the presence of a high electric field. This PL degradation is intrinsic to the "fragile" Si–H_n bond and thus unavoidable. Hence, it is necessary to find a substitute for the Si–H bond, and the most obvious candidate is silicon dioxide. Silicon dioxide and its interface with crystalline silicon can be of very good quality, and in fact they are in large part responsible for the dominant role of silicon in microelectronics.

The stability of the luminescence efficiency of porous silicon passivated by silicon dioxide (SiO_2) has been shown to be excellent (Fauchet *et al.*, 1997). Oxide-passivated porous silicon can be prepared by different approaches: anodization at a low current density with light assistance, furnace oxidation, rapid thermal oxidation, or even aging the sample in air. A marked improvement in stability is observed when the Si–H bonds are replaced by Si–O bonds by using anodization with light assistance. After rapid thermal oxidation at 900 °C, the PL efficiency is comparable to that of Si–H–passivated PSi because the densities of dangling bonds present in as-anodized and oxidized samples are comparable. The difference is that stability of the Si/SiO_2 interface is

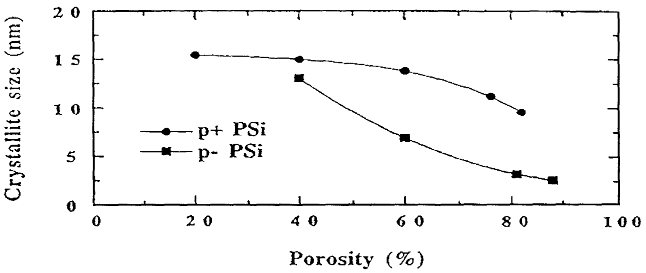

FIG. 4. The crystallite size in PSi depends on the porosity and the doping level of the starting Si wafer.

such that no additional dangling bonds are produced even under most adverse conditions. Annealing at high temperatures is necessary for forming a high-quality oxide and a high-quality Si/SiO_2 interface. To avoid the complete oxidation of the Si skeleton and the transformation of the PSi layer into a porous glass, the high-temperature oxidation is performed in an atmosphere poor in oxygen and for a short time.

2. PROPERTIES

2.1 Structural

2.1.1 X-Ray Scattering X-ray scattering from porous silicon (Lehmann *et al.*, 1993) shows that PSi simultaneously exhibits the characteristics of a monocrystalline solid (long range order) and an inhomogeneous solid (short range order) (Naudon *et al.*, 1995). The average size of the Si nanocrystallites present in PSi films can be calculated from an analysis of the x-ray lineshape by applying the Scherer equation (Cullity, 1978) to the broad peak profile. The variation of size with porosity for p^- and p^+ PSi films is plotted in Fig. 4 (Fauchet *et al.*, 1997). It should be noted that this technique is most useful when applied to samples with a single particle size. X-ray diffraction also shows that the lattice constant of PSi increases with the porosity and depends on whether the surface is covered by SiO_2 or Si–H_n. A value of the strain as large as 0.1% is possible.

2.1.2 Electron Microscopy Although techniques such as scanning-electron and atomic-force microscopies reveal some of the features of PSi, its nanostructure is best examined by transmission-electron microscopy (Berbezier, 1995; Cullis *et al.*, 1997). TEM, which is capable of a resolution down to ≈ 1 Å, has provided very detailed images of PSi. Crystallites as small as 1 nm and their lattice planes have been imaged. Scanning-electron microscopy and atomic-force microscopies do not provide the same atomic scale resolution and are better suited to the study of mesoporous and macroporous PSi.

Figure 5 shows cross-sectional TEM images of PSi prepared from a p^+ Si wafer (Beale *et al.*, 1985). In these samples, the pores are ≈ 10 nm wide and run perpendicular to the Si wafer surface (along the ⟨100⟩ direction, a general trend for all substrate orientations). For the highest porosity (79%) shown in Fig. 5, the structure becomes open, the pores are interconnected, and it is difficult to identify individual pores. In contrast, the TEM image of Fig. 6 shows that in microporous PSi formed from a p^- Si wafer, the nanostructure is coral-like or sponge-like, with characteristic dimensions on the 1–3-nm scale (Cullis *et al.*, 1992). This is the type of PSi that produces the brightest luminescence. In addition, we note that PSi can be produced with pores on two widely different length scales ($\approx$nm and sub-μm) by using light during the anodization of n^+ Si wafers.

Lattice-plane imaging shows that the crystallographic orientation of the substrate is maintained after anodization, with a trend to a small misorientation at the highest porosities. Transmission electron diffraction patterns also indicate that, in general, PSi maintains the crystalline nature of the substrate, although the presence of some disordered material has sometimes been reported.

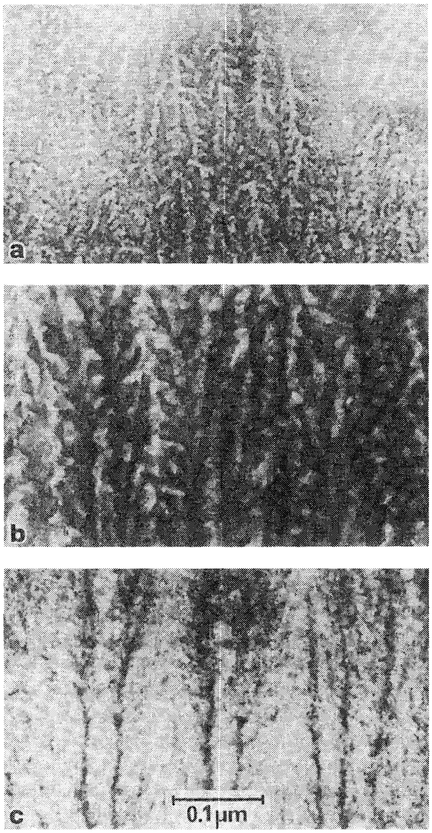

FIG. 5. Cross-sectional transmission-electron microphotographs of PSi samples prepared from a p^+ Si wafer. The porosities are 31%, 51%, and 79%, from top to bottom.

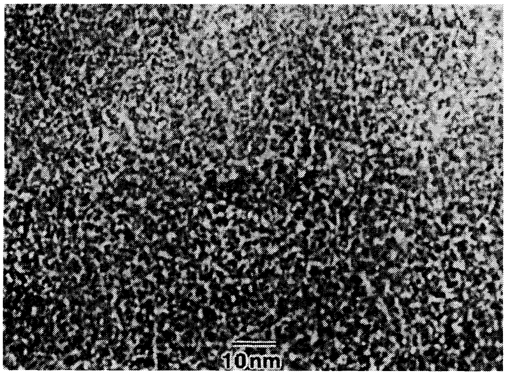

FIG. 6. Cross-sectional transmission-electron microphotographs of PSi prepared from a p^- Si wafer. The spongy structure is made of highly interconnected micropores.

2.2 Mechanical

The mechanical properties of PSi depend critically on the porosity. The open structure of high-porosity PSi makes it a very fragile material. One convenient characterization technique, which can provide useful information regarding material strength, crystallite size, and surface quality, is a hardness measurement. Hardness is defined as the resistance of a solid to plastic deformation. The method most widely used for measuring hardness is indentation. In the Vickers test, a square-based pyramidal indenter produces a diamond-shaped indent on the surface and the hardness H is related to the applied load P_L (in kg f) and the diagonal of the indent d (in mm) by

$$H = 1.8544(P_L d^{-2}) \tag{1}$$

The load dependence of hardness (indentation size effect) provides useful information regarding the nature of a material (brittle, ductile). A power law relationship exists between the applied load and the indentation diagonal:

$$P_L = K_L d^n, \tag{2}$$

where n is called the Meyer index.

Figure 7 compares the hardness of different PSi films, as a function of porosity (Duttagupta *et al.*, 1997a). The hardness of the p^+ PSi films is comparable to that of the p^- PSi films. At low porosities, there is a moderate decrease of hardness with porosity. This is expressed by the full line in Fig. 7 as $H = H_0(1-P)^m$ ($m = 0.67$), where H_0 is the hardness of crystalline Si (11.5 GPa). However, in the porosity range of 70–80%, the hardness drops appreciably and there is considerable deviation from the previous $(1-P)^{2/3}$ proportionality. This deviation indicates the change in the morphology of the films from isolated pores to isolated Si columns near that porosity. The trend of decreasing hardness with increasing porosity in confirmed by measurements of the Young's modules *versus* porosity in p^+ PSi films using nanoindentation (Bellet *et al.*, 1996).

The Meyer's index may be used to gauge the nature of a material. For Si, the value of n is 1.7 for c-Si (brittle, ordered), while that for

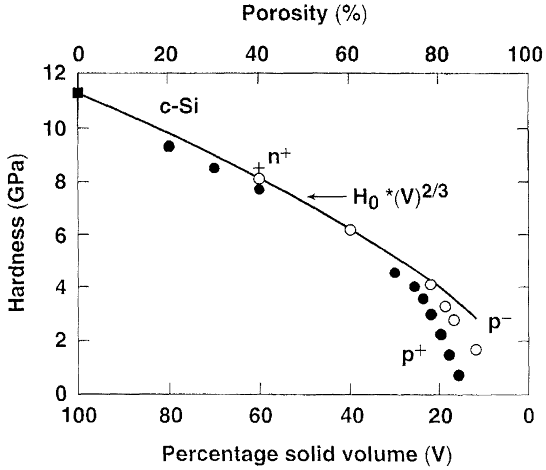

FIG. 7. The hardness of PSi depends on the porosity and the doping level of the starting Si wafer. The open circles are data from PSi prepared from p^- Si wafers, the closed circles are data from p^+ Si wafers and the cross is from n^+ Si wafers.

amorphized Si (softer, highly disordered) is 2. In PSi even at 80% porosity, $n = 1.75$ for p^- PSi and $n = 1.72$ for p^+ PSi. This is a further confirmation of the crystalline nature of porous silicon.

2.3 Thermal

The thermal conductivity of PSi depends strongly on porosity and is expected to be much below that of c-Si as the porous structure becomes less dense. At very high porosities, the preferred heat transfer could switch from conduction to radiation. The thermal conductivity of PSi has been measured by several techniques (Lang *et al.*, 1995; Duttagupta, 1997b). It depends not only on the porosity but also on the pore nanostructure (whether the material is macro-, meso-, or microporous) and on whether oxidation has been performed or not. The thermal conductivity of several PSi samples prepared from a p^+ Si wafer is shown in Fig. 8 (Duttagupta, 1997b). At high porosities, the thermal conductivity of PSi drops below that of glass.

2.4 Vibrational

The Si crystallite size in PSi films can be measured by Raman spectroscopy (Fauchet and Campbell, 1988). In unstrained bulk crystalline silicon the Si—Si peak is narrow, symmetric, and centered at 520 cm^{-1} with a full width at half maximum of approximately 4 cm^{-1}. This peak broadens, becomes asymmetric, and is downshifted with increasing porosities. In addition, a broad peak often arises around 480 cm^{-1}, which is the signature of amorphous (disordered) Si. The changes in the 520-cm^{-1} peak can be used to deduce the average crystallite size (and in some cases, its shape as well). Figure 9 shows that the crys-

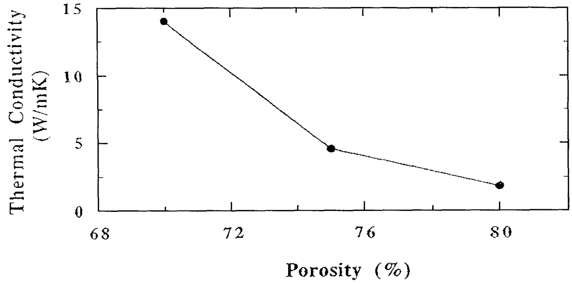

FIG. 8. The thermal conductivity of PSi decreases with increasing porosity and is much lower than that of bulk c-Si (150 W m^{-1} K^{-1}). The samples are prepared from a p^+ Si wafer.

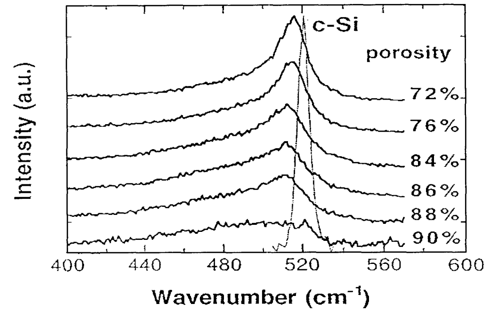

FIG. 9. Dependence of the Raman spectrum of PSi on porosity for samples prepared from a *p* Si wafer. The optic phonon Raman spectrum of bulk c-Si is shown for comparison.

tallite size decreases with increasing porosity (von Behren *et al.*, 1998). Below 25 Å, Raman spectroscopy can no longer be used as a reliable tool to measure the nanocrystal size. Additionally, stress affects the phonon line shape of nanocrystalline films, resulting in a shift of the Raman line for a uniform, homogeneous stress and a broadening of the Raman line for nonuniform, inhomogeneous stress.

2.5 Electrical

The current density (J)–voltage (V) characteristic of a simple metal/PSi/c-Si device is shown in Fig. 10 (Peng *et al.*, 1996). The J-V curve is rectifying and follows, in forward bias, a power law relationship $J = KV^m$ where $m \approx 2$. This power-law relationship is typical of a space-charge–limited current and shows that the current is dominated by carrier transport in the high-resistivity ($\approx 10^{10}\,\Omega\,\mathrm{cm}$) PSi layer. The entire device can be modeled as an insulator sandwiched between two conductors (the top metal contact and the Si substrate) with negligible band bending at the two interfaces. When the injected-carrier concentration exceeds the thermal-carrier concentration, a departure from Ohmic behavior is observed, and for double-carrier injection, the J-V relationship is given by

$$J = \varepsilon\varepsilon_0\mu_{\mathrm{eff}}V^2/d^3 \tag{3}$$

where $\varepsilon\varepsilon_0$ is the dielectric function of PSi (in $\mathrm{F\,m^{-1}}$), d is the thickness of the PSi layer, and μ_{eff} is the effective carrier mobility. The measured dependence of J on both V and d satisfies Eq. (3).

Two methods have been employed to measure the carrier mobility. In the first method, the response of the electroluminescence (EL) to a small alternating (ac) bias is measured as a function of frequency in a device held under a large forward bias (Peng and Fauchet, 1995). The injected carriers drift through the PSi layer where they recombine radiatively, and the transit time through the device (τ_t) is given by

$$\tau_t = d^2/\mu_{\mathrm{eff}}V. \tag{4}$$

When the modulation frequency of the ac bias becomes large, the electric field reverses itself in a time shorter than the transit time and the magnitude of the ac EL decreases. Figure 11 plots the 3 dB frequency f_0 (the frequency

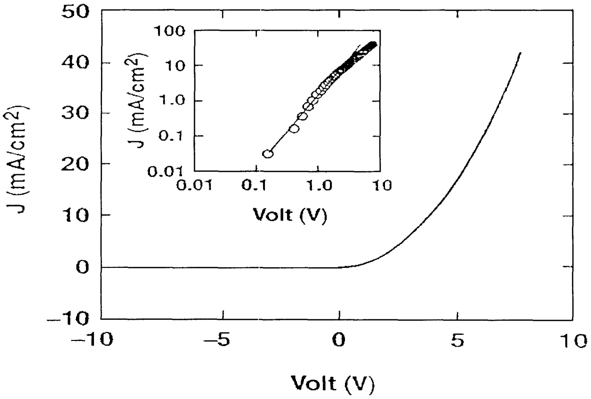

FIG. 10. Current density–voltage relation for a Au/PSi/c-Si device structure. The inset shows that the current density increases as the square of the voltage.

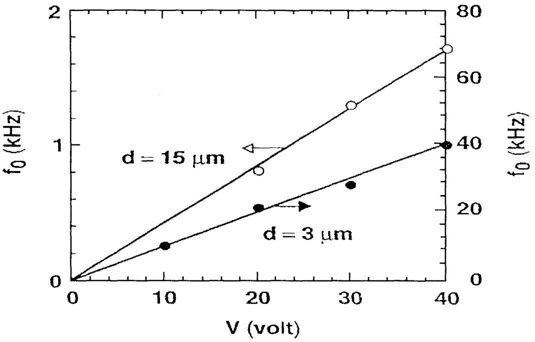

FIG. 11. The 3dB frequency of the electroluminescence response of device structures similar to that of Fig. 10 depends on the applied voltage and the thickness of the PSi layer. The solid lines are a fit using Eq. (4) and a mobility of $10^{-4}\,\mathrm{cm^2\,V^{-1}\,s^{-1}}$.

at which the magnitude of the ac EL drops by 50%) *versus* dc bias for two devices having PSi layers of 3 and 15 μm, respectively. Other measurements have confirmed that f_0 scales with d^{-2} and with V. Thus, f_0 is equal to the inverse of τ_t, and the effective mobility obtained in PSi of ≈75% porosity is $10^{-4}\,\mathrm{cm^2\,V^{-1}\,s^{-1}}$. This measurement does not indicate whether the mobility is that of the electrons, the holes, or a combination of both.

Another method to measure the mobility is the time-of-flight technique. Here, the device is held in reverse bias, and a short laser pulse injects electrons and holes on one side of the PSi layer. One type of carrier is then swept through the PSi layer under the effect of the electric field, producing a current that is detected as a function of time after injection. These experiments performed on PSi layers of ≈75% porosity and passivated by ≈2 monolayers of SiO_2 have shown that the electron drift mobility is between 10^{-4} and $10^{-5}\,\mathrm{cm^2\,V^{-1}\,s^{-1}}$ and is weakly dependent on temperature from 400 to 77 K (Rao *et al.*, 1997). Electron transport is found to be dispersive and not Gaussian. This behavior has implications for the nature of electronic transport is PSi, which have not yet been explored throroughly.

2.6 Optical: Experiments

2.6.1 Absorption/Transmission The influence of the porosity (P) on the optical properties is most easily seen in transmission experiments performed on free-standing PSi films separated from the c-Si substrate by a lift-off step. The transmission spectrum of high-quality thin films is modulated by Fabry–Pérot interference fringes in the transparency region. The transmission can reach 100%, which is indicative of high-quality films having parallel front and back surfaces and negligible light scattering. The optical transmission spectra of thicker free-standing porous silicon films of various P are shown in Fig. 12 and compared with that of c-Si (von Behren *et al.*, 1998). The absorption edge shifts by more than 1.5 eV toward the blue when the porosity increases from 0% (bulk c-Si) to 92%. Since the index of refraction is close to unity for $P \geq 80\%$ (Fauchet *et al.*, 1998), the optical thicknesses of these films are equal, and the changes in transmission with porosity are a direct proof of the opening of the band gap by quantum confinement. An additional contribution comes from the fact that as the porosity increases, a smaller fraction of the volume of film is made of Si. The absorption coefficient of Si nanocrystals of average sizes from 43 to

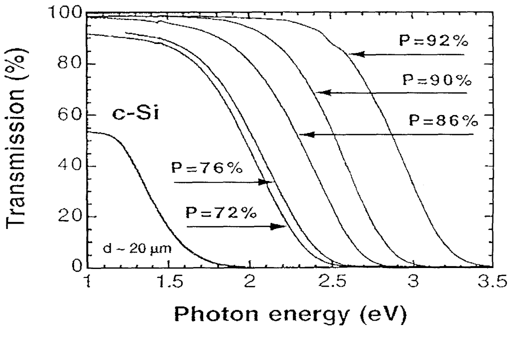

FIG. 12. The transmission spectra of 20-μm-thick PSi films depend on the porosity. The samples are prepared from a *p*-Si wafer and the spectrum of bulk c-Si is shown for comparison.

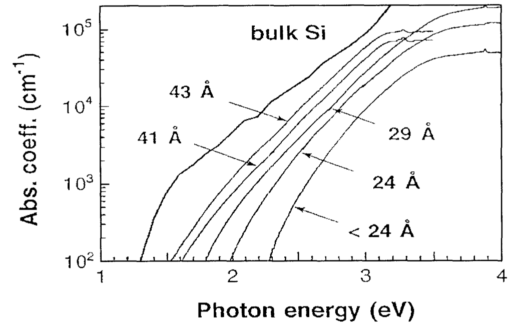

FIG. 13. The absorption spectra of the nanocrystallites present in PSi depend on the crystallite size. The samples are those of Fig. 12.

24 Å is plotted in Fig. 13 (von Behren *et al.*, 1998). The shape of the spectra shows that PSi remains an indirect-gap semiconductor even at the highest porosities/smallest crystallite sizes.

2.6.2 Dielectric Function and Index of Refraction The dielectric function ε of PSi maintains the spectral dependence of bulk crystalline Si at low porosities. With increasing porosity, the peaks in the imaginary part of ε at the E_1 and E_2 critical points broaden and decrease in amplitude. Finally, the imaginary part of ε approaches that of amorphous silicon (Koshida *et al.*, 1993), consistent with the loss of infinite long-range order. The index of refraction of PSi at or below the band gap is strongly dependent on the porosity. Figure 14 shows that the index of refraction decreases to near 1.1 at porosities of 90% and above (Fauchet *et al.*, 1998). This decrease is predicted by effective-medium theories.

2.6.3 Luminescence Radiative recombination of an electron with a hole across the band gap of a semiconductor produces luminescence at an energy equal or close to the band-gap energy. In direct-gap semiconductors such as GaAs, the electron and hole have the same momentum, the radiative recombination rate is large, and the radiative lifetime is short (a few nanoseconds). To obtain a large PL efficiency, the nonradiative recombination rate must be smaller than the radiative recombination rate. The quantum efficiency of the luminescence is defined by

$$\eta = \tau_{\text{nonrad}}/(\tau_{\text{nonrad}} + \tau_{\text{rad}}), \tag{5}$$

where η is the quantum efficiency, τ_{rad} is the radiative lifetime and τ_{nonrad} is the nonradiative lifetime. Nonradiative recombination occurs at the surface (surface recombination) and in the bulk (Auger recombination, recombination at defects).

In silicon, an indirect-gap semiconductor (see SILICON, CRYSTALLINE), the radiative recombination of an electron and a hole is possible only if another particle capable of carrying a large momentum is involved. The participation of a third particle (*e.g.*, a phonon) makes the radiative rate much lower and pushes the radiative lifetime into the millisecond regime. The quantum efficiency decreases by several orders of magnitude because the competing nonradiative processes take over, even for high-purity materials and good surface passivation. At room temperature, the quantum efficiency of bulk c-Si is usually on the order of 10^{-6}–10^{-7}. To improve this number, one can either increase the radiative rate

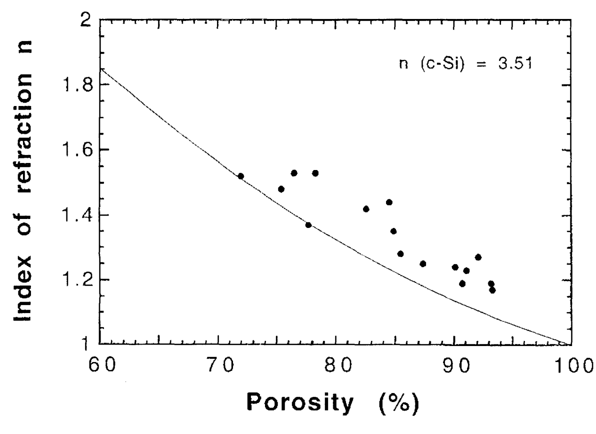

FIG. 14. The index of refraction of PSi depends on the porosity, in qualitative agreement with the prediction of an effective-medium theory, shown by the solid line.

or decrease the nonradiative rate. In PSi, both occur, although the large quantum efficiency is in large part due to the decrease in the nonradiative rate by a proper surface passivation.

The most common PL band is in the red/near-infrared part of the spectrum (Fauchet, 1996). This "red" band (or "slow" band) extends from slightly above the band gap of crystalline silicon to the blue-green part of the spectrum. The PL characteristics are wide spectrum (100–500 meV), large efficiency under UV pumping (1–10% at room temperature, greater at cryogenic temperatures), and long decay time (< 1–100 μs at room temperature, up to 10 ms at cryogenic temperatures). Figure 15 shows the evolution of a typical PSi spectrum after pulsed excitation and the temperature dependence of the PL lifetime and intensity (Vial *et al.*, 1993). In general, the shorter the emission wavelength, the shorter the PL lifetime. The PL decay does not follow a simple law and can be fitted very well using a stretched exponential function (Kanemitsu, 1993). Tuning of the red PL band can be achieved by many parameters, such as the porosity/crystallite size (by changing the HF concentration, current density, wafer doping), the use of light during anodization, or post-anodization treatments (Fauchet, 1996).

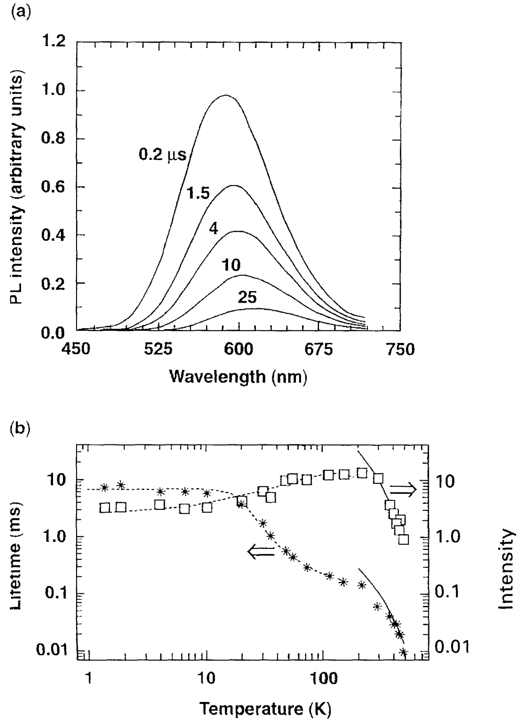

FIG. 15. (a) Temporal evolution of the PL spectrum of red-emitting PSi after pulsed UV excitation. (b) The PL intensity and the PL lifetime depend on the measurement temperature.

Although ultrahigh-porosity PSi that has not been exposed to air can luminesce weakly in the blue, strong blue PL follows high-temperature oxidation ($T_{ox} \geq 1000\,^{\circ}\mathrm{C}$) of PSi. Figure 16 shows the PL spectrum and dynamics in PSi oxidized at 1100 °C for 2 min (Tsybeskov *et al.*, 1993). The broad PL band (FWHM > 0.5 eV) with a peak near 2.6 eV and the decay on a nanosecond time scale are typical of these samples. The decay is non-exponential, as for the red band, but in contrast to the red band, no significant wavelength dependence of the "blue" (or "fast") PL decay is observed from 440 to 650 nm, the decay dynamics does not change appreciably when the measurements are performed at cryogenic temperatures, and the decay dynamics is not fitted well by a stretched exponential. The highest quantum efficiency of the blue PL can approach that of the red PL, especially after long-term exposure to water vapor and contaminants containing carbon (Loni *et al.*, 1995a).

Theory indicates that for crystallites of ≈ 1 nm diameter, the band gap should be in the blue/near UV (Wang and Zunger, 1996), and phononless, fast (approximately nanosecond) radiative recombination should dominate (Hybertsen, 1994). This model, however, cannot explain the reversible quenching of the blue PL in methanol after high-temperature oxidation of PSi (Rehm *et al.*, 1995), since the very small Si nanocrystallites, if they exist at all, are protected by a very thick oxide layer. Silicon dioxide itself is known to luminesce efficiently in the visible range under appropriate conditions, and a nanosecond blue PL has been reported after excitation by UV photons in high-purity, wet synthetic silica (Anedda *et al.*, 1993). However, the fact that the blue PL increases with exposure to water vapor and car-

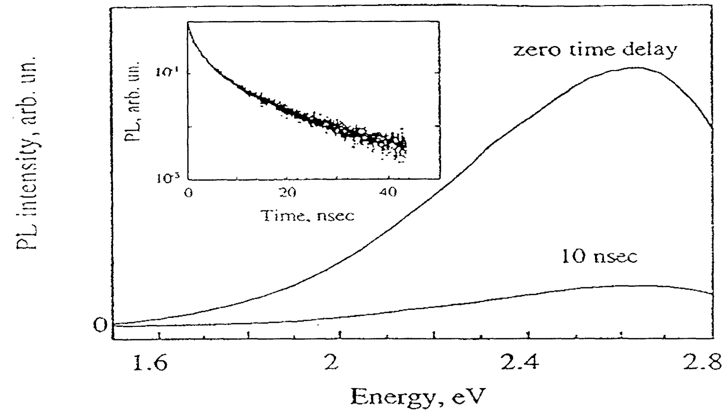

FIG. 16. Temporal evolution of the PL spectrum of blue-emitting PSi after UV excitation. The inset shows the temporal decay of the PL intensity.

bon compounds (Loni *et al.*, 1995a) strongly suggests that a chemical species adsorbed on the inner surface of the porous oxide is responsible for the blue PL. Silanol has been suggested as one candidate, but no conclusive identification has been made so far.

PSi can also emit light in the infrared. Figure 17 shows the normalized PL spectra after annealing in vacuum at different temperatures (Fauchet *et al.*, 1993). This PL band is tunable from ≈0.8 eV to past 1.2 eV, depending on the sample preparation and processing conditions, and has a nonexponential lifetime in the ≈1-μs range. Its intensity increases after annealing in ultrahigh vacuum at a temperature as high as ≈500 °C, when most of the hydrogen that passivates PSi has been desorbed and the red PL has disappeared. The tunable infrared band has been associated with dangling bonds. Figure 18 shows that the peak energies of the red and infrared bands vary linearly with each other (Petrova-Koch *et al.*, 1995). This can be explained if the infrared band corresponds to recombination of a near–band-edge electron with a hole trapped at a dangling bond whose absolute energetic position is insensitive to size, ≈0.3 eV above the bulk silicon valence-band edge.

PSi containing large crystallites also produces a PL near 1.1 eV, which coincides with

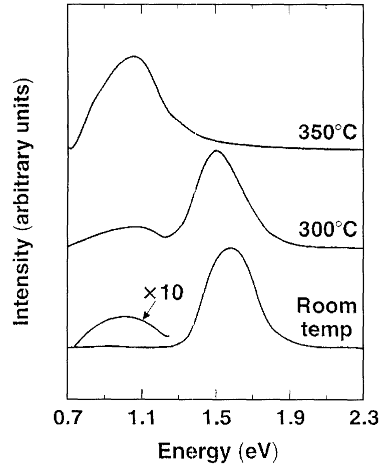

FIG. 17. Normalized PL spectra of PSi before and after annealing in vacuum at two temperatures.

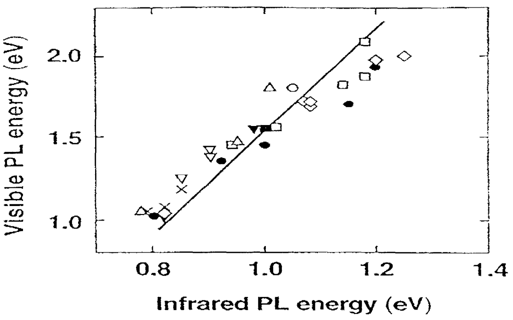

FIG. 18. Correlation between the red PL peak energy and the infrared PL peak energy over a wide range of samples prepared under different conditions. The line has a slope of 3.

the PL spectrum observed in bulk c-Si (Tsybeskov *et al.*, 1996a), including all the phonon replicas. As the temperature increases toward 300 K, the PL spectrum widens, but the PL efficiency remains unchanged near or above 0.1%. The PL is due to radiative recombination in well-passivated, large crystallites ($\gg 10$ nm).

2.7 Optical: Theory

2.7.1 Band Gap The band gap of low-dimensional Si nanostructures is larger than that of bulk Si because of quantum confinement in one, two or three dimensions. In the simple particle-in-a-box model, when electrons in the conduction band and holes in the valence band are confined spatially by potential barriers, the lowest energy for optical transitions increases by

$$\Delta E = h^2/8[1/m_c + 1/m_v] \sum 1/L_i^2 \qquad (6)$$

where h is Planck's constant, m_c and m_v are the effective masses in the conduction and valence bands respectively, L_i is the dimension of the confined region in direction i, and the number of confined directions may be 1, 2, or 3 corresponding to a quantum well, wire, or dot, respectively (Collins *et al.*, 1997). This expression assumes that the bands are parabolic, there is only one conduction (valence) band, and the potential barrier is infinitely large. Thus, it can only be used as a guide, since none of these assumptions is entirely valid.

Various techniques have been employed to calculate the band gap of Si quantum wells, wires, and dots. Calculations have been performed using different types of tight-binding and local-density approximations, mostly using a (semi)empirical approach (Delerue *et al.*, 1993; Wang and Zunger, 1994; Delley and Steigmeier, 1995; Ogut *et al.*, 1997). Figure 19 compares the band gap for wells, wires, and dots calculated by the effective-mass approximation and by a pseudopotential approach (Wang and Zunger, 1996). The band gap increases faster with decreasing size when the number of confined directions increases. The effective-mass approximation overestimates the band gap by a very large amount (≈ 1 eV for ≈ 1 nm wells, ≈ 2 nm wires, and ≈ 3 nm dots). This overestimate occurs because theory shows that ΔE scales with size as $L^{-1.3}$ instead of L^{-2} (Delerue *et al.*, 1993). Furthermore, theory (Ren and Dow, 1992) and experiments (van Buuren *et al.*, 1993) indicate that the quantization energy in the valence band is larger than in the conduction band [$\Delta E_v \approx (1.5\text{–}2) \times \Delta E_c$], also in contrast with the effective-mass approximation (which predicts that $\Delta E_v \sim 1/m_v < \Delta E_c \sim 1/m_c$).

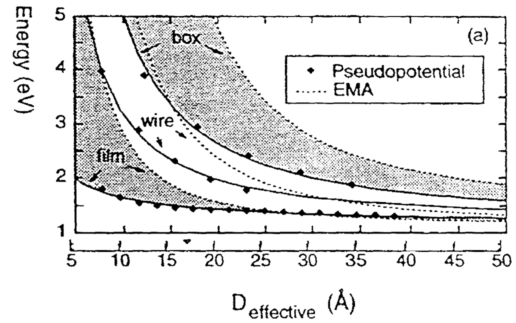

FIG. 19. Comparison of the band gap calculated by the effective-mass approximation [Eq. (6)] and a pseudo-potential approach, for Si quantum dots (box), wires, and wells (films).

Most of the calculations have been performed for H-terminated Si nanostructures. It is expected that the exact numerical answers will be affected by a change in the surface termination, especially a change from H to O passivation following partial oxidation. At this time, the models are not sophisticated enough to account properly for effects such as strain that exist at such an interface.

Despite the profound effect that quantum confinement has on the magnitude of the band gap of the Si nanocrystals present in porous silicon, the nature of the optical transition remains identical to that of bulk c-Si, in the sense that phonon-assisted optical transitions continue to predominate over transitions involving no phonons. Theory suggests that the oscillator strength for phonon-assisted transitions continues to exceed that for phononless transitions down to sizes of ≈ 1 nm (Hybertsen, 1994). Thus porous silicon behaves as an indirect-gap semiconductor, as confirmed by the presence of pronounced phonon steps in resonant PL measurements performed at low temperatures (Calcott *et al.*, 1993).

2.7.2 Luminescence The models that attempt to explain the luminescence in porous silicon can be divided into two broad categories (Fauchet 1996):

1. The PL occurs in quantum-confined crystalline silicon nanostructures, and
2. the PL occurs elsewhere—for example, in a disordered tissue material, in specific bonds or molecules (such as siloxene) that would be present on or attached to the surface, or in the nonbridging oxygen hole center present in silicon dioxide.

The overwhelming experimental evidence indicates that carriers confined in the Si nanocrystals produce the strong, tunable PL. The remaining question is whether the PL energy coincides with the band-gap energy. If recombination involves carriers confined to the nanocrystal, the PL energy should equal the band gap minus the binding energy of the exciton. If, on the other hand, the PL energy is less than the band gap, one or both carriers may be trapped, either in surface states (Koch, 1993) or as self-trapped excitons (Allan *et al.*, 1996). Because the nanocrystals present in PSi do not all have the same size, the absorption edge reflects the presence of large crystallites while the PL is dominated by the smaller crystallites, which are less likely to contain a defect or to suffer from Auger recombination. Thus, the PL and absorption measurements may not sample the same fraction of the nanocrystal population, which makes a comparison difficult.

Changes in the surface chemistry and in the chemical environment can lead to modifications in the PL properties. Although this has been invoked to support recombination involving trapped carriers, changes in surface properties can also modify the electronic states in the interior of the nanocrystals. Despite the difficulties with a comparison of the band-gap and PL energies as mentioned above, this is the only type of experiment that can directly address the question.

The band gap measured from absorption measurements should be equal to the one-electron band gap minus the binding energy of the free exciton confined to the nanocrystal. The free-exciton binding energy increases with decreasing radius size (Wang and Zunger, 1996) for two major reasons: namely, because the Coulombic attraction increases when the exciton is confined to a radius smaller than the bulk-exciton Bohr radius, and because the dielectric constant decreases dramatically for sizes below 2–3 nm. Realistic calculations of the exciton binding energy indicate that the binding energy approaches 0.5 eV for sizes of ≈2 nm. The calculated excitonic band gap, defined as the one-electron band gap minus the exciton binding energy, is in agreement with measurements of the absorption edge, in the size regime below 4.5 nm (Fig. 20) (von Behren *et al.*, 1998). The measured PL peak energy is consistently lower than the band-gap energy, especially for smaller sizes. This Stokes shift between band-gap and PL energies increases with decreasing size, as shown in Fig. 21 (Fauchet, 1998). The origin of this Stokes shift is still under discussion. A possible candidate is that the exciton becomes self-trapped at the surface. Model calculations of self-trapping at the Si–H bond show that the nanocrystal size necessary for self-trapping is much too small, below 1 nm (Allan *et al.*, 1996). However, trapping of an electron, or a hole, or even an exciton, could occur for more reasonable sizes with oxide-covered nanocrystals. This would produce, for smaller nanocrystallites, an increase of the PL energy that is much smaller than the increase of the band-gap energy.

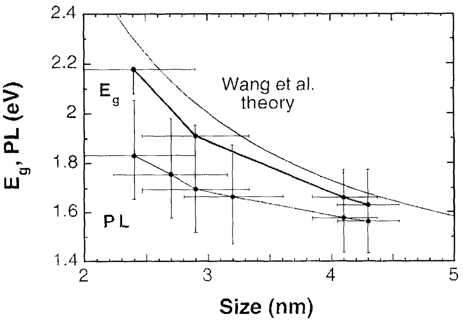

FIG. 20. Measured and calculated band gaps (E_g) for Si nanocrystallites of different sizes. The PL peak energy in samples exposed to air is also shown for comparison.

3. APPLICATIONS

3.1 Light-emitting Devices

Electroluminescence (EL) was observed in PSi shortly after Canham's report of strong

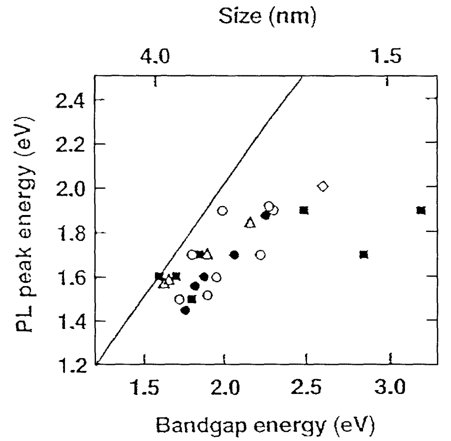

FIG. 21. Dependence of the PL peak energy on the band gap and crystallite size for the Si nanocrystals found in PSi. The data would fall on the solid line if the two energies were identical.

room-temperature PL—first in solution during anodic oxidation (Halimaoui *et al.*, 1991) and then in solid-state devices (Richter *et al.*, 1991; Kalkhoran *et al.*, 1992; Bassous *et al.*, 1992; Koshida and Koyama, 1992). Many different device structures have been demonstrated, and strong (0.1%–1% efficiency), voltage-tunable EL has even been reported under cathodic polarization of n-type PSi using liquid contacts (Bsiesy *et al.*, 1993). Research has focused on solid-state devices because of their technological importance and because liquid contacts are inherently unstable. A typical PSi light-emitting device (LED) consists of a transparent or semitransparent contact (metal, ITO, or conducting polymers) and a 1- to 10-μm-thick PSi layer on a crystalline silicon (c-Si) substrate (*p* or *n* type). Typical threshold conditions for EL are $V \approx 10\,\mathrm{V}$ and $J \approx 10\,\mathrm{mA\,cm^{-2}}$, although for the best devices V is now $\approx 2\,\mathrm{V}$ and $J \ll 1\,\mathrm{mA\,cm^{-2}}$ (Loni *et al.*, 1995b). The EL external quantum efficiency has also improved to >0.1%, and the irreversible degradation that plagued the early devices has been eliminated.

Initially, the stability of the early PSi LEDs was poor because the Si–H bonds that passivate the Si nanocrystal surfaces are very fragile and can be easily broken by exposure to light, ambient air, moderate temperatures, and large electric fields. To improve the stability, the fragile Si–H bonds have been replaced by the stronger Si–O bonds and the devices have been engineered to provide better heat sinking and greater mechanical stability, leading to no degradation after weeks of operation under ambient conditions. Figure 22 shows the results of stability tests, performed under pulsed drive conditions well above EL threshold for a PSi LED (Tsybeskov *et al.*, 1996b). No degradation is seen for several weeks. A key factor in achieving stable devices is to minimize the density of states at the interfaces between the different layers present in the structure. Devices that contain too many interface states suffer from reversible degradation, produced by the charging of the interface states (Fauchet *et al.*, 1997).

The two main factors that keep the EL efficiency one to two orders of magnitude below the PL efficiency are the difficulties in injecting carriers from the contact into the PSi and the poor transport properties in PSi. By improving the contacts and keeping the PSi layer thickness below 1 μm, the power efficiency of the

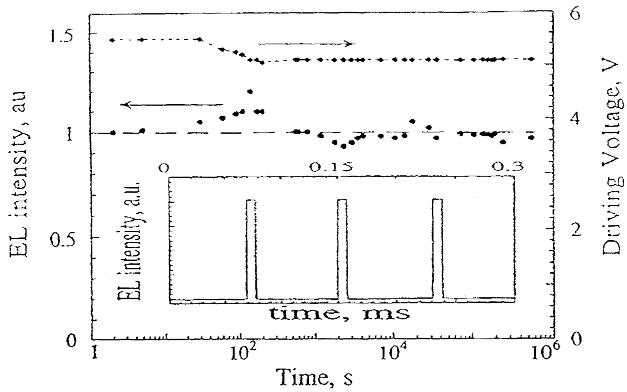

FIG. 22. Stability of the electroluminescence intensity under pulsed current excitation conditions for a PSi LED.

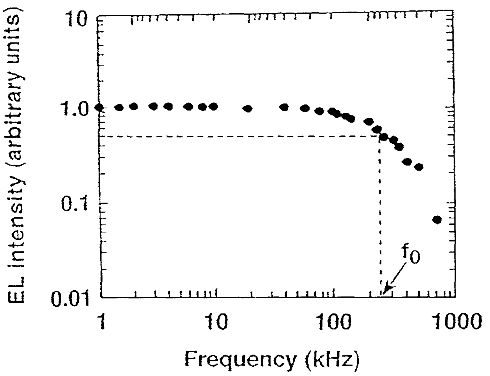

FIG. 23. The amplitude of the ac electroluminescence depends on the modulation frequency. The measurement was performed on a p–n PSi junction LED. The 3-dB frequency is indicated.

best PSi LEDs has been increased to greater than 0.1%. The internal quantum efficiency, defined as the ratio of the number of photons generated inside the PSi layer to the number of carriers injected inside the PSi layer, is estimated to be $>1\%$, which is comparable to the PL efficiency. The threshold voltage (2 V) and current density ($1\,\mu\mathrm{A\,cm^{-2}}$) of some of these devices makes them compatible with microelectronic technology.

The response time of PSi LEDs is an important parameter that determines their suitability in applications such as optical interconnects and real-time optical signal processing. The speed of the LEDs can be obtained by measuring the frequency response in the small-signal limit. The device is held at a large forward bias, well above the threshold for detectable EL. A small ac voltage is applied, which modulates the EL. The amplitude of the ac EL is monitored as a function of frequency, as already mentioned in Sec. 2.5. Figure 23 shows that the magnitude of the ac EL signal remains constant up to a critical frequency beyond which it drops quickly (Peng and Fauchet, 1995). The 3-dB frequency, which is defined as the frequency at which the ac EL has dropped by a factor of 2, has been found in Sec. 2.5 to be the inverse of the transit time. The 3-dB frequency determines the maximum frequency response of the diode in this small-signal analog test. Thus, the response time of the EL is limited by the time it takes carriers to cross the PSi layer, and not the PL lifetime, which is usually shorter. By making the PSi layer thinner than 1 μm or by using a PSi *p-n* junction, the 3-dB frequency can approach 1 MHz, when it is limited by the luminescence lifetime. Clearly, the small-signal ac modulation speed of these PSi LEDs is not likely to approach 1 GHz, unless they can be made using blue-emitting PSi, whose PL lifetime is ≈ 1 ns.

Since the PL can span the spectrum from the infrared to the blue, it is reasonable to expect that EL can cover the same range of wavelengths. As early as 1992, LEDs with peak wavelengths ranging from the deep red to the blue were fabricated. The EL efficiency of these devices was between 0.005% and 0.01%. LEDs operating in the infrared are also attractive. For example, 1.5-μm radiation is eye-safe and compatible with fiber communication systems. In addition, it is not absorbed by the c-Si wafer, which may be an advantage for the integration of PSi LEDs in close proximity to microelectronic circuits. PSi LEDs emitting 1.1-μm light and 1.5-μm light have been demonstrated, using oxidized mesoporous Si and Er-doped oxidized PSi, respectively (Fig. 24) (Fauchet *et al.*, 1997).

Ultimately, the success or failure of PSi-based technology rests on the compatibility of PSi LEDs with standard microelectronic processing. An integrated bipolar transistor/PSi LED structure has been demonstrated (Hirschman *et al.*, 1996). The complete structure, shown in Fig. 25, was fabricated using accepted silicon microelectronic fabrication procedures. The LED could be turned on and off by applying a small current pulse to the base of the bipolar transistor. Arrays of such integrated structures can easily be fabricated. This represents a critical first step toward the integration of silicon-based LEDs into VLSI circuits.

3.2 Solar Cells

Solar cells have been made using PSi, either as the photovoltaic material or as a passive layer intended to improve the performance of the c-Si solar cell. The use of PSi in photovoltaic devices has been reported as early as 1982 (Prasad *et al.*, 1982). This involved the anodization of p^+/n c-Si solar cells to form a

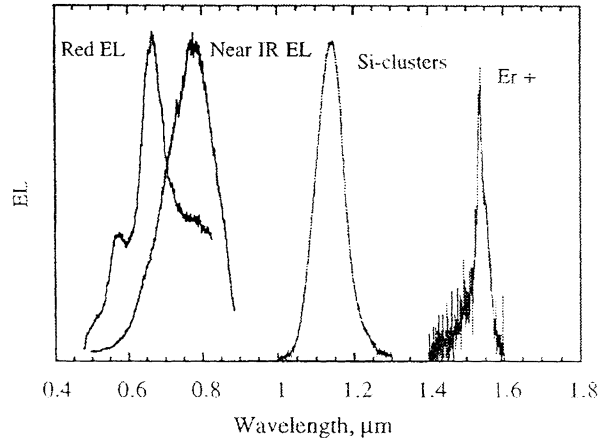

FIG. 24. Electroluminescence spectra for four PSi LEDs. The red/near-infrared LEDs were prepared with a nanoporous light-emitting layer. The two infrared LEDs were prepared with a mesoporous light-emitting layer, which was doped with erbium for the 1.5-µm device.

thin porous layer, which was oxidized at 500–600 °C. As a result, the reflectance of the solar cell was reduced from 37% to 8% in the 300- to 800-nm region, which increased the short-circuit current density (J_{sc}) by 25%. The potential advantages of PSi-based photovoltaic devices include the following:

1. Its highly textured surface increases light trapping and reduces loss due to reflection.
2. The band gap of PSi may be optimized for the absorption of sunlight (the maximum theoretical solar-cell efficiency vs. band gap curve peaks at around 1.5 eV).
3. The efficient photoluminescence of PSi might be used to down-convert higher-energy solar radiation (blue/UV) into longer-wavelength light (red/IR), which is absorbed more efficiently in bulk silicon.

Solar cells in which PSi is the photovoltaic material have been demonstrated with an efficiency in excess of 10% (Duttagupta and Fauchet, 1998). A µc-Si film deposited on *n*-type (100) c-Si substrates (1 Ω cm) at 580 °C using low-pressure chemical vapor deposition was doped *in situ* with phosphorus (SiH_4/PH_3) and boron (SiH_4/B_2H_6). The p^+-n films were anodized, and the average porosity *P* was varied to achieve maximum efficiency. Under illumination, an ideal solar cell is equivalent to a constant-current generator in parallel to a *p*-*n* junction diode. With increasing porosity, the series resistance first increases slightly and

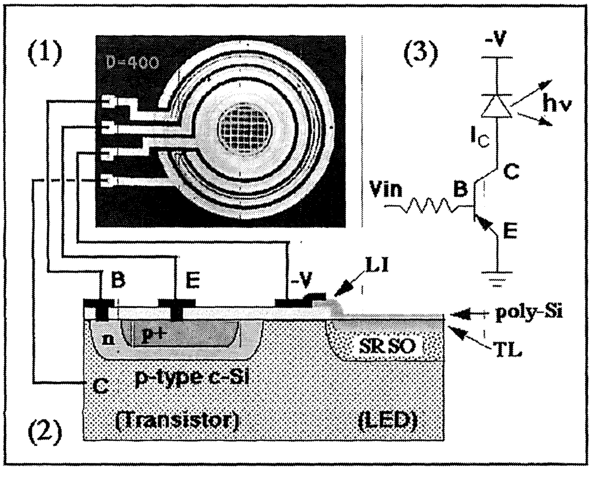

FIG. 25. Photograph, cross section, and equivalent circuit of a PSi LED integrated with a bipolar transistor. The LED surface is covered by the cross-hatched Al contacts. FIG. 26. Dependence of the reflectance and the series resistance on porosity for a solar-cell device made of porous microcrystalline silicon.

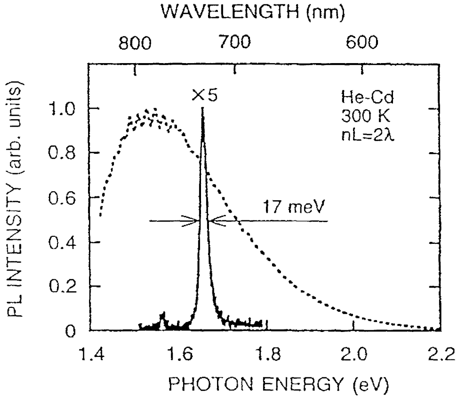

FIG. 27. Narrowing of the PL spectrum when porosity superlattices are used to shape the emission spectrum of PSi.

then, above a porosity of 50%, increases by several orders of magnitude. In contrast, the reflectance decreases monotonically with increasing porosity (Fig. 26). As a result, the short-circuit current has a maximum around 40% porosity. The best solar energy efficiency of 10.2% has been achieved for devices with a 40% average porosity, which also exhibit an enhanced blue response Note that photodetectors, which are devices closely related to solar cells, have also been made using PSi (Zheng *et al.*, 1992).

3.3 Mirrors and Photonic Band Gap

High-reflectivity mirrors made of PSi can be fabricated with reflectivities in excess of 99%. They consist of a stack of alternating high-porosity/low-porosity layers (Berger *et al.*, 1994), produced by changing the current density periodically during anodization or by anodizing under a constant current density alternating c-Si layers having high and low doping concentrations. These porosity superlattices, which can be viewed as Fabry–Pérot resonators or Bragg reflectors, have a high reflectivity in specific wavelength regions only. They have been inserted in PSi structures to narrow the spectral width of the luminescence by more than one order of magnitude, as shown by Fig. 27 (Araki *et al.*, 1996).

PSi containing periodically spaced macropores (initiated by means of a mask on the wafer) has been used as a two-dimensional photonic band gap structure (Gruning *et al.*, 1996). A photonic band gap material is to photons what a semiconductor crystal is to electrons: it prevents the propagation of light in a range of photon energies by the destructive interference produced by the alternating regions of high index of refraction (Si) and low index of refraction (pores), provided that the periodicity is on the order of the wavelength in PSi. Attenuation of electromagnetic waves by more than two orders of magnitude has been observed near 5 μm using a triangular lattice of 75-μm-deep pores spaced by 2.3 μm.

3.4 Waveguides

Optical waveguides require that a region of high index of refraction be sandwiched between regions of low index of refraction. Because the index of refraction of PSi can easily be controlled by changing the porosity, PSi waveguides can be readily fabricated. PSi waveguides can be useful in Si optoelectronic integrated circuits (OEICs), where they could manipulate optical signals. PSi waveguides with losses as small as $\leq 1\,\mathrm{dB\,cm^{-1}}$ have been demonstrated (Bondarenko *et al.*, 1995). They have also been used to collect efficiently the electroluminescence produced by PSi LEDs.

3.5 Sensors

Because the properties of PSi are very sensitive to the state of its internal surface, it should be a useful material in detecting the presence of chemical compounds, humidity, *etc.* PSi sensors could operate on the basis of a reversible or irreversible change in optical properties (PL), electrical properties (conductivity), or even structural properties. PSi sensors have been developed for detecting humidity in integrated circuits. They have also been proposed for detecting environmentally important chemicals (smokestack gases) and alcohols (breathalyzers) (Sailor and Lee, 1997). Although PSi sensors with promising properties have been demonstrated, one common problem is the lack of specificity.

3.6 SOI Technology

In the silicon-on-insulator (SOI) technologies, the electronic devices are manufactured on a thin Si film on an insulating substrate, which minimizes problems associated with parasitic capacitances, latch up, and radiation damage. PSi was first used in the FIPOS (full isolation by porous oxidized silicon) process and then in a variety of SOI applications (Tsao, 1987). In these applications, the oxide layer was formed by the full oxidation of PSi usually formed from heavily doped layers. This approach has been abandoned in favor of alternative techniques.

3.7 Micromachining

Micromachining of Si is a technological area of rapidly growing importance because it allows the development of micro-electro-mechanical systems (MEMS) devices that can be used in a variety of applications, such as pressure sensors. PSi, as a sacrificial layer, is well suited to micromachining (Lang, 1996) because the etching rate of Si depends strongly on the doping density and the dopant type and on the current density. An etching hierarchy (from most easily etched to less easily etched) has been introduced: n^+ Si under illumination, p^+ Si under illumination, p and n Si under illumination, p Si in the dark, n Si in the dark and amorphized Si. A combination of etch stops (*e.g.*, using layers of different resistivities) and masking techniques (using photoresists and/or silicon nitride or carbide protective layers) permits the micromachining of Si in three dimensions. Examples of integrated microsensors fabricated using the PSi technology include bolometers.

3.8 Biomedical Applications

Electronic components are increasingly used inside the human body (*e.g.*, pacemaker, drug delivery systems). In these applications, the Si chip is isolated from the biological medium by a package that is more bio-compatible or has the desired bioactivity. Unlike bulk Si, which is mostly bio-inert, PSi has been shown to induce the nucleation and growth of calcium phosphate (Canham, 1995). This implies that PSi can naturally coat to bone and other soft tissues in the human body. Interestingly, the kinetics of calcification can be controlled electrically. Thus, chips containing PSi regions could be used to bind to specific sites on demand. This field is just in its early infancy, and future developments (Canham *et al.*, 1997) will tell whether the early promises transform into real applications.

3.9 Capacitors

Capacitors have been manufactured using PSi technology (Lehmann *et al.*, 1995). Macroporous PSi was formed by seeding the pores with a 3.5-μm pitch. The resulting gain in surface area over a bulk sample was 85. The PSi was then doped heavily n-type and a 30-nm-thick dielectric layer was grown inside the pores. Such devices, which showed excellent characteristics, can be integrated on the back side of Si chips, thus saving valuable real estate and avoiding parasitic effects in high-quality RC timing circuits.

GLOSSARY

Hole: An empty energy level in the valence band of a semiconductor; it behaves as a particle carrying a positive charge.

Luminescence: Emission of a photon during the recombination of an electron with a hole. If the electron and hole have been injected optically, it is called photoluminescence; if they have been injected electrically, it is called electroluminescence.

Pore: Region from which the silicon atoms have been removed by the etching process.

INTRODUCTION

The Sun is the foundation for the study of stars. Its surface and global properties can be determined to much higher precision than for other stars; traditionally these have been combined with theoretical models to deduce the internal properties of the Sun. The study of the Sun has been revolutionized, however, by the availability of diagnostics of its internal properties. Neutrino experiments provide direct evidence for nuclear reactions in the core of the Sun; the frequencies of acoustic waves in the Sun provide a means of determining the speed of sound and the rotation rate as functions of depth. In addition, the relative abundances of elements in meteorites can be measured precisely. Meteoritic data can provide information about the composition of the material that the Sun was formed from, and a comparison of the current surface abundances with the initial abundances can be used to test for changes in the surface abundances during the lifetime of the Sun. This wealth of data has

Table 1. Global properties of the sun.

Mass	1.9891×10^{33} g
Radius	6.9598×10^{10} cm
Luminosity	$3.844(1 \pm 0.004) \times 10^{33}$ erg s^{-1}
Age	4.57 ± 0.02 Ga
T_{eff}	5770 K

provided astronomers with a stringent test of the standard models of the structure of stars, as well as evidence that allows an assessment of the importance of physical processes usually neglected in theoretical stellar models.

Section 1 of this article summarizes the global and surface properties of the Sun. Section 2 introduces the main components of the theoretical models. In Section 3, the diagnostics of the internal properties of the Sun are discussed. The inferred internal structure of the Sun is discussed in Sec. 4. The results are summarized in Sec. 5.

1. GLOBAL AND SURFACE PROPERTIES

1.1 Mass, Radius, Luminosity, Surface Temperature, and Age

Table 1 summarizes some of the important global properties of the Sun (Lang, 1991). Note that these properties, especially age, are determined far more accurately than for stars in general. For example, the solar mass is inferred from the orbital periods of the planets, and the primary uncertainty is the value of the gravitational constant *G*. It is extremely difficult to infer directly the age of a single star such as the Sun. However, the time scale for the formation of the Sun, planets, and smaller bodies of the solar system is short compared with the age of the Sun. The age of the Sun is therefore most accurately determined by radioactive age dating of meteorites, and the primary uncertainty is the possibility of a small difference in age between the meteorites and the Sun (see Bahcall *et al.*, 1995; this article also discusses updated values for the solar luminosity and other properties of the Sun).

In general the radius and luminosity (total energy output per second) of the Sun will change over both long and short time scales. The effective temperature (T_{eff}) of the Sun is the surface temperature that a blackbody emitting the same flux per unit area would have. Radius (R), luminosity (L), and the effective surface temperature are related by

$$L = 4\pi R^2 \sigma {T_{\mathrm{eff}}}^4, \tag{1}$$

where σ is the Stefan–Boltzmann constant. In Table 2 we show the time dependence of the solar radius and luminosity inferred from theoretical models (see Sec. 2). The long-term changes in the solar energy output are of interest for understanding the time evolution of the climate of the Earth. Shorter-term changes in brightness and radius can arise from phenomena such as the solar sunspot cycle (Sec. 1.4; see also SOLAR RADIATION).

Table 2. Changes in global solar properties as functions of time.

Time (10^9 a)	Radius ($R_\odot$)	Luminosity ($L_\odot$)	Convection-zone depth ($M_\odot$)
0.0	0.868	0.673	0.0329
0.04	0.874	0.698	0.0310
0.27	0.883	0.724	0.0300
0.5	0.889	0.736	0.0291
1.0	0.900	0.763	0.0282
1.5	0.912	0.792	0.0282
2.5	0.937	0.850	0.0268
3.5	0.965	0.916	0.0252
4.57	1.000	1.000	0.0240

1.2 Composition—Photospheric and Meteoritic

The composition of a star exerts a strong influence on its structure and evolution. The Sun is primarily composed of hydrogen (≈ 0.70 by mass fraction), with most of the rest of the material in the form of helium (≈ 0.28) and only about 0.02 in the form of heavier elements. Meteorites provide the most accurate means of measuring the relative abundances of heavy elements in the protosolar nebula. They do not, however, provide a means of determining the mass fractions of abundant volatile species, such as H, He, C, N, O, and Ne. In the solar photosphere we can measure the current surface mass fractions of different species, with the notable exception of ^{4}He, relative to hy-

Table 3. Abundances in the solar photosphere ($\log N_{\mathrm{H}} = 12.0$).

Element	Photosphere	Meteorites

drogen. These measurements, however, are not as accurate as those in the meteorites.

To infer the initial composition of the Sun, data from the two sources are combined. Meteorites are used to set the relative initial abundances of the species when possible, on a logarithmic scale relative to Si, where log(Si) = 6. The photospheric abundances are measured relative to hydrogen, on a logarithmic scale where log(H) = 12. The meteoritic scale is converted into the photospheric scale by measuring the ratios of the abundances on the two different scales for well-measured species (see Anders and Grevesse, 1989). The mass fractions of abundant species in the Sun from Anders and Grevesse (1989) are given in Table 3.

The initial ^{4}He abundance of the Sun is determined indirectly. In astronomy, the mass fractions of hydrogen, helium, and all other elements combined (referred to as "metals") are denoted by X, Y, and Z, respectively, and satisfy $X + Y + Z = 1$. The surface abundances give the ratio Z/X. Because the luminosity of a star depends on its initial composition, the requirement that a solar model has the luminosity of the Sun at the age of the Sun can be used to infer the initial ^{4}He mass fraction (Y). In addition, helioseismic data can be used to infer the current surface Y (Sec. 3.2).

The light elements Li and Be are significantly more abundant in meteorites than in the solar photosphere (by factors of 100 and 2, respectively). This constitutes evidence for mild mixing in the solar envelope, as these species burn at temperatures of 2.5 and 3.5 MK, respectively (Sec. 2.4.1). The current surface Y is also lower than the initial Y, which is evidence for the gravitational settling of helium out of the surface layers of the Sun (Sec. 2.4.2). Both theoretical models and the sound speed inferred from helioseismology require the burning of helium in the core of the Sun (Sec. 2, Sec. 3.2).

1.3 Surface Rotation and Oblateness

The Sun rotates at a rate that depends on the latitude at the surface; Libbrecht and Morrow (1991) give the surface rotation frequency as a function of latitude as

$$\nu(R_\odot, \phi) = 462 - 75 \sin^2\phi - 50 \sin^4\phi \ \mathrm{nHz}, \tag{2}$$

which implies an equatorial rotation period of about 25.4 d and a polar period of order 34 d. Helioseismic data can be used to infer the internal rotation as a function of depth (Sec. 3.2.2).

The measured solar oblateness is

$$\varepsilon = 8.63 \pm 0.88 \times 10^{-6} \tag{3}$$

where $\varepsilon = 2(R_{\mathrm{eq}} - R_{\mathrm{pole}})/(R_{\mathrm{eq}} + R_{\mathrm{pole}})$. This provides not only a measurement of the local distortion of the surface of the Sun, but an indication of the quadrupole moment and a constraint on the internal solar rotation. The distortion from spherical symmetry induces small corrections to the equations of stellar structure. We have evidence that the Sun is experiencing angular-momentum loss (Sec. 1.5), and young solar analogs rotate more rapidly than the present-day Sun. This distortion could therefore have been larger in the past. Rotation can also induce circulation currents and mixing, which could have a more significant impact on the structure of the Sun.

1.4 The Solar Sunspot Cycle and Magnetic Fields

The existence of sunspots has been known for centuries; they are regions with high magnetic field strengths of 2–3 kG and cover a fraction of the solar surface ranging up to about 0.001. Sunspots appear dark relative to the rest of the surface because they are significantly cooler than the rest of the photosphere; they are also surrounded by active regions that are hotter than the mean surface temperature (and therefore brighter). We have extensive records that indicate that the number of such spots varies with a period of order 22 years (including a reversal in polarity; the number of sunspots varies over an 11-year cycle). The flux per unit area is different in and around sunspots than for the rest of the solar surface; as a result, these changes in spot coverage can cause changes in the energy output of the Sun. The amplitude of the modulation of the total solar irradiance during the sunspot cycle is 0.08%. In some spectral regions the variation in the amplitude is higher (see SOLAR RADIATION). For an extensive discussion of the solar activity cycle, see the chapters in Sec. IV of Cox *et al.* (1991).

The sunspot cycle is intimately linked with the generation of the solar magnetic field. The dynamo theory postulates that differential rotation in the solar interior leads to an amplification of the internal magnetic field strength. At some point the fields become strong enough to be subject to magnetic instabilities, and magnetic flux can then rise to the surface. In the outer layers ($R > 0.713 R_\odot$) of the Sun, energy is transported by mass motions (convection), with an overturn time scale of the order of a month. The most likely site of the solar dynamo is therefore below the surface convection zone, where the magnetic field can grow over a longer time scale than is permitted in the convection zone.

1.5 Solar Chromosphere, Corona, and Wind

Above the solar photosphere there are three different regions. The Sun has a chromosphere hotter than the photosphere, a very hot and extended corona, and a steady stream of material escaping from the Sun referred to as the solar wind. The measured solar mass loss rate is $3 \times 10^{-14} M_\odot/\mathrm{a}$, which implies that only a small fraction of the Sun's mass has been lost over the 4.5 Ga of its lifetime.

The heating mechanism for the chromosphere and corona has been a subject of some controversy. Turbulent motions in the solar atmosphere can generate acoustic waves, which increase in velocity as the density decreases outwards until they become shock waves. Alfvén waves may also contribute to the heating of the chromosphere. The temperature in the chromosphere rises from the minimum at the top of the photosphere of 4500 K to a maximum temperature of 20 000 K. There is then a transition region above the chromosphere where the temperature rises to of order 10^6 K in the corona. The properties of the chromosphere and corona change significantly during the course of the solar sunspot cycle.

2. THEORY OF STELLAR STRUCTURE AND EVOLUTION

Much of our understanding of the interior of the Sun comes from theoretical models of its structure constrained by the surface and global properties outlined in Sec. 1. In this section the ingredients of a theoretical stellar model are described. In Sec. 4 the internal structure of a theoretical solar model is described and compared with the diagnostics of the internal properties of the Sun described in Sec. 3. We begin by outlining the equations of stellar structure and then comment on the input physics, method for constructing a solar model, and some additional physical processes not usually included in standard solar models.

2.1 Basic Equations and Assumptions

The basic equations of stellar structure are expressions of the conservation of mass, energy, and momentum, along with a prescription for the transport of energy. The continuity equation gives

$$\frac{\mathrm{d}M}{\mathrm{d}r} = 4\pi\rho r^2 \tag{4}$$

where $M(r)$ is the mass, r is the radius, and

$\rho(r)$ is the density. Hydrostatic equilibrium can be expressed as

$$\frac{\mathrm{d}P}{\mathrm{d}r} = -\rho g \tag{5}$$

where $P(r)$ is the pressure and $g = GM/r^2$ neglecting departures from spherical symmetry. The high mass of the Sun implies that a very large internal pressure gradient is required to balance the force of gravity. Energy generation requires

$$\frac{\mathrm{d}L}{\mathrm{d}r} = 4\pi\rho r^2 \varepsilon, \tag{6}$$

where $L(r)$ is the luminosity ($\mathrm{erg\,s^{-1}}$) and $\varepsilon(r)$ is the energy generation rate (which includes nuclear energy generation, energy loss from neutrino emission, and changes in gravitational potential energy).

The temperature gradient is the minimum of that for energy transport by radiation and that for energy transport by mass motions (convection); for transport by radiation,

$$\frac{\mathrm{d}T}{\mathrm{d}r} = -\frac{3}{16\pi ac}\frac{\kappa L}{r^2 T^3}, \tag{7}$$

where $T(r)$ is the temperature, c is the speed of light, a is the radiation constant, and $\kappa(T, \rho, \text{composition})$ is the opacity of matter to radiation.

These equations must be supplemented by an equation of state that relates the pressure, temperature, and density; a convection theory that determines the temperature gradient in regions where energy is carried by mass motions; and a prescription for changes in abundance induced by nuclear reactions as a function of time. The standard model assumes spherical symmetry, neglects magnetic fields and mass loss, and does not include either mixing processes linked with rotation or gravitational settling of heavy elements with respect to lighter ones.

2.2 Input Physics

In Fig. 1 the energy generation rate ε and the opacity κ are shown as functions of fractional radius in a model of the present-day Sun. Energy generation is primarily through nuclear reactions in the Sun and is highly temperature sensitive. The final luminosity of the Sun, however, is set by the balance between energy generation and energy transport. In the inner part of the Sun, the opacity of matter to radiation is low and energy transport is primarily by radiation. When the opacity is too high material becomes convectively unstable; the strong increase in opacity in the outer layers of the Sun indicates that energy transport is primarily through convection above $0.713R_\odot$. The nuclear-reaction rates, equation of state and energy transport in the solar interior are reviewed below.

2.2.1 Nuclear-Reaction Rates The conversion of hydrogen into helium is the primary energy source for the Sun [see Bahcall (1989) for a discussion of nuclear-reaction rates relevant for the Sun; cross sections are summarized in Bahcall and Pinsonneault (1992) and Bahcall *et al.* (1995)]. In most cases the cross sections for the relevant reactions can be measured experimentally; because the typical energies in the Sun ($\approx 1\,\mathrm{keV}$ at the center) are much lower than the regime which is accessible experimentally ($> 100\,\mathrm{keV}$), the experimental results are extrapolated to the low-temperature regime. There are two principal mechanisms for hydrogen burning. In the proton–proton (pp) chain,

$$^1\mathrm{H} + {}^1\mathrm{H} \rightarrow {}^2\mathrm{H}, \quad {}^1\mathrm{H} + {}^2\mathrm{H} \rightarrow {}^3\mathrm{He}, \tag{8}$$

and either

$$^3\mathrm{He} + {}^3\mathrm{He} \rightarrow {}^4\mathrm{He} + 2\,{}^1\mathrm{H} \text{ (85\% of the time)} \tag{9}$$

or

$$^3\mathrm{He} + {}^4\mathrm{He} \rightarrow {}^7\mathrm{Be} \text{ (15\% of the time).} \tag{10}$$

The ^{7}Be then either experiences an electron capture or a proton capture, and is ultimately processed into two ^{4}He nuclei. Some of these reactions produce neutrinos that can be detected experimentally. This chain accounts for 98% of the energy output of the Sun.

In the carbon–nitrogen–oxygen (CNO) cycle the C, N, and O nuclei are used as cata-

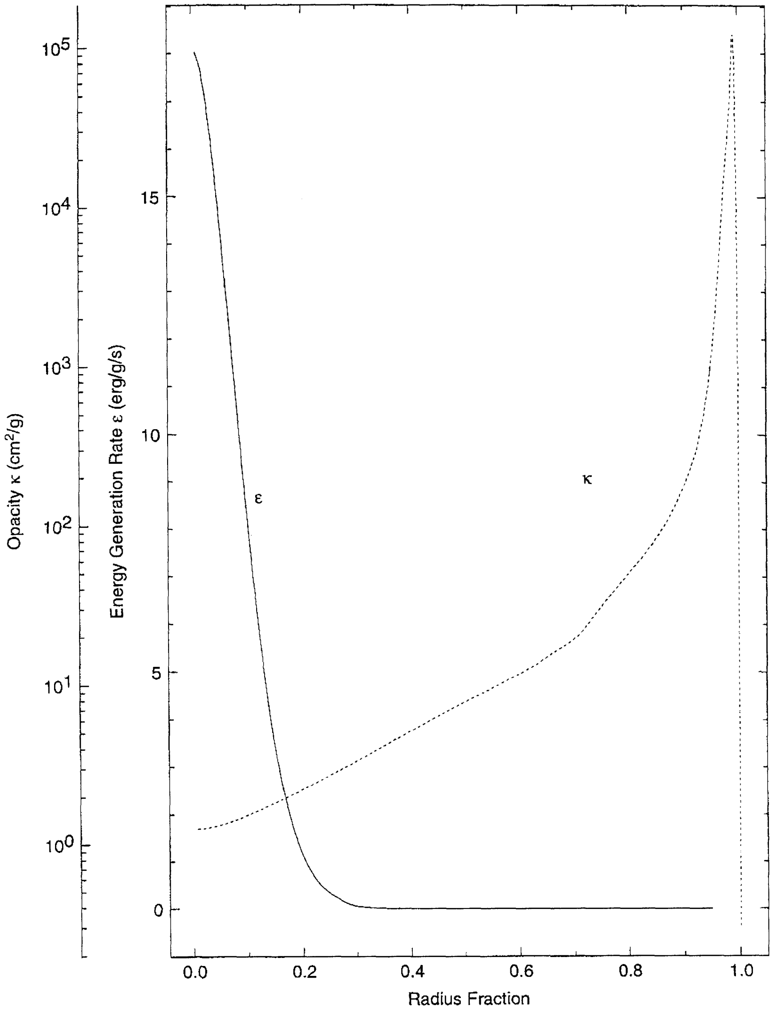

FIG. 1. The energy generation rate (solid line, first linear scale) and opacity (dashed line, second logarithmic scale) as functions of the fractional radius in a theoretical solar model.

lysts, and hydrogen is converted into helium through a series of proton captures. These reactions are more temperature sensitive than the pp chain and predominate in stars more massive than the Sun (accounting for only 2% of the solar luminosity). They produce some neutrinos that can be detected experimentally. The Sun is not hot enough to burn He and heavier elements.

2.2.2 Energy Transport The mean free path of a photon in the solar interior is of the order of 1 cm. Because the Sun is much hotter at the center ($\approx 15.6\,\mathrm{MK}$) than it is at the surface ($\approx 5770\,\mathrm{K}$), the photons produced at a given radius will on average be more energetic than those produced at a slightly larger radius; when these photons interact with matter there will be a net transport of energy outwards. As a result of the small length scale, the transport of energy by radiation can be treated as a diffusion process. Theoretical models rely on quantum mechanical calculations of the opacity of matter to radiation, such as the recent work of Iglesias and Rogers (1996), to compute the temperature gradient needed to carry the solar flux via radiation. If we denote the actual temperature gradient by $d \ln T / d \ln P =$

∇, then convection takes over as the dominant mode of energy transport whenever the radiative temperature gradient ∇_{rad} is greater then the adiabatic temperature gradient ∇_{ad}. The mode of energy transport switches from radiative to convective near $0.713 R_{\odot}$; there is a discontinuity in the speed of sound as a function of depth at this point that can be detected through the study of solar oscillations (Sec. 3.2). The temperature gradient in the convective region of the Sun is determined using mixing-length theory. In the deeper layers of the solar convection zone, the actual temperature gradient is close to the adiabatic gradient; it can depart significantly from the adiabatic gradient in the outermost layers of the Sun.

2.2.3 Equation of State The bulk of the mass of the Sun is in the form of hydrogen and helium, which ionize at low temperatures; most of the heavier elements are in the form of C, N, and O, which are fully ionized at modest temperatures of order 1 MK. As a result, the interior of the Sun is essentially fully ionized and is also close to an ideal gas. An important quantity for the solar equation of state is the mean molecular mass μ, defined by

$$P = \rho \Re T / \mu \tag{11}$$

where $\Re$ is the gas constant.

The mean molecular mass in the solar interior changes in regions of partial ionization. For the purposes of computing the pressure, free electrons are as important as ions; for example, there will be twice as many particles per gram in an ionized hydrogen gas as in a neutral hydrogen gas. There are more particles per gram in fully ionized hydrogen (2) than there are in fully ionized helium (3/4) or heavier elements ($\approx 1/2$), and so composition changes can affect the equation of state; nuclear burning and gravitational settling in the solar interior will therefore also cause changes in μ as a function of radius and time. Modern equations of state include relativistic effects, electron degeneracy, radiation pressure, and electrostatic corrections. In the outer layers, the partial ionization of H, He, and metals needs to be computed. Partial ionization is important for the thermal structure in the outer layers because of the strong dependence of the number of free particles per gram on the ionization state of the matter. Other thermodynamic properties, such as the adiabatic temperature gradient (see Sec. 2.2.2), are also strongly affected by partial ionization. Most modern solar models use tabulated equations of state that include the above effects; examples include the OPAL equation of state (Rogers *et al.*, 1996).

2.3 Constructing a Calibrated Solar Model

Stellar evolution is an initial-value problem. A model with the mass of the Sun is evolved to the age of the Sun. A calibrated model reproduces the solar surface Z/X, radius, and luminosity at the age of the Sun. The initial Y of the Sun is adjusted to reproduce the solar luminosity, while the mixing length α (the distance in pressure scale heights that a fluid element travels before releasing its heat) in the convective portion of the Sun is adjusted to reproduce the solar radius. The inferred initial Y depends on the other input physics, but is typically in the range 0.27–0.29 by mass fraction.

2.4 Physical Processes not in the Standard Solar Model

Standard solar models do not incorporate rotation and element-separation processes. However, there is evidence that these phenomena have a measurable impact on the observed properties of the Sun; solar and stellar models that include rotation and element separation have been constructed.

2.4.1 Rotation Rotation has a direct effect on the structure of the Sun; in addition, it can induce mixing from meridional circulation and hydrodynamic instabilities triggered by differential rotation with depth. A full treatment of rotation in the Sun includes the effect of rotation on the structure of the Sun, the initial angular momentum in the protostellar phase, angular-momentum loss via the solar wind, and internal angular-momentum transport. Solar models with rotation can explain the surface light-element abundances of the Sun, but rotation has only a modest impact on the thermal structure of the solar models (Richard *et al.*, 1996). In other areas of stellar evolution rotational mixing can produce dramatic observational effects.

2.4.2 Microscopic Diffusion Heavy elements sink with respect to lighter ones in the presence of gravity; in addition there is a net downward flux of heavier elements in the presence of a temperature gradient. These diffusion effects are included in recent solar models; they result in a lowering of the surface abundances of elements heavier than hydrogen, a deepening of the surface convection zones in the models, and an increase in the inferred central temperature and the expected solar neutrino fluxes.

3. DIAGNOSTICS OF THE INTERNAL PROPERTIES OF THE SUN

The global and surface properties of the Sun can be used to infer its internal properties in conjunction with the theoretical models described in Sec. 2. However, there are also diagnostics of the internal properties of the Sun. Neutrinos are produced in nuclear reactions in the solar core; because of their weak interaction with matter, they can pass through the Sun and be detected on the Earth. Acoustic waves in the Sun also provide information about the speed of sound and rotation as a function of depth.

3.1 Solar-Neutrino Fluxes

Some of the nuclear reactions that occur in the Sun emit neutrinos. Because the cross section of neutrinos in matter is extremely low, these neutrinos escape from the Sun and can be detected in terrestrial experiments. Different reactions emit neutrinos with different energies, and there are now four experiments, which are sensitive to neutrinos with different energies. The resulting neutrino spectrum can be compared with that predicted by theoretical models. The detection of solar neutrinos constitutes evidence that nuclear reactions from hydrogen burning are the predominant solar energy source.

However, the observed fluxes are significantly less than the predicted rates. This persistent discrepancy between theory and experiment is the *solar neutrino problem*, and its solution involves either significant modifications of the theoretical solar models or new neutrino physics. In Sec. 4.6, the observed and predicted fluxes are compared. Here we briefly review the processes that produce solar neutrinos. Bahcall (1989) contains a detailed description of the different solar neutrino experiments.

The different neutrino experiments currently under way include the following:

1. The Homestake experiment is a radiochemical experiment that observes neutrinos via the reaction

$$\nu_e + \mathrm{Cl}^{37} \rightarrow \mathrm{e}^- + \mathrm{Ar}^{37}. \tag{12}$$

   The radioactive Ar^{37} is extracted from a C_2Cl_4 fluid. The threshold energy is 0.8 MeV.
2. The Kamiokande experiment is based on neutrino–electron scattering in water. The direction of the neutrinos can be inferred in this experiment, but it has a very high threshold neutrino energy of 7.5 MeV. A scaled-up version of the Kamiokande experiment (Super-Kamiokande) is currently in progress; it will permit far better statistics and a detailed analysis of the neutrino energy spectrum.
3. The GALLEX and SAGE experiments detect the absorption of neutrinos in gallium via the reaction

$$\nu_e + \mathrm{Ga}^{71} \rightarrow \mathrm{e}^- + \mathrm{Ge}^{71}. \tag{13}$$

   The threshold energy for this process is low (0.23 MeV), making it possible to detect the majority of the neutrinos produced in the Sun. These are radiochemical experiments, similar to the Homestake experiment.
4. The SNO experiment, currently underway, uses heavy water to observe Cherenkov light from electrons interacting with deuterium in addition to the neutrino–electron scattering to which the Kamiokande experiment is sensitive. The charged-current reaction

$$\nu_e + \mathrm{H}^2 \rightarrow \mathrm{e}^- + \mathrm{p} + \mathrm{p} \tag{14}$$

   is sensitive to the electron neutrinos produced by the Sun, while the neutral-current reaction

$$\nu + H^2 \rightarrow \nu + p + n \qquad (15)$$

is sensitive to other neutrino flavors. This could provide an important test of some theories of new neutrino physics, which explain the solar neutrino deficit by postulating that some of the electron neutrinos produced in the Sun are converted into other flavors as they travel from the center of the Sun to the Earth.

The major processes that produce neutrinos in the Sun are as these:

1. The pp reaction produces a low-energy neutrino. The GALLEX and SAGE experiments are sensitive to this neutrino, as well as those from the other reactions listed below.
2. The pp reaction can be mediated with an electron (the pep reaction). All of the experiments except Kamiokande can detect pep neutrinos.
3. After ^{3}He is produced, there are two branches of the pp chain. ^{3}He + ^{3}He occurs 85% of the time and does not produce a neutrino; ^{3}He + ^{4}He occurs 15% of the time and has two possible terminations, each of which produces a neutrino (^{7}Be and ^{8}B). The ^{8}B neutrino is highly energetic and can be detected in all of the experiments; Kamiokande and SNO are sensitive only to the ^{8}B neutrinos. The other experiments can also detect some of the lower-energy ^{7}Be neutrinos.
4. The Sun can also process hydrogen into helium by using the C, N, and O nuclei as catalysts; these reactions are responsible for about 2% of the Sun's luminosity and produce neutrinos that can be detected by GALLEX, SAGE, and the Homestake experiment.

The cross section for neutrino capture is extremely small; for the Homestake experiment the measured capture rate is $2.55 \pm 0.17(\text{stat}) \pm 0.18(\text{syst})$ solar neutrino units (SNUs), which are units of 10^{-36} events per target atom per second. Detecting such rare events is technically challenging (see Bahcall, 1989, for a discussion of the experimental techniques). By comparison, the theoretical fluxes are of the order of 8–9 SNUs (Sec. 4.3.3). Different experiments are sensitive to neutrinos of different energies and the results of different experiments can therefore be combined to form a neutrino energy spectrum of the Sun. One of the most interesting developments in the solar neutrino problem has been the apparent strong dependence of the discrepancy between theory and observation on neutrino energy; this feature is difficult to explain by changing the theoretical fluxes alone. The comparison between theory and observation is discussed in Sec. 4.6.

3.2 Solar Oscillations

Solar oscillations can be observed through either intensity fluctuations or Doppler shifts on the solar surface as a function of position and time. The amplitudes are at the centimeter per second level, with characteristic periods of the order of 5 min. These fluctuations arise because internal waves in the Sun can be refracted by the strong density gradient in the outer layers of the Sun. Therefore, the Sun acts as an acoustic cavity, and there will be constructive interference for certain characteristic frequencies. The frequencies ($\approx 10^7$ modes of oscillation) with which it oscillates can be used to deduce a variety of internal properties. The restoring force for the solar oscillations detected to date is pressure, and so they are sometimes referred to as p-mode oscillations. These modes have their maximum amplitude in the outer layers, making them an ideal diagnostic of the outer layers of the Sun. Waves where the restoring force is gravity (g modes) have not yet been unambiguously identified; because they have their maximum amplitude in the core, a detection of solar g modes would provide important tests of the conditions at the center of the Sun. An extensive discussion of the observational and theoretical studies of the solar oscillations, referred to as helioseismology, can be found in Part II of Cox *et al.* (1991).

3.2.1 Oscillations as a Diagnostic of the Thermal Structure Expressed in terms of spherical harmonics (n, l, m), the depth to which a given p mode will penetrate depends strongly on l: lower-l modes can penetrate further into the Sun. Information from these modes can be combined to form a map of the speed of sound as a function of depth in the solar interior. The errors are largest in the deep interior because there are few p modes that penetrate very deeply, and the frequencies of these low-l modes have proven difficult to measure. However, high-quality data for the low-l p modes (and therefore good information on the physical conditions in the deep interior of the Sun) have recently become available (Tomczyk *et al.*, 1995). The sound speed inferred in the solar interior is compared with theoretical predictions in Sec. 4.

3.2.2 Internal Rotation In the presence of rotation, there is a splitting of the p-mode frequencies that can be used to infer the internal solar rotation as a function of latitude and depth. The rotation in the deep solar interior is currently uncertain, but there is good information on the rotational properties outside the core of the Sun.

4. INTERNAL STRUCTURE OF THE SUN

The internal properties of the Sun that are described in this section are inferred from a theoretical solar model (Sec. 2) that satisfies the global properties of the Sun as described in Sec. 1. Throughout this section theory will be compared with data on the internal properties of the Sun (Sec. 3); current theoretical models are in good agreement with solar oscillation data but conflict with solar-neutrino data. We begin with an overview of the major components of the internal structure of the Sun in Secs. 4.1–4.3; a detailed discussion of the different layers of the solar interior is then presented in Secs. 4.4–4.6.

4.1 Mass and Luminosity Distributions

The mass fraction M and luminosity L of the Sun as functions of radius are shown in Fig. 2. The Sun is highly centrally concentrated; 60% of its mass is contained within $0.3R_\odot$, 90% of the mass is contained within $0.5R_\odot$, and 98% of the mass is contained within $0.7R_\odot$. The central density of $156\,\mathrm{g\,cm^{-3}}$ is far higher than the mean density of $1.4\,\mathrm{g\,cm^{-3}}$. The energy generation of the Sun is concentrated in the deep interior; 46% of the luminosity is generated within $0.1R_\odot$, 95% of the energy is generated within $0.2R_\odot$, and effectively all of the energy (with the exception of energy from gravitational contraction) is generated within $0.4R_\odot$. Significant conversion of hydrogen into helium is also concentrated in the inner $0.2R_\odot$ (see Sec. 4.3 below). In the sections that follow, this will be referred to as the solar core.

4.2 Thermal Structure

The pressure, temperature, and density of the Sun as functions of radius are shown in Fig. 3. Note that the temperature declines much less rapidly than the density, which in turn declines much less rapidly than the pressure. The speed of sound as a function of depth inferred from seismology is shown in Fig. 4(a); the fractional difference between the sound speed of the Sun and that of the theoretical model discussed in this article is shown in Fig. 4(b). Theory agrees with observation to an accuracy of 0.2% throughout the solar interior. The deviations from the predictions of the model are interesting and will be discussed below.

The actual, adiabatic, and radiative temperature gradients are compared in Fig. 5. Energy is carried by radiation in the interior; in the outer layers energy is carried by convection (conduction is not an important mode of energy transport within the Sun). The time scale for convection is short compared with the solar age, which implies that the outer layers of the Sun are fully mixed; the interior can experience composition gradients due to nuclear burning and gravitational settling, and these gradients can be reduced by mixing. We can therefore divide the outer layers of the Sun into a surface convection zone and a radiative mantle above the nuclear burning core.

There is a change in the derivative of the speed of sound as a function of depth at the base of the surface convection zone. The base of the convection zone inferred from helioseismology is $0.713 \pm 0.003R_\odot$. Theoretical models that include the latest radiative opac-

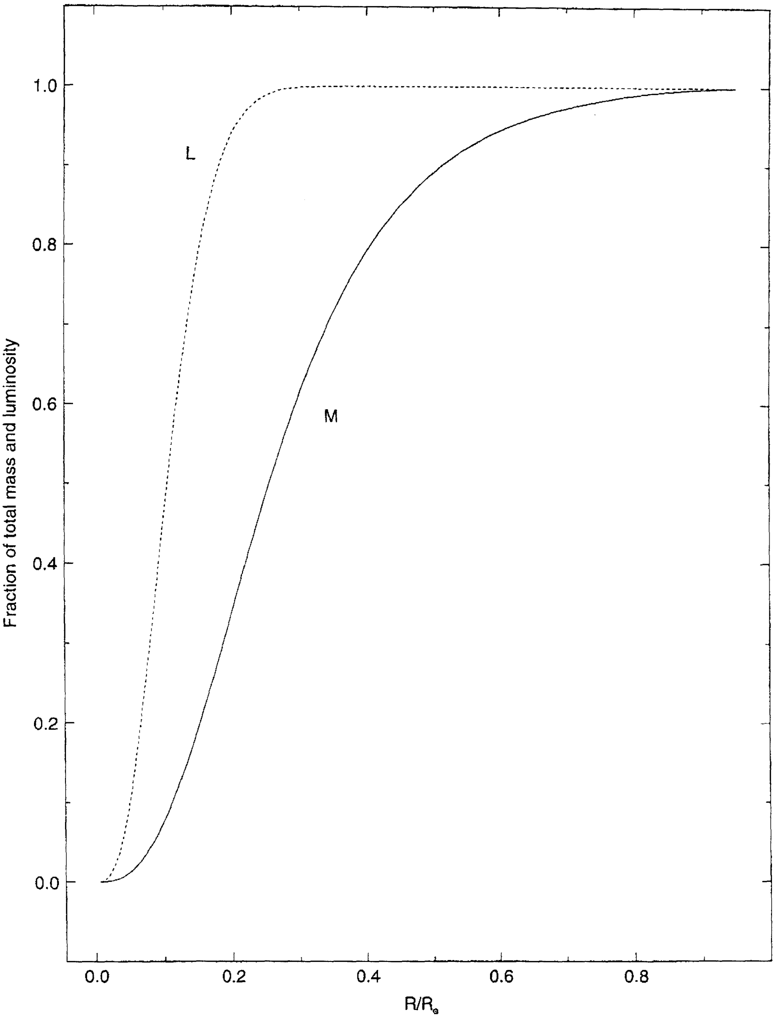

FIG. 2. The fractions of the total luminosity (dashed line) and mass (solid line) as functions of radius fraction in a theoretical solar model.

ities and the gravitational settling of helium are in good agreement with the measured depth of the surface convection zone.

4.3 Abundance Profiles

The hydrogen and metal abundances as functions of radius are shown in Fig. 6. The strong decrease in the central hydrogen abundance within $0.2R_\odot$ is caused by hydrogen burning; the increase in hydrogen in the surface layers is a consequence of the gravitational settling of ^{4}He. Because the Sun is not burning elements heavier than ^{4}He, the radial profile of the metal abundance shows the effect of gravitational settling of heavy elements from an initial mass fraction of 0.02. There is a 10% drop in the surface metal abundance and a 5% increase in the central metal abundance that result from settling.

Different species burn at different temperatures; the abundances as functions of radius of ^{3}He and the major isotopes involved in the CNO cycle are shown in Fig. 7. The small increases in abundance of C, N, and O below the convection zone are caused by diffusion (diffusion of ^{3}He was not included in this calcula-

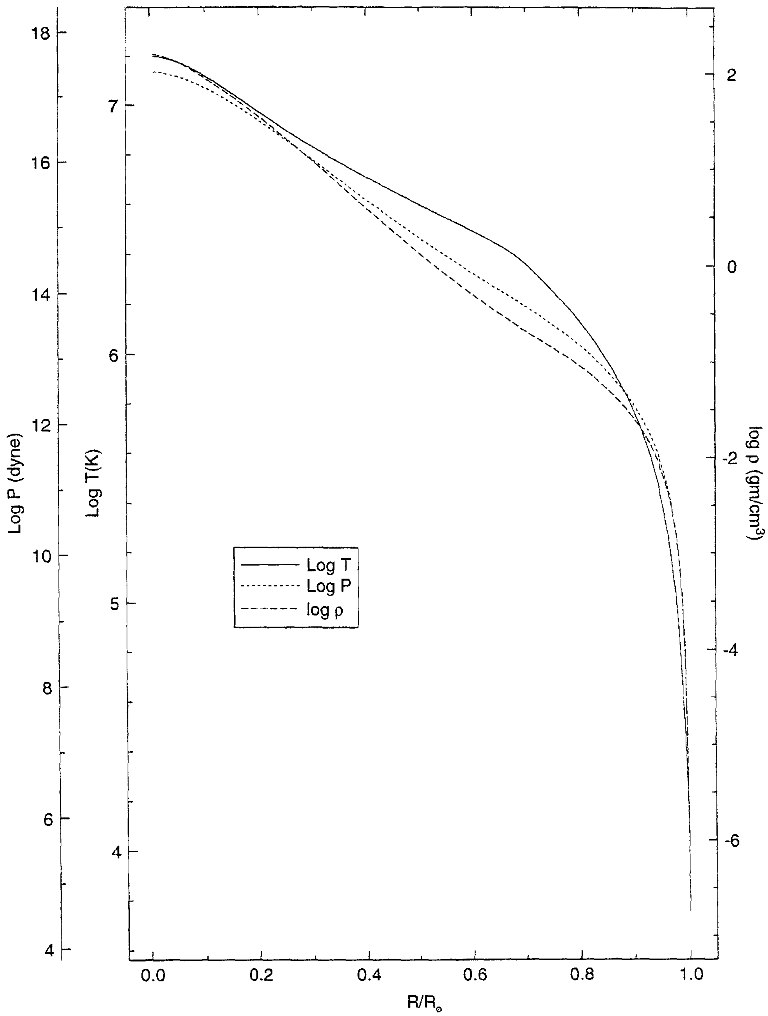

FIG. 3. Pressure, temperature, and density on a logarithmic scale as functions of radius fraction in a theoretical solar model.

tion). The peak in the abundance of ^{3}He at $0.26R_\odot$ and the peak in the abundance of ^{13}C at $0.18R_\odot$ are caused by nonequilibrium nuclear burning. ^{12}C burns into ^{13}C at a lower temperature than ^{13}C burns into ^{14}N; there will therefore be a region where ^{13}C is produced more efficiently than it is destroyed. A similar phenomenon occurs for ^{3}He. The strong increase in N and decrease in C interior to $0.15R_\odot$ occurs because the surface C/N ratio (3) is different from the C/N nuclear equilibrium ratio of 1/200. As the temperature rises, the rate of the reactions that destroy ^{3}He rise faster than the rate of the reaction that produces ^{3}He; as a result, the ^{3}He abundance decreases dramatically in the solar core. There is a slight depletion of O and increase in N in the very central region from partial processing of oxygen into nitrogen, which occurs only at relatively high temperatures.

We discuss the detailed properties of the three major layers of the Sun (convective envelope, radiative mantle, and nuclear burning core) separately below.

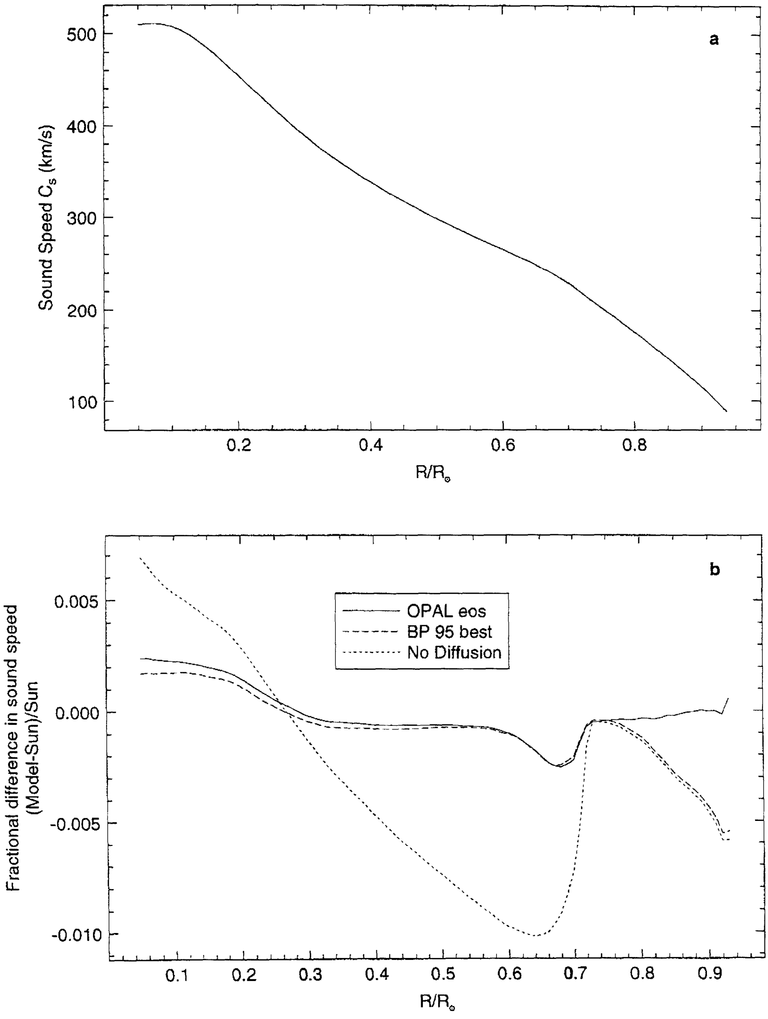

FIG. 4. (a) The sound speed as a function of radius fraction that is inferred from helioseismology; the outer layers ($R > 0.94R_\odot$) are not shown. Data are from S. Basu and J. Christensen-Dalsgaard (personal communication). (b) The difference between the real Sun and different theoretical models. The short-dashed line is the standard model of Bahcall and Pinsonneault (1992), which does not include gravitational settling; the long-dashed line is the model of Bahcall *et al.* (1995), which includes gravitational settling; the solid line is the same model with the improved OPAL equation of state (Rogers *et al.*, 1996).

4.4 Convection Zone

The opacity of matter to radiation is high at low temperatures and in regions where ionization is occurring; both conditions characterize the outer layers of the Sun. The ionization structure of the outer layers of the Sun is illustrated in Fig. 8. In this region, energy is transported through mass motions (convection). Because the time scale for energy transport via convection is short (of the order of a month) compared with the lifetime of the Sun (4.57 Ga) the convection zone is fully mixed. Typical convective velocities are of order 1 km s^{-1} and gradually decline with increased depth.

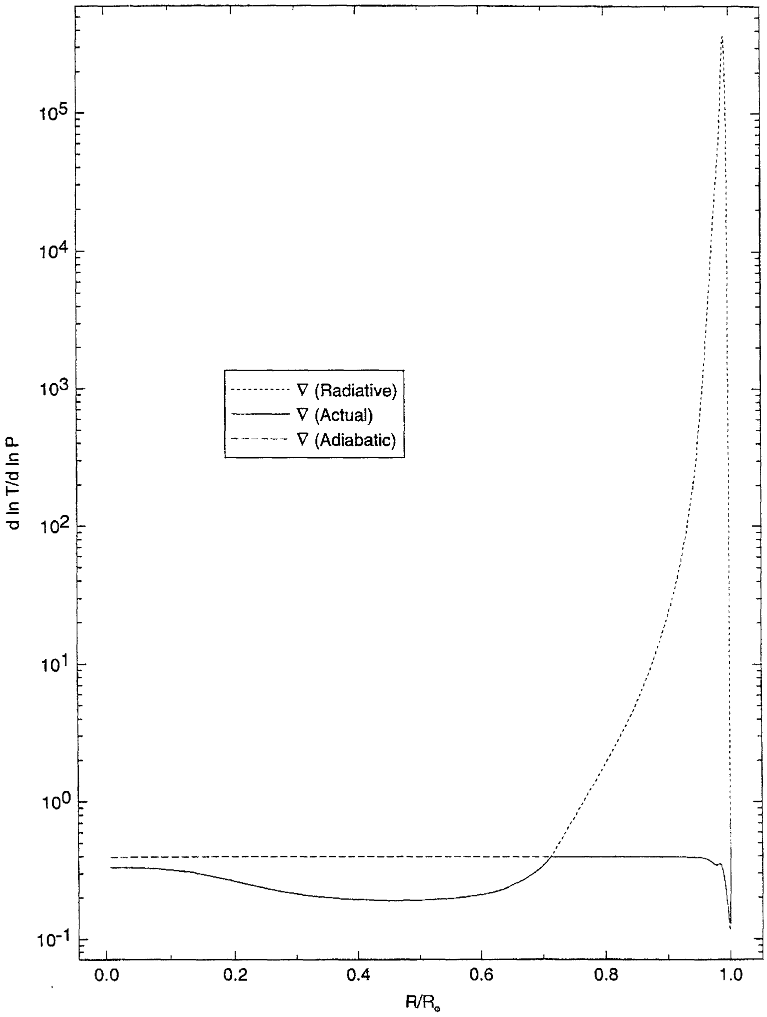

FIG. 5. Actual, radiative, and adiabatic temperature gradients as functions of radius fraction in a theoretical solar model. The actual and radiative gradients are identical for $R < 0.713R_\odot$; the actual gradient is very close to the adiabatic gradient for $R > 0.713R_\odot$ except for a thin layer near the surface (see Fig. 9).

4.4.1 Superadiabatic Layer In the outer layers of the Sun there is a transition from mostly neutral H and He at the surface to full ionization. In this region the adiabatic temperature gradient drops and the actual temperature gradient differs significantly from the adiabatic value (Fig. 9). In this superadiabatic region the model properties are sensitive to the treatment of convection. In the lower portion of the convection zone the superadiabatic temperature gradient is small.

4.4.2 Surface versus Initial Abundances The surface mass fraction of ^{4}He inferred from helioseismology is 0.242 ± 0.003, while the initial Y found from solar models ranges from 0.27 to 0.29. This is evidence for mild gravitational settling of ^{4}He; theoretical calculations predict a comparable degree of settling for heavier elements ($\approx 10\%$).

The surface abundances of both Li and Be are significantly below their meteoritic values, and the base of the convection zone is not deep

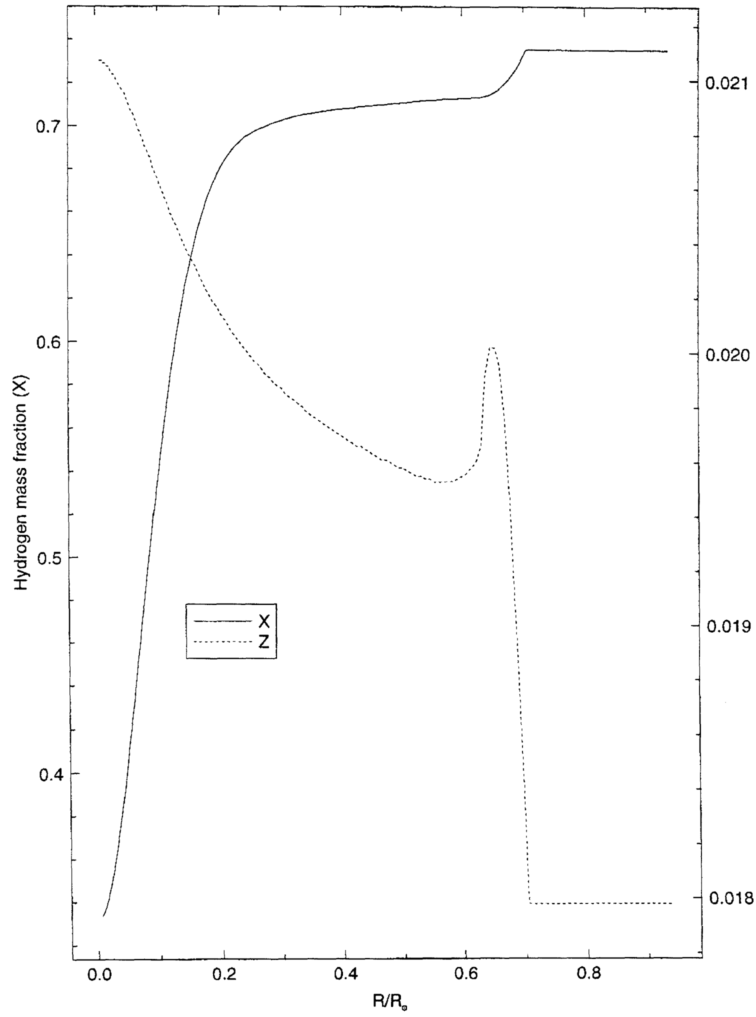

FIG. 6. Mass fractions of hydrogen (solid line, left axis) and all elements heavier than helium (dashed line, right axis) as functions of radius fraction in a theoretical solar model.

and hot enough to burn either. Although stars like the Sun do experience mild Li depletion early in their lifetime, they are observed to have abundances much higher than the current solar photospheric value. The expected degree of gravitational settling for Li is of of order of that found for He, and the degree expected for Be is smaller. A mild mixing mechanism, in addition to convection, is therefore required to explain the surface light element abundances, Models that include mixing induced by rotation are capable of reproducing the observed surface abundances of both Li and Be.

4.4.3 Rotation as a Function of Depth and Latitude The seismic inversions indicate that the surface differential rotation as a function of latitude persists throughout the surface convection zone. The rotation as a function of depth at a given latitude is nearly constant through the surface convection zone. There is a narrow region at the base of the surface

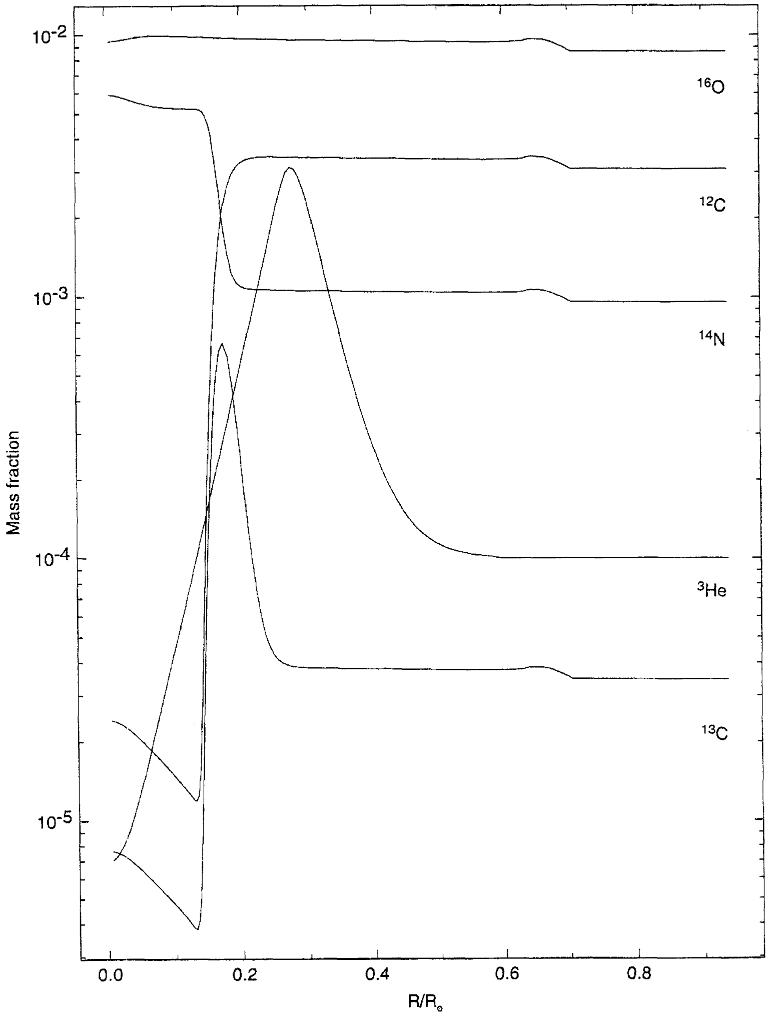

FIG. 7. Mass fractions of ^{3}He and the important C, N, and O isotopes on a logarithmic scale as functions of radius fraction in a theoretical solar model.

convection zone where differential rotation as a function of latitude vanishes; the depth of this region is currently unresolved. The layer below the surface convection zone is the likely seat of the solar dynamo, responsible for the sunspot cycle and the generation of the Sun's magnetic field.

4.5 Radiative Mantle

Below $0.713R_\odot$ the Sun is stable against convection. Nuclear energy generation does not become significant until about $0.2R_\odot$; the intervening region can be considered to be a radiative mantle surrounding the nuclear-burning core.

4.5.1 Evidence for Microscopic Diffusion and Mixing The depth of the solar convection zone and the surface He abundance inferred from helioseismology both require gravitational settling of helium in the solar envelope. Models with only *diffusion*, however, predict a sharp change in the mean molecular mass below the surface convection zone, which is not seen; this produces the discrepancy between the model and the Sun seen

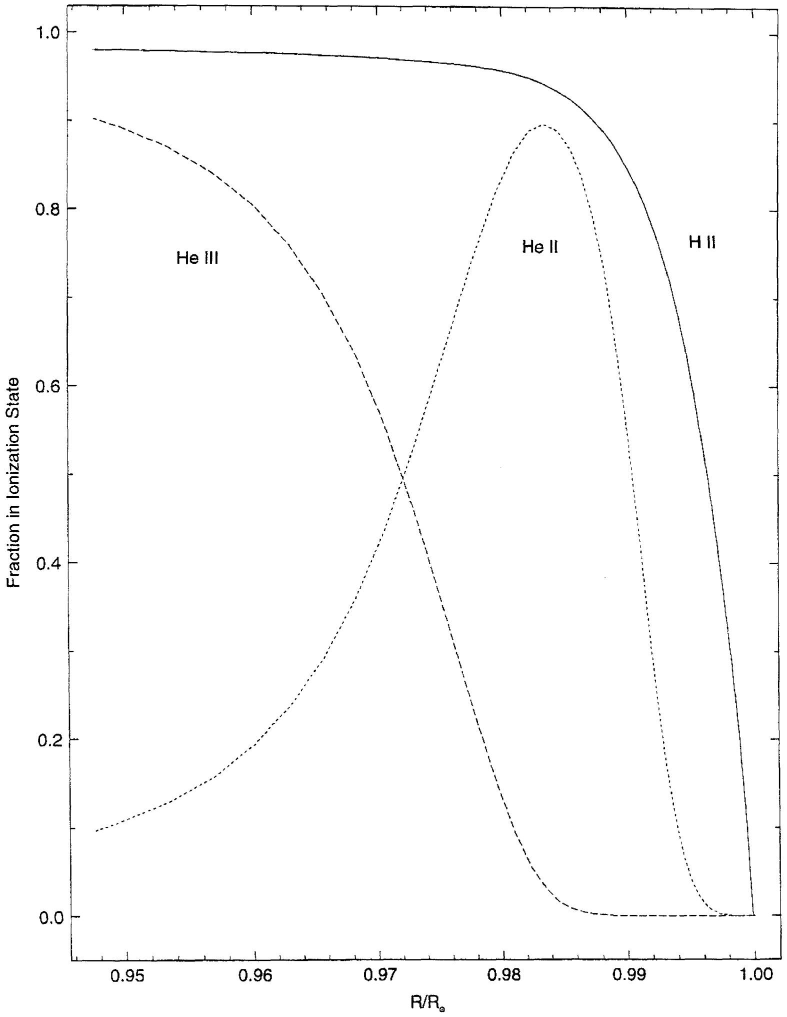

FIG. 8. The fractions of hydrogen that is fully ionized (H II, solid line), helium that is singly ionized (He II, short-dashed line) and helium that is doubly ionized (He III, long-dashed line) as functions of radius fraction in the outer layers of a theoretical solar model.

in Fig. 4(b). In addition, the surface abundances of lithium and beryllium require a slow mixing mechanism. The survival of these light elements places strong constraints on how much mixing can have occurred, and calculations indicate that mixing consistent with the surface abundances cannot entirely remove the effects of gravitational settling. Combined with the data on the solar rotation curve, this implies that the mantle of the Sun is the site of both slow separation and mixing processes not present in standard stellar models.

4.5.2 Rotation as a Function of Depth

There is general agreement that the rotation of the Sun depends neither on latitude nor on depth between a transition region near the base of the convection zone and $\approx 0.4R_\odot$. The shear at the base of the solar convection zone is a likely site for the solar dynamo that gives rise to the Sun's magnetic field. There have been contradictory claims, ranging from a mild decrease to rigid rotation to increased rotation in the region between $0.2R_\odot$ and $0.4R_\odot$. The most recent inversions of seismic data

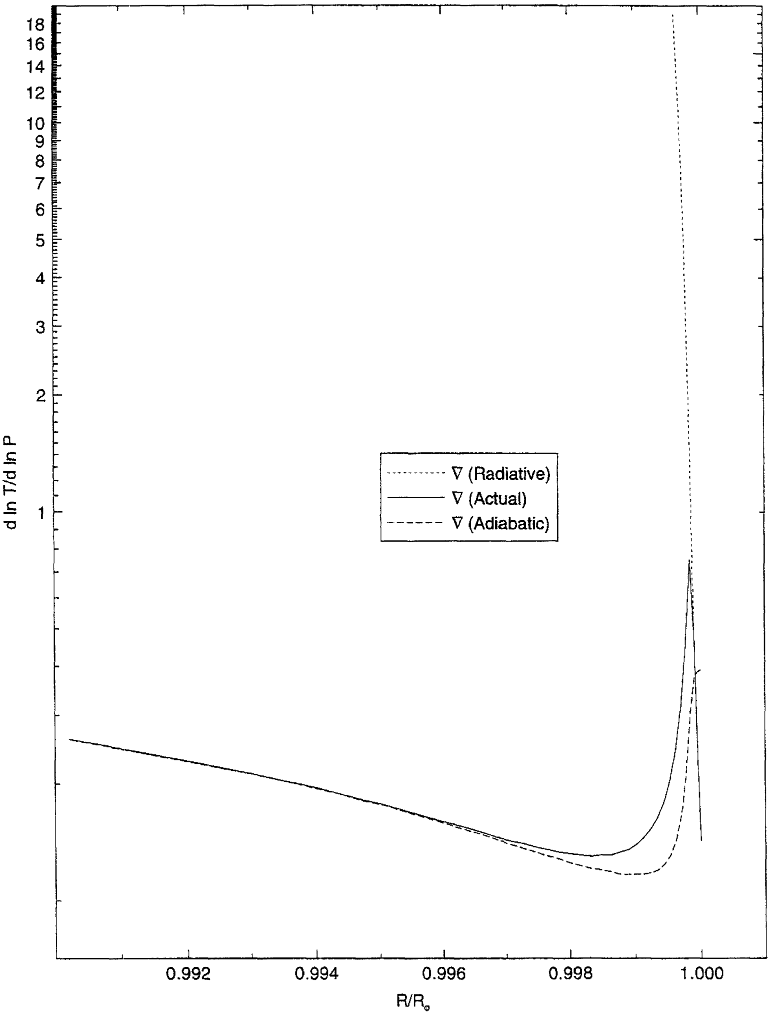

FIG. 9. An enlarged portion of Fig. 5, showing the behavior of the adiabatic, radiative, and actual temperature gradients near the solar surface as functions of radius fraction. The actual temperature gradient starts to depart significantly from the adiabatic gradient at 0.996; the radiative gradient is off the scale before 0.9985 and drops sharply with increased radius, becoming less than the adiabatic gradient just below the solar atmosphere.

favor essentially solid-body rotation down to $0.2R_\odot$ (Tomczyk *et al.*, 1995). Because the Sun is experiencing angular-momentum loss via the solar wind, this implies that the time scale for angular-momentum transport in the radiative core is less than the age of the Sun.

4.6 Nuclear-Burning Core

The deep core is the site of the Sun's energy generation. Conditions in this region are tested directly by the solar neutrino experiments, which are in disagreement with theory. The helioseismic data, however, are in much better agreement with the theoretical models in the core. Because large changes in the solar-model fluxes would required large changes in the thermal structure of the solar core, this severely restricts the allowed classes of solar-model solutions for the solar neutrino problem.

4.6.1 Thermal Structure Nuclear burning has altered the composition and temperature of the core of the Sun since its birth. To first order, the local sound speed scales as $(T/\mu)^{1/2}$. The agreement between observation and theory is at the 0.2% level in the core, which would require finely tuned changes in the temperature and composition to preserve the close observed match between the two.

4.6.2 Abundances and Energy Generation as Functions of Depth A series of different nuclear reactions produce energy in the Sun. Because nuclear reactions are strongly temperature sensitive, the reaction rates are usually a maximum at the center of the Sun. The differing temperature dependences of the individual reactions, however, imply that the degree of central concentration of the energy generation will differ from one reaction to the next. This in turn is reflected in the detailed abundance profiles seen in Figs. 6 and 7. In later phases of evolution the convection zone of Sunlike stars becomes much deeper and incorporates partially processed material from the core into their surface convection zone where it can be seen. Surface abundance changes from this dredge-up have been seen and are in fairly good agreement with theoretical predictions.

4.6.3 Predicted Neutrino Fluxes The neutrino fluxes from the different experiments are in contradiction with those predicted by theoretical models. The measured thermal structure is in good agreement with theoretical models; this implies that a large reduction in the neutrino fluxes predicted by these models is unlikely. The most likely explanation is that the Sun is producing neutrinos in the amount expected from the theoretical models, but they are being converted from electron neutrinos (which can be detected) into other kinds of neutrinos, which cannot be measured by the current generation of experiments. If there is a nonzero neutrino mass, electron neutrinos can be converted into other flavors between the region where they are produced and the Earth. The SNO experiment, which is currently under way, is sensitive to both neutral- and charged-current reactions. If the electron neutrino oscillates into a μ or τ neutrino, SNO should be able to provide direct experimental confirmation of this phenomenon. Below we compare the theoretical predictions and the observational data.

4.6.3.1 Kamiokande. The measured flux of ^{8}B neutrinos (with energies above 7.5 MeV) is $[3.0 \pm 0.41(\mathrm{stat}) \pm 0.35(\mathrm{syst})] \times 10^6\,\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$. This compares with a theoretical prediction of $6.6(1.0^{+0.14}_{-0.17}) \times 10^6\,\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$. The observed flux is thus only about 45% of the predicted value.

4.6.3.2 Homestake. The Homestake experiment is sensitive to both the higher-energy ^{8}B neutrinos and those from other sources, such as ^{7}Be and the pep reaction. It is not sensitive to the lowest-energy neutrinos arising directly from the pp reaction. The measured flux (in units of 1 SNU, or 10^{-36} interaction per target atom per second) is $2.55 \pm 0.17(\mathrm{stat}) \pm 0.18(\mathrm{syst})$ SNU; the theoretical prediction is $9.3^{+1.2}_{-1.4}$ SNU. This discrepancy is particularly difficult to explain with standard models in conjunction with the Kamiokande data discussed above. The measured Kamiokande flux can be converted into a minimum flux expected for the Homestake experiment, which leaves little or no room for any contribution from neutrinos produced by other reactions to which Homestake is sensitive.

4.6.3.3 GALLEX/SAGE. The GALLEX and SAGE experiments are sensitive to all of the neutrinos detected by the Homestake and Kamiokande experiments, plus the low-energy pp neutrinos. The measured fluxes from GALLEX and SAGE are, respectively, $79 \pm 10(\mathrm{stat}) \pm 6(\mathrm{syst})$ SNU and $69 \pm 10(\mathrm{stat}) \pm 6(\mathrm{syst})$ SNU. This compares with a theoretical prediction of 137^{+8}_{-7} SNU, which is relatively weakly model dependent. Of this total about 70 SNU arises directly from the pp reaction; the magnitude of this component is fixed by the measured energy output of the Sun.

5. SUMMARY

The Sun can be divided up into three distinct layers: the nuclear-burning core, a radiative mantle, and a surface convection zone. The speed of sound as a function of depth provides strong constraints on theoretical models, and the overall agreement between theory and observations is at a level (0.2% in the sound speed) not typically found in astronomy. The observed solar neutrino fluxes do not agree with those expected from theoretical models; the most likely explanation is a nonzero neutrino mass. A detailed comparison of model properties with the solar data provides evidence for element-separation processes and mild envelope mixing below the surface convection zone.

GLOSSARY

Adiabatic Temperature Gradient (∇_{ad}): The logarithmic derivative of temperature with respect to pressure for a fluid element that does not exchange heat with its surroundings. If the radiative temperature gradient exceeds the adiabatic temperature gradient in a given region, the region is unstable with respect to convection and energy is transported by mass motions rather than by photon diffusion.

CNO Cycle: A series of nuclear reactions in which carbon, nitrogen, and oxygen nuclei are used as catalysts for the conversion of hydrogen into helium. These reactions account for about 2% of the solar energy output.

Convection Zone: A region where energy is transported by mass motions; this occurs in the outer layers of the Sun.

g Mode: A mode of oscillation in the Sun where the restoring force of the wave is gravity; these modes have not been definitively identified in the Sun, but are predicted to have a characteristic period of 3 h.

Helioseismology: The study of the internal structure of the Sun deduced from the properties of nonradial oscillations observed at the solar surface.

Mixing-Length Theory: A simplified theory of convective energy transport used extensively in theoretical solar models, in which a characteristic length scale α is assumed and the characteristic velocities of fluid elements and the temperature gradient are then calculated. The value of the mixing length α is usually adjusted to reproduce the solar radius at the solar age.

Opacity: A measure of the mean free path of photons in the presence of matter; a typical length scale is 1 cm in the Sun. Astrophysical calculations use a weighted average over photon frequency, called the Rosseland mean opacity, and solve a diffusion equation to infer the temperature gradient needed to carry a given flux.

p Mode: An acoustic mode of oscillation in the Sun where the restoring force of the wave is pressure; these modes have a characteristic period of 5 min.

pp Chain: A series of nuclear reactions in which protons combine directly to form the intermediate species deuterium and helium-3, followed by three different branches that produce helium-4. These reactions produce 98% of the solar energy output.

Radiative Core: A region where energy is transported by photon diffusion; this occurs in the inner layers of the Sun.

Radiative Temperature Gradient (∇_{rad}): The logarithmic derivative of temperature with respect to pressure that would be required to carry the local flux by the diffusion of photons.

INTRODUCTION

The two common isotopes of helium, ^{3}He and ^{4}He, are unique in remaining liquid down to absolute zero temperature. At low temperatures the liquid phases of both isotopes become superfluid. The most apparent property of a superfluid is its ability to flow without friction. This leads to the possibility of non-decaying persistent currents flowing indefinitely around loops. However, on a more fundamental level, the really unique aspects of superfluidity lie in the influence of the underlying quantum mechanics on the macroscopic behavior of the liquid.

Superfluidity was first observed in ^{4}He just before the second World War, and the effect was elucidated and named by Kapitza in Moscow in 1942. The superfluid transition temperature in liquid ^{4}He is close to 2 K. The superfluid transition in liquid ^{3}He does not occur until much lower temperatures, about 1 mK, and was first observed in 1971 by Osheroff, Richardson, and Lee, who received the Nobel Prize for this work in 1996.

The properties of the two helium isotopes are almost identical at ordinary temperatures; they are inert gasses with very weak interatomic forces. Nevertheless, their superfluid states are very different. The differences arise as a direct consequence of the nuclear spin, which is zero for ^{4}He and $\frac{1}{2}$ for ^{3}He. Even though the interatomic forces are almost identical for the two isotopes, quantum mechanics

dictates that liquids at very low temperatures will behave very differently depending on the net intrinsic spin of the constituent particles.

Superfluidity, unlike the analogous superconductivity seen in some metals and conducting ceramics, has as yet found very few practical applications outside low-temperature research. The real impact of the superfluid state is the simplicity with which it can be described. Quantum mechanics describes a superfluid, consisting of countless numbers of atoms, as a single macroscopic object (wave function). These systems therefore provide a very rich laboratory for testing ideas from other areas of physics, even extending as far as particle physics and cosmology.

1. WHAT IS SUPERFLUIDITY?

The two isotopes of helium, the common isotope ^{4}He and the lighter isotope ^{3}He, are so light and so weakly interacting that their behavior is dominated by quantum mechanics much more than that of heavier elements. As a result, helium in the liquid phase is often described as a quantum fluid.

The laws of thermodynamics dictate that a system becomes more ordered as the temperature is reduced. A typical example is the solidification of a substance (such as the freezing of water) as the temperature is reduced below the melting point. The level of order of the system is increased on solidification, since in the liquid the component atoms or molecules are randomly distributed in space, whereas in the solid they take up fixed positions relative to each other and in general form a regular ordered crystalline structure.

The property of superfluidity in helium follows from the fact that helium is unique in remaining liquid down to absolute zero temperature and will only solidify if a pressure of some 30 atm is applied. It is the unusually strong influence of quantum mechanics on helium that prevents solidification. To form a solid, each atom must be confinable in its place in the crystal. However, a particle may only be confined within a region of space at the expense of increasing its energy (the zero-point energy). For helium, which has weak interatomic forces, this energy is large enough to overcome the attractive forces between the atoms that would otherwise lead to solidification at a sufficiently low temperature.

While liquid helium cannot increase its order by becoming solid, there are other ways in which it may order. In fact, at some low temperature the atoms in the liquid begin to fall into the same-lowest energy quantum mechanical state. It is this process that leads to superfluidity. The term was first coined by Kapitza to describe the properties of liquid ^{4}He.

Once a significant fraction of the atoms occupy the same quantum mechanical state, the behavior becomes quite different from what we intuitively expect for normal liquids. For example, there is no viscosity. Viscosity implies the process whereby atoms are mutually scattered (with each atom changing its state) and information about velocity inhomogeneities is gradually transmitted through the liquid. If all the atoms are in the same state in the first place, then such scattering processes cannot occur; *i.e.* the viscosity is zero. With zero viscosity, flows of the liquid can be set up without any pressure gradient. Furthermore, in the absence of scattering processes, these currents may, in principle, continue indefinitely. It is this behavior that gave rise to the term superfluidity in analogy with the term superconductivity, which describes the closely related behavior of the electron gas in certain metals.

1.1 Bosons, Fermions

While both isotopes of helium (^{4}He and ^{3}He) become superfluid, the mechanism by which the ordering takes place is very different for the two isotopes.

All particles have an intrinsic angular moment or spin. Quantum mechanics distinguishes between two types of particle depending on the magnitude of their spin. These are known as fermions and bosons and have very different properties. Fermions are particles having a half-integral spin quantum number, whereas bosons have an integral spin quantum number. The building blocks of matter (neutrons, protons and electrons) are all fermions, whereas particles that carry information about forces—for example, photons (telling about the motion of charges)—are bosons. The distinction applies also to composite objects. An object made up of an even number of

Population

FIG. 2. Bose–Einstein condensation; below a critical temperature a macroscopic number of particles begins to populate the lowest energy state.

fermions becomes a boson (because the total spin in now integral), while an object constructed of an odd number of fermions remains a fermion.

A ^{4}He atom is made up of two electrons, two protons and two neutrons. The ^{4}He atom is therefore a boson (with spin 0). In contrast, ^{3}He is made from two electrons, two protons but only one neutron, and therefore the atom (with spin $\frac{1}{2}$) is a fermion.

The quantum mechanical distinction between these classes of particle comes into play when we have several particles occupying the same space. As shown schematically in Fig. 1, fermions are only allowed to occupy a quantum mechanical state singly, *i.e.*, no more than one particle per state. Bosons, on the other hand, face no such restriction, and there is no limit to how many particles may be in the same state with identical energies and momenta.

1.2 Bose–Einstein Condensation

At high temperatures, an assembly of bosons will be distributed over a large number of states. As the temperature is reduced the particles take up a distribution centered on lower and lower energies until at some temperature particles start filling the lowest state or ground state. This process is known as the Bose–Einstein condensation, and the temperature at which it begins is the Bose–Einstein condensation temperature (T_{BE}). This process is illustrated in Fig. 2. When a macroscopically large number of the particles occupy a single state the level of order in the system increases. In this case, unlike in a crystal, the order is not in terms of position but in terms of momentum, since the particles collect in the lowest state where the momentum is zero.

A system of bosons which are all in the same state displays some very unusual properties. If all the bosons are identical in every sense then they must behave as a single "object". It is meaningless to think of the system in terms of distinct individual particles since (according to quantum mechanics) it is fundamentally impossible to distinguish one particle from another. In consequence, while the bosons are governed by the laws of quantum mechanics only on the *microscopic scale for* temperatures higher than T_{BE}, at lower temperatures, once there is a macroscopic occupation of the lowest state, the bosons coalesce into a single macroscopic "object" represented by a single wave function. The system is still governed by quantum mechanics, but now operating on the entire macroscopic sample. Such an assembly of particles described by a common wave function is known as a coherent state.

1.3 Cooper Pairing

Direct Bose–Einstein condensation is impossible for a system of independent fermions since no more than one fermion may occupy a single state. Indeed, at moderately low temperatures a system of weakly interacting fermions has all the low-lying single-particle states singly occupied up to a cutoff energy called the Fermi energy. Nevertheless, liquid ^{3}He undergoes a transition into a superfluid state and also the conduction electrons of many metals undergo an analogous transition into a superconducting state. The superfluid state clearly exhibits properties associated with a coherent quantum state and therefore must represent an ordering related to Bose–Einstein condensation but in a system of fermions.

The solution to the problem was provided by Bardeen, Cooper, and Schrieffer (BCS) in 1957 (Bardeen *et al.*, 1957) who found that an attraction between two fermions with energies close to the Fermi energy will always lead to the formation of bound pairs at sufficiently low temperatures. These pairs are known as Cooper pairs. While the work of BCS was in the context of superconductivity, their ideas are equally applicable to ^{3}He atoms. The pairs prefer to form from fermions with equal and opposite momenta such that the combined momentum of the pair is zero. Furthermore, since an even number of fermions is involved, each pair is itself a boson. Therefore at sufficiently low temperatures, any attractive force between the fermions will lead to the production of Cooper-pair bosons, which are free to form a coherent ground state. This is, of course, a variant of Bose–Einstein condensation in which the bosons are formed from pairs of fermions.

The binding energy of the Cooper pairs ensures that the pairs have a lower energy than the constituent unbound particles. This means that there must be a minimum energy difference between an unpaired particle and those particles which are paired. This is known as the energy gap, usually represented by Δ. When a Cooper pair is broken, at least two unpaired particle excitations must be produced, needing a minimum energy of 2Δ.

2. SUPERFLUID ^{4}He

2.1 Cooling Methods

To reach the temperature at which liquid ^{4}He becomes superfluid at around 2 K requires only quite modest equipment. All that is needed is a simple insulating glass Dewar flask that may be filled with liquid ^{4}He and a modest vacuum pump to reduce the pressure of the vapor phase to reduce the temperature. A suitable system is shown in Fig. 3. It is particularly convenient for experimentalists that the superfluid transition can be reached simply by the reduction of the pressure over the liquid phase.

Liquid ^{4}He in equilibrium with its vapor at

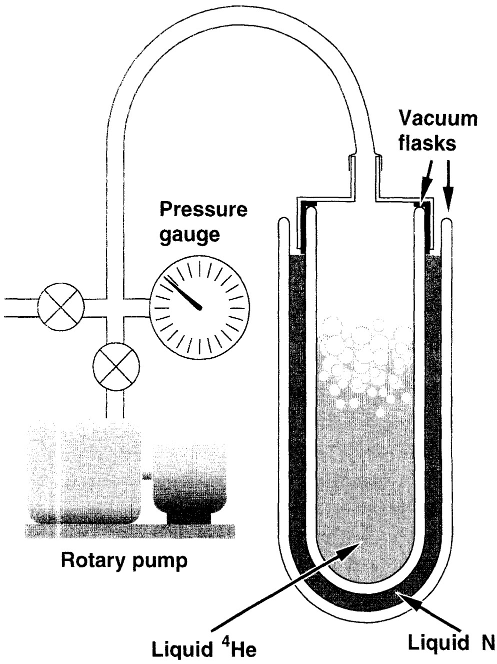

FIG. 3. A simple arrangement for reaching the superfluid transition in liquid ^{4}He.

one atmosphere sits at a temperature of 4.2 K. If the pressure above the liquid is slowly reduced the liquid will cool from the extraction of the latent heat of evaporation. At the modest vapor pressure of around 0.05 atm the temperature of the liquid–vapor mixture has fallen to 2.2 K, at which point the transition to superfluidity occurs.

The unique behavior of the superfluid state can already be appreciated with the naked eye even with such a modest arrangement. As the liquid is cooled to the transition temperature, it boils violently. A striking feature of the phase transition is the abrupt cessation of boiling once the superfluid state has been entered. The process of boiling arises from temperature gradients in the fluid. In a pan of boiling water, vapor bubbles will form in the hottest regions of the water at the heated surface of the pan. The abrupt disappearance of boiling in liquid ^{4}He below the transition suggests that temperature gradients must be greatly reduced in the superfluid phase. Clearly something very unusual has happened to the thermal properties, since the thermal conductivity of the superfluid phase must be extremely high. Vapor must still evaporate from the superfluid when the pressure is further reduced, but the vapor now forms at the free surface of the liquid rather than on the walls of the container. Many properties of superfluids are similarly unusual and quite at variance with what would be expected for a normal liquid.

2.2 The Superfluid Mechanism

The basic mechanism for superfluidity in ^{4}He is the Bose–Einstein condensation of the ^{4}He atoms. The calculated "ideal" Bose–Einstein condensation temperature falls within a factor of two of the measured superfluid transition temperature. However, the real situation is more complex than the ideal case. The ^{4}He atoms cannot be considered weakly interacting, since the superfluidity occurs in the liquid phase where interactions are obviously important. They are in any case responsible for the liquid state itself. Therefore it is not surprising that an ideal Bose–Einstein condensation provides only a very qualitative description of superfluidity in ^{4}He.

Nevertheless, the superfluid properties of ^{4}He are certainly due to a boson condensate. The nonideality of the superfluid ^{4}He condensate is, in many ways, responsible for many of the more interesting superfluid properties. For example, neutron-scattering experiments (Campbell, 1983; Sears *et al.*, 1982) show that even at very low temperatures, the fraction of ^{4}He atoms in the zero-momentum state is only about 15% compared with the ideal Bose-gas prediction of 100%. However, as one consequence of the interatomic forces, the superfluid ground state incorporates a mixture of momentum states.

2.3 The Lambda Transition

Since the superfluid state is highly ordered, the entropy of the liquid must fall rapidly below the transition, and this should give rise to an anomaly in the heat capacity. The measured heat capacity plotted against temperature is shown in Fig. 4. The form of the heat capacity is reminiscent of the Greek letter λ.

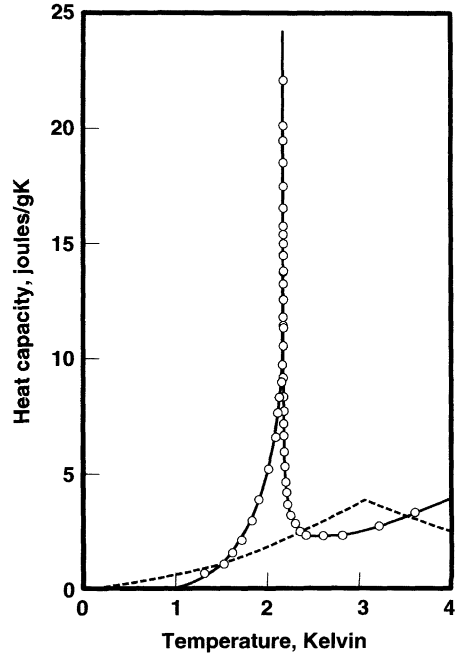

FIG. 4. The heat capacity of liquid ^{4}He showing the extremely steep lambda transition. The heat capacity for an ideal Bose–Einstein condensation in a gas of similar density is shown by the dashed line. (After Buckingham and Fairbank, 1961.)

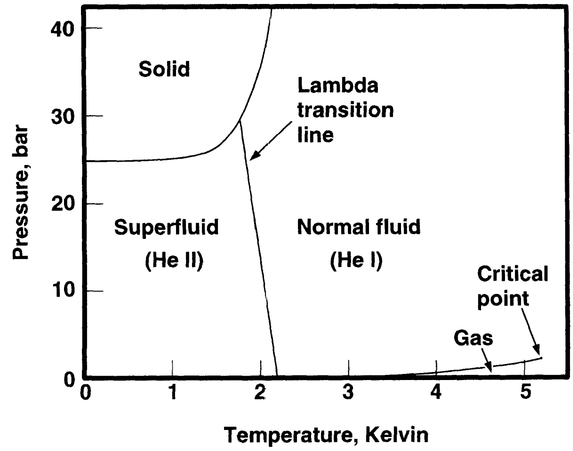

FIG. 5. The phase diagram for ^{4}He. Since liquid extends to zero temperature, there is no triple point. The designations He I for the normal liquid above the transition, He II for the superfluid phase, are often used.

Consequently the superfluid transition in ^{4}He is commonly known as the lambda transition. There is a logarithmic singularity at the transition in which the heat capacity rises dramatically and approaches infinity. This indicates the differences from the ideal Bose-gas case as indicated in Sec. 2.2 above, since the ideal Bose-gas heat capacity should display a cusp at the transition temperature as shown by the dashed curve in Fig. 4.

2.4 The Phase Diagram

The phase diagram for ^{4}He at low temperatures is shown in Fig. 5. Quite apart from the superfluidity itself, this is a very unusual system. We see, for example (as discussed in Sec. 1), that the liquid state extends all the way to zero temperature. This being so, there is clearly no triple point. Furthermore, the level of order in both the liquid and solid phases at low temperatures is virtually complete. In other words, the entropy of both phases is very small. The superfluid phase is often referred to as helium II, in contrast to the normal liquid, helium I.

2.5 The Two-Fluid Model

At absolute zero temperature, all the ^{4}He atoms may be considered to be in their lowest-energy state and therefore contribute to the superfluid properties, since, by definition, at absolute zero there are no thermal excitations. At higher temperatures there will be a finite number of excitations. In an ideal noninteracting boson system, these excitations simply represent those particles not in the ground state. However, in the case of liquid ^{4}He, which is strongly interacting, the excitations represent collective modes of the liquid involving many atomic states. These are phonons and, at higher energies, rotons, which are unique to liquid ^{4}He. At a microscopic level we cannot distinguish between atoms in the ground state and those contributing to the excitations. However, that having been said, it is very convenient to consider the liquid below the transition as consisting of a mixture of two freely interpenetrating fluid components, namely the superfluid and a normal fluid. The superfluid component has zero entropy and zero viscosity, whereas the normal component has a finite entropy and viscosity. This is the two-fluid model. The density (ρ) of the fluid can be separated into two terms:

$$\rho = \rho_s + \rho_n, \tag{1}$$

where ρ_s represents the superfluid density and ρ_n the normal-fluid density. At the lambda temperature, ρ_s is zero while $\rho_n = \rho$. As the temperature is reduced ρ_s increases and ρ_n decreases until at absolute zero $\rho_s = \rho$ and $\rho_n = 0$. Although we have noted that it is meaningless to label any particular atom as belonging to either component, nevertheless the two-fluid model, as we show below, is very successful in explaining many of the superfluid

properties and is a very convenient concept for describing the behavior.

2.5.1 Hydrodynamic Heat Flow We can now explain the virtually infinite thermal conductivity of the superfluid state as a natural consequence of two-fluid behavior. The superfluid component has zero entropy and therefore cannot conduct heat. Since the ratio of the amounts of normal fluid and superfluid depends on temperature, a temperature gradient imposed on the superfluid phase must be associated with a gradient in the superfluid-to-normal fluid ratio such that there is a higher density of the normal fluid towards the warmer regions of the sample. The concentration gradient gives rise to an osmotic pressure, which drives the normal fluid towards lower temperatures and the superfluid towards higher temperatures (*i.e.*, the osmotic pressure acts to restore thermal equilibrium), as shown in Fig. 6. The counterflow of the two components leads to an extremely effective "hydrodynamic" heat flow in which the heat is carried bodily by the flow of normal fluid. The effective thermal conductivity is thus extremely high, in analogy with the heat transfer by the two-phase (but much less efficient) counterflow in a heat pipe.

2.5.2 Thermomechanical Effect The high thermal conductance is just one manifestation of an important consequence of two-fluid behavior, which is the linking of mechanical and thermal behavior. This has no analogies with the behavior of normal fluids. In these thermomechanical (and mechanothermal), effects a temperature gradient gives rise to a pressure gradient (and *vice versa*). Because of the very large thermal conductivity it is difficult to maintain a significant temperature gradient in the bulk fluid. However, it is easy to establish a temperature difference between two volumes of fluid that are connected by a device that only allows the passage of the superfluid component (analogous to a semipermeable membrane). Such a device, called a "superleak", consists of an array of very narrow passages, usually those threading a porous medium, such that the normal component is very effectively clamped by its finite viscosity, while the zero-viscosity superfluid component is free to pass. When a temperature difference is maintained between the two volumes, there must be a corresponding difference in the concentrations of the superfluid component on the two sides of the superleak. The osmotic pressure gradient will force some of the superfluid component through the superleak into the hotter of the two volumes leading to a hydrostatic pressure difference. The flow will continue until in equilibrium the hydrostatic pressure difference balances the osmotic pressure difference. Conversely, if a hydrostatic pressure gradient is applied across the superleak, superfluid is forced through the superleak thus "diluting" the normal component in one volume and concentrating it in the other leading to a temperature gradient.

A rather striking demonstration of such

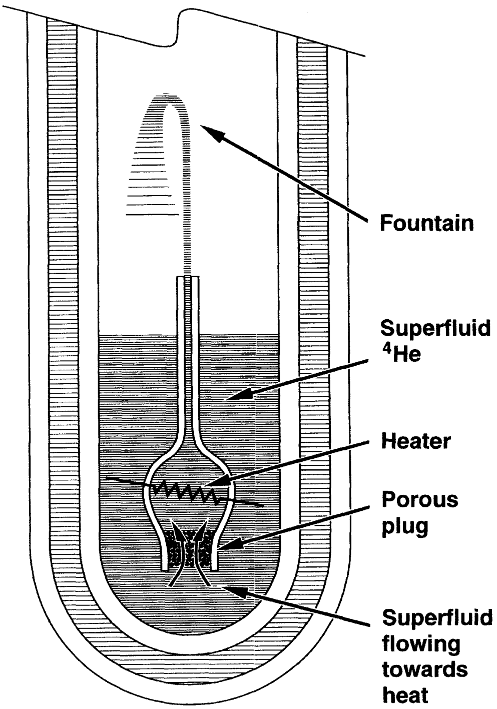

FIG. 7. The fountain effect. On heating the liquid in the container, superfluid flows in through the porous plug from the surrounding bath. The normal fluid cannot flow out to compensate. The excess liquid is therefore ejected upwards through the narrow tube as a fountain.

thermomechanical properties is provided by the fountain effect illustrated in Fig. 7. Here, a container with a narrow open neck at the top and a porous plug below is lowered into a reservoir of superfluid, such that the neck is above the liquid level. If the fluid inside the flask is then heated, the superfluid component is forced to flow from the reservoir into the flask via the pores which impede the flow of normal fluid. Since the only other outlet is the neck, the excess liquid is ejected from the neck of the flask in the form of a fountain. The effect is very dramatic: it is relatively easy to produce fountains more than 30 cm high. By this process we can pump superfluid ^{4}He around an apparatus simply by heating it.

2.5.3 Second Sound Ordinary sound consists of propagating density (or pressure) waves. Two-fluid behavior gives rise to the possibility of temperature waves in which the normal fluid and superfluid density oscillate in antiphase to each other, but such that the total density remains constant. This is called second sound and can be generated and detected in superfluid ^{4}He with a simple heater and thermometer arrangement.

2.6 Excitations and Superflow

Since the superfluid has zero viscosity, flow of the liquid must occur without the production of any excitations. The reason for this can be inferred from the energy-momentum spectrum (dispersion relation) for the excitations as shown in Fig. 8. In the superfluid phase there are two types of thermal excitation. Phonons are collective density oscillations of the liquid (sound waves) travelling at the speed of sound c_1, which is approximately constant at about

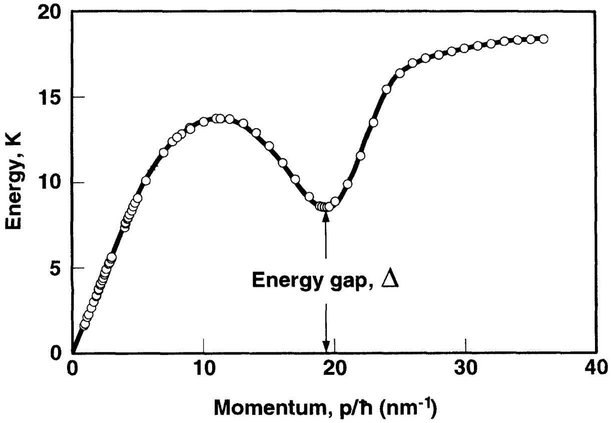

FIG. 8. The energy–momentum relationship (dispersion curve) for the excitations in superfluid ^{4}He. Phonons lie on the straight part of the curve near the origin, rotons around the minimum. The energy gap Δ to the minimum is indicated. (After Donnelly *et al.*, 1981.)

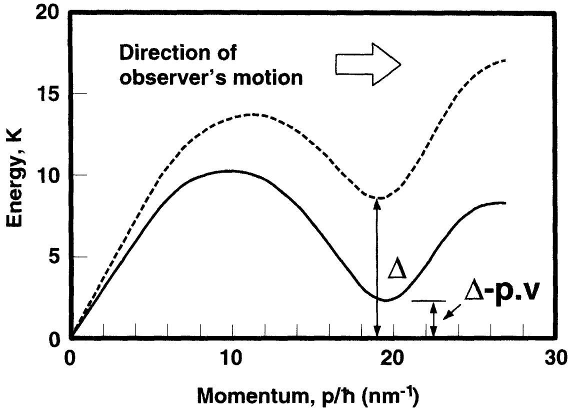

FIG. 9. The dispersion curve of Fig. 8 as seen in a reference frame moving at velocity $-\boldsymbol{v}$ relative to the superfluid. In this frame the roton minimum energy falls by $\boldsymbol{p} \cdot \boldsymbol{v}$. At the Landau velocity, when the minimum falls to zero energy, a scatterer moving at this velocity can freely create excitations.

$240\,\mathrm{m\,s^{-1}}$. Their dispersion relation is therefore approximately linear and described by the expression $E = c_1 p$. At higher energies and momenta the phonon excitations are gradually transformed into excitations called rotons, which have a minimum in the dispersion curve at an energy Δ and at a finite momentum p_0. In consequence, rotons that have momenta less than p_0 have a group velocity ($v_g = \mathrm{d}E/\mathrm{d}p$) which is in the opposite direction to their momenta; in other words they are "hole"-like excitations. Rotons with momenta greater than p_0 have group velocities in the same direction as their momenta and may be thought of as "particle"-like excitations. While the dispersion relation for rotons is well known, their microscopic nature remains a matter of conjecture.

The dispersion curve shown in Fig. 8 is valid in the stationary reference frame of the superfluid. Let us assume we have flow and that the superfluid is moving with velocity v_s with respect to some boundary wall. To a stationary observer in the rest frame of the wall the excitation energies will be shifted by an amount $-\boldsymbol{p} \cdot \boldsymbol{v}_s$ in accordance with the appropriate Galilean transformation. In other words, excitations with momenta approaching the observer, looking into the flow direction, are seen to have a higher energy and those retreating a lower energy. The resulting dispersion curve becomes canted as shown in Fig. 9. Since any scattering process must conserve energy in the rest frame of the scatterer (in this case the wall), new excitations can only be created at zero energy. As the figure shows, there are no such possibilities until the superflow exceeds the value $v_L = \Delta/p_0 \simeq 50\,\mathrm{ms^{-1}}$, at which velocity the dispersion-curve minimum reaches zero energy and excitations may be freely created. This process clearly extracts energy from the flow, *i.e.*, is dissipative. The velocity at which this process begins is known as the Landau critical velocity (Landau, 1941). From these arguments, superfluid ^{4}He should exhibit nondissipative superflow for velocities less than the critical value. It is interesting to note here that the dispersion curve for an ideal Bose gas follows the classical relation $E = p^2/2m$. In this case the Landau critical velocity is zero and there would be no regime of zero viscosity.

In practice it is found that the critical flow velocity for dissipation is very much smaller than the Landau velocity. Measured critical velocities vary according to the precise experimental geometry, but are generally of order $10\text{–}100\,\mathrm{mm\,s^{-1}}$, or some three orders of magnitude less than the Landau value. These velocities correspond to those needed to generate quantized vortices in the superfluid (superfluid turbulence), which we describe in Sec. 2.9.

2.7 Persistent Currents

A firm experimental test of nondissipative flow is given by the demonstration of persistent currents. Persistent currents have been observed in "superfluid gyroscopes" (Clow and Reppy, 1972) consisting of a toroidal flow channel packed with fine powder. The powder is required to clamp the normal component and to prevent the motion of vortices, which would otherwise lead to mutual friction between the superfluid and normal components and thus to dissipation of the superflow. The superfluid is set into motion by rotating the torus about its axis of symmetry above a certain critical angular velocity. The torus is then held stationary while the superfluid continues to circulate around the torus with negligible dissipation. The superflow can be detected by tipping the torus, which induces a precession of the symmetry axis by the gyroscope effect. In such gyroscopes supercurrents have been observed to persist without noticeable loss for several months, demonstrating that the viscosity of the superfluid component is immeasurably small.

2.8 The Wave Function and Phase Coherence

As discussed in Sec. 2.5, the ^{4}He superfluid component corresponds to the macroscopic occupation of the ground-state energy level in the fluid. All particles contributing to the superfluid component can thus be described by a single wave function of the form $\psi = \psi_0 \exp(i\theta)$. The magnitude of the wave function is determined by the density of the superfluid component, $\psi_0 = \sqrt{\rho_s}$. The value of the phase θ of the wave function is arbitrary; however, gradients of this phase determine the velocity of the superfluid component via the relationship $\hbar\nabla\theta = m_4 v_s$ where m_4 is the mass of a ^{4}He atom. The fact that a single phase factor describes all the atoms associated with the superfluid component is known as phase coherence.

2.9 Vortices

The existence of quantized vortex lines in superfluid ^{4}He (and the analogous flux lines in superconductors) is a direct consequence of the existence of a single macroscopic wave function describing the entire sample. Since a gradient in the phase of the wave function implies a flow of the superfluid, which must have some kinetic energy, the most energetically favorable configuration for a given volume of superfluid will be one with a slowly varying phase (small superflows) throughout; and for the special case of a stationary sample, the phase should be constant everywhere. However, in practice it is very difficult to realize this ideal configuration in any given experiment.

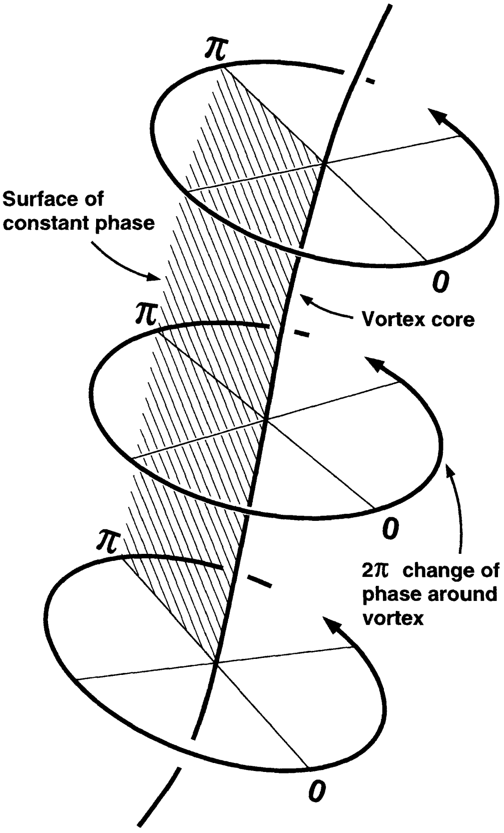

FIG. 10. The 2π change of the phase of the wave function around a vortex. Along the axis there must be a singularity where the phase cannot be defined.

Since the wave function must be single-valued throughout the superfluid, the change in the phase around any closed path has to be an integer multiple of 2π. If we imagine such a path with a phase change of 2π around it, then we can shrink the path arbitrarily while still maintaining the 2π phase change, until the path becomes a single point. From Fig. 10 we see that there must be a line of such points through the liquid defining a linear topological defect. This represents the core of a vortex. The 2π phase change around the core leads to a circulating superflow with a velocity described by the expression

$$v_s = \hbar/m_4 r \tag{2}$$

where r is the distance from the core. The velocity thus decreases inversely with distance. The circulation of liquid, defined as $\kappa = \int v_s \cdot dl$ around a loop surrounding the core, is thus quantized in units of h/m_4.

We now appear to face a contradiction since, first, the phase of the wave function cannot be defined along the actual core and, second, adjacent to the line the gradient of the phase approaches infinity implying an infinite velocity of the superfluid. There is only one way of avoiding these contradictions: the magnitude of the wave function must vanish at the core of the vortex; *i.e.*, the core comprises normal fluid. The length scale over which the wave function is suppressed at the vortex core is called the coherence length and is of the order of an interatomic spacing. Since the velocity field extends to infinite distance from the core these vortices do not have a unique energy per unit length since the kinetic energy stored in the flow field depends on the extent of the container.

It is worth noting at this point that similar difficulties with infinite velocities are a feature of most types of vortex and are invariably resolved in the same way by the exclusion of the motion from the axis. For example, the vortex formed by water running out of the plughole of a bath has a cylindrical air core, which excludes the velocity field of the water from the axis.

2.9.1 Rotating Superfluid ^{4}He

If the wave function of the superfluid is continuous (*i.e.*, contains no voids or vortex cores) then the change in phase of the wave function around any loop must be zero. This means that the superflow is irrotational ($\nabla \times \boldsymbol{v}_s = 0$). This has the important consequence that solid-body rotation of the superfluid is impossible. Furthermore, in the absence of vortices, the net rotation of the superfluid must be zero with respect to the fixed stars. If a bucket of normal liquid ^{4}He is set into rotation (with sufficiently small angular velocity) and then cooled below the lambda transition, the superfluid component will be stationary. This could in principle be seen from the shape of the free liquid surface. the surface would take up a parabolic profile in the normal state in response to the centrifugal force acting on the rotating helium. However as the liquid is cooled well below the transition temperature the surface should become flat since the superfluid component cannot rotate.

As the rotation speed of the container is increased, then eventually the relative velocity between the stationary superfluid and the moving walls will exceed the critical velocity for vortex creation. A small loop of vortex is then created which is immediately dragged around by the friction force of the rotating normal fluid. Here the Magnus force on the vortex from the moving superfluid comes into play. (The Magnus force is the sideways force acting on a rotating cylinder moving transversely in a fluid). The Magnus force causes the vortex line to grow outwards from the container wall and eventually take up a position along the rotation axis of the container as illustrated in Fig. 11. As the rotation is further increased, more vortex lines are produced, which move towards the center of the cell forming a regular lattice of vortex lines parallel to the rotation axis. Photographic images of the vortex line lattice have been produced by Yarmchuk *et al.* (1979). The vortex lattice is analogous to the flux-line lattice produced by a magnetic field applied to a type II superconductor. In this sense, rotation applied to a superfluid is exactly analogous to a magnetic

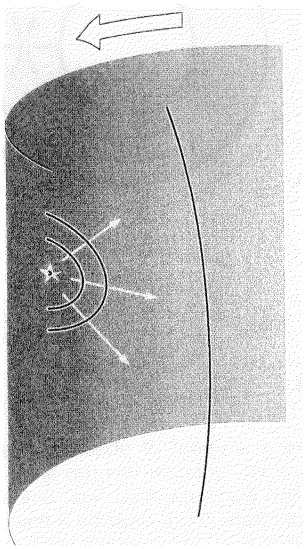

FIG. 11. In a rotating container, microscopic vortex loops created at the moving wall grow, under the influence of the Magnus force, and take up a position parallel to the axis of rotation.

field applied to a superconductor, since in the former case the rotation is quantized (circulation of mass) and in the latter flux is quantized (circulation of charge). The analogy may be taken further since another important property of a superconductor is the expulsion of magnetic field (the Meissner effect), which is analogous to the expulsion of solid-body rotation in a superfluid.

2.9.2 Measurement of Absolute Rotation with Superfluid ^{4}He Since superfluid ^{4}He is irrotational with respect to the fixed stars, a measurement of the superfluid rotation with respect to its container constitutes a measurement of the rotation of the container with respect to the fixed stars. In this manner, superfluid ^{4}He can be used to measure absolute rotation. This principle has already been tested by Schwab *et al.* (1997), who have recently measured the rotation of the Earth. The device they used is shown schematically in Fig. 12. A toroidal container incorporating a small aperture is filled with superfluid ^{4}He. The container is stationary with respect to the Earth and thus rotating with respect to the fixed stars. Since the superfluid cannot rotate, there must be a superflow with respect to the container which is magnified as the superfluid flows through the small aperture. The flow through the aperture may be measured, from which the rotation of the container (the Earth) is inferred. The device shown in Fig. 12 is actually the superfluid analog of a superconducting SQUID, which measures magnetic fields in a similar manner.

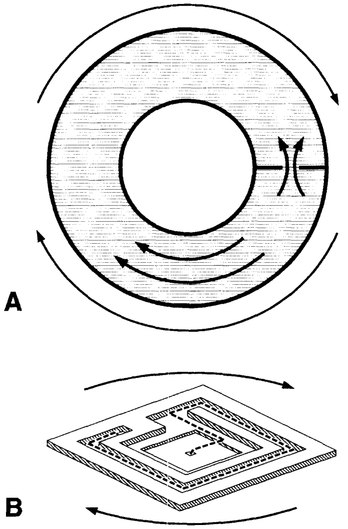

FIG. 12. Measurement of absolute rotation. (a) A rotating toroidal container incorporating a small aperture is filled with superfluid ^{4}He. Since the superfluid cannot rotate, there must be a flow through the aperture. This flow can be measured and the rotation of the toroid inferred. (b) In the actual device, the channel is formed in a thin slab. The flow loop, indicated by the dashed line, passes through the small aperture sited at the center. (After Schwab *et al.*, 1997.)

3. SUPERFLUID ^{3}He

Superfluid ^{3}He was first observed by Osheroff, Richardson, and Lee in 1971 (Osheroff *et al.*, 1972). Although the superfluid transition in ^{3}He had long been predicted, the observation of the superfluid transition was at first mistakenly associated with the solid phase. However, soon afterwards, the experiment was repeated with the use of nuclear magnetic resonance (NMR) techniques with spatial resolution that allowed the identification of two superfluid phases, designated the A phase and the B phase.

The arguments of Bardeen, Cooper, and Schrieffer for Cooper pairing discussed in Sec. 1.3 above were originally proposed in the context of superconductivity. The Cooper pairs that form in conventional superconductors are relatively simple, having zero spin, zero orbital angular momentum, and therefore no internal structure. (The form of the pairs in high-T_c materials is still under debate at the time of writing.) In contrast, the Cooper pairs in superfluid ^{3}He have spin unity and orbital angular momentum unity. The ^{3}He pairs thus have a more complex internal structure, which has a dramatic effect on the superfluid properties, not least in ensuring that there are several distinct superfluid phases.

3.1 Cooling Techniques

The superfluid transition temperature for ^{3}He varies between about 1 and 3 mK depending on the pressure. Even with current cooling techniques these temperatures are not straightforward to attain. The most usual methods in use rely on a continuously operating dilution refrigerator to produce a steady temperature in the millikelvin regime from which base a further cooling stage to reach the superfluid region is used. For this final stage nuclear cooling is currently almost universally used, but in the past Pomeranchuk cooling (see Sec. 3.1.1) has also been used successfully. A dilution refrigerator may be obtained commercially. However, while a modern commercial dilution refrigerator will typically have a base temperature of around 5 mK this is not as good as the best in-house produced machines, which currently can reach around 2 mK.

3.1.1 Pomeranchuk Cooling During the early 1970s before nuclear cooling had become established, the only other practical methods for cooling ^{3}He to low millikelvin temperatures were by the Pomeranchuk effect and, for work just reaching the superfluid transition, magnetic cooling using cerium magnesium nitrate. In fact Pomeranchuk cooling was the method employed by Osheroff *et al.* (1972) when in 1971 they first observed superfluidity in ^{3}He. The technique relies on an unusual property of the ^{3}He phase diagram shown in Fig. 13. At low temperatures, the pressure at which solidification occurs in liquid ^{3}He falls as the temperature rises. This follows from the unusual property of ^{3}He that the entropy of the solid phase is actually higher than that of the liquid phase below 0.3 K. In other words, the solid phase in more disordered than the liquid phase. While Fermi statistics ensure that the entropy of the liquid is low, the solid has almost complete disorder of the nuclear spin system above 1 mK. Consequently, an increase in pressure that causes solidification of the liquid will produce cooling from the latent heat of solidification, *i.e.*, will force the liquid–solid mixture to follow the solidification line to lower temperatures as the pressure is increased. This is the principle utilized in Pomeranchuk cooling.

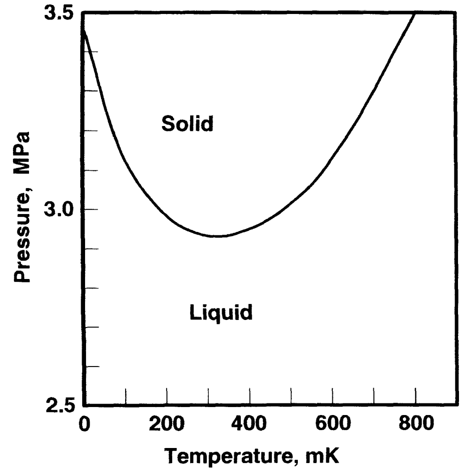

FIG. 13. The liquid–solid region of the ^{3}He phase diagram.

Pomeranchuk cooling has the advantage that the ^{3}He is itself the refrigerant, thus overcoming any problems of establishing thermal contact to the specimen at low temperatures. The disadvantages of this technique are

1. that the specimen will always contain a mixture of solid and liquid ^{3}He;
2. that the specimen is always at melting pressure, thus preventing studies at lower pressures; and
3. that the minimum temperature that can be achieved is limited by the magnetic ordering temperature of the solid (about 1 mK).

These limitations have meant that the Pomeranchuk technique has largely been replaced as a cooling method by the far more versatile technique of nuclear cooling.

3.1.2 Nuclear Cooling The principle of nuclear cooling is shown schematically in Fig. 14. A material containing weakly interacting spins (magnetic moments) is placed in a high magnetic field and then precooled to some temperature T_i. The high magnetic field B_i produces Zeeman splitting of the magnetic energy levels, and the precooling ensures a relatively high population of the lower energy levels as shown in the figure. The magnetic entropy of the system depends only on the relative populations of the energy levels, which in turn depend only on the ratio $\mu B_i/kT_i$ where μ is the magnetic moment associated with the spin. Now suppose that we can reduce the magnetic field adiabatically, *i.e.*, such that no thermal energy can be exchanged between the outside world and the spin system. Since no heat is exchanged the populations of the various levels must remain the same. Therefore, during "adiabatic demagnetization" the entropy of the spin system must remain constant,

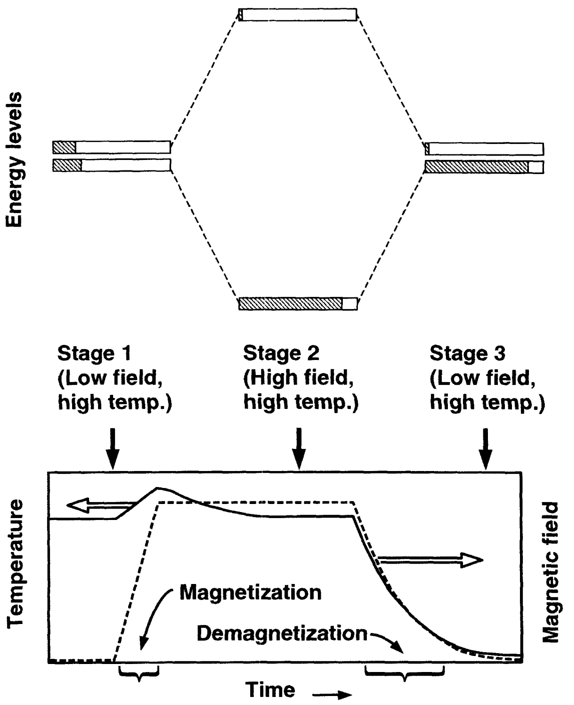

FIG. 14. Nuclear cooling. At the top is a schematic illustration of the energy levels and populations as the field is applied and removed. Below is shown schematically the variations of the magnetic field and the temperature during the process.

ensuring that the ratio $\mu B/kT$ is also constant. Therefore a reduction of the field to some final value B_f results in a lower temperature T_f as given by:

$$T_f = (B_f/B_i)T_i.$$

In principle the technique of nuclear cooling could not be simpler. When the field applied to a material containing nuclear magnetic moments is reduced the temperature falls in the same ratio. In practice, of course, it is not so straightforward.

The minimum temperature possible with nuclear cooling is ultimately limited to the temperature at which the nuclear spins spontaneously order as a result of the interactions between spins, which we neglected above. However, in the case of copper, the most widely used nuclear refrigerant, this ordering temperature lies in the nanokelvin regime and does not present any drawback for cooling liquid ^{3}He to the millikelvin and microkelvin regimes. In practice the minimum ^{3}He temperature achievable by this method is limited by a combination of heat leaks into the specimen and the very poor thermal contact between the specimen and the nuclear coolant. Since the nuclear heat capacity of copper is not very large compared with that of liquid helium, a volume of copper comparable to that of the liquid helium specimen is necessary to generate enough cooling power. Typical starting conditions for demagnetization are a starting temperature of 5–10 mK (well within the range of a dilution refrigerator) in a field of 6–8 T (readily generated by a commercial superconducting solenoid). By reducing the magnetic field by a factor of 1000, temperatures around 100 μK are attainable in the superfluid ^{3}He. This is already low enough that to achieve significantly lower temperatures we may need to consider shielding the specimen against the heating from cosmic rays. A practical system is shown schematically in Fig. 15.

3.2 A Multiplicity of Possible Phases

Since the Cooper pairs in superfluid ^{3}He have spin angular momentum $\boldsymbol{S} = 1$ and orbital angular momentum $\boldsymbol{L} = 1$, they have in-

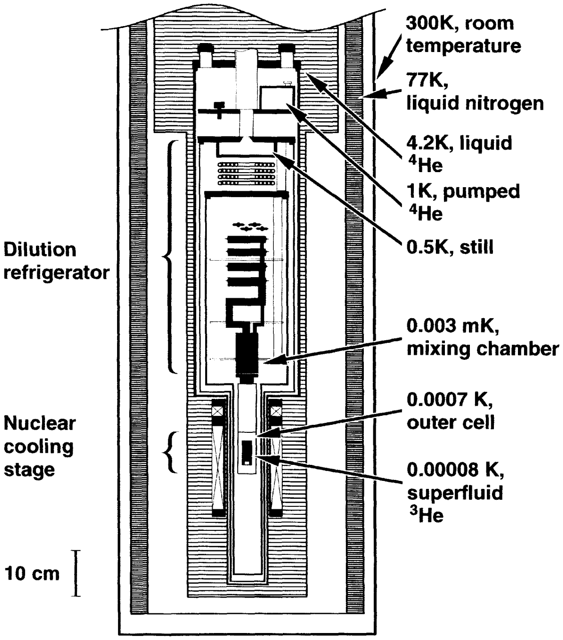

FIG. 15. A nuclear cooling cryostat for achieving superfluid temperatures in liquid ^{3}He.

ternal structure in the sense that there are two axes defined by the directions of the spin and orbital angular momenta. The internal degrees of freedom are specified by the spin projection quantum numbers $m_S = +1, 0, -1$ and orbital angular momentum projection $m_L = +1, 0, -1$. Therefore there are $3 \times 3 = 9$ different types of Cooper pair allowed in superfluid ^{3}He, and correspondingly the superfluid wave function has 9 complex components (18 parameters). This complex structure places superfluid ^{3}He in a class of its own. In contrast, superfluid ^{4}He can be described by a simple two-parameter wave function $\psi = \psi_0 \exp(i\theta)$ (see Sec. 2.8), which is also the case for conventional superconductors where the Cooper pairs have zero spin and zero orbital angular momentum and therefore have no internal structure.

One immediate consequence of the multiplicity of possible Cooper pair states in superfluid ^{3}He is the possibility of several distinct superfluid phases. It is a tribute to modern theoretical physics that several of the possible phases of systems with $\boldsymbol{S} = 1$ and $\boldsymbol{L} = 1$ Cooper pairs had been studied theoretically (albeit in the context of superconductivity) long before the discovery of superfluid ^{3}He. There are 13 possible phases but only three occur under normal experimental conditions. Which phase is preferred depends on temperature, pressure, and magnetic field. The phase diagram for the two phases that occur in zero magnetic field is shown in Fig. 16.

3.2.1 The A Phase

As shown in Fig. 16, the preferred phase at high temperatures and pressures is known as the *A* phase. The Cooper-pair structure of this phase was first considered theoretically by Anderson, Brinkman, and Morel (ABM) (Anderson and Morel, 1961; Anderson and Brinkman, 1973). In this phase the Cooper-pair spin projection may only take the values $m_S = +1$ and $m_S = -1$. Furthermore, the orbital angular momentum of every pair points along a common direction called the orbital angular momentum vector (or $\boldsymbol{l}$ vector). The pairs are constructed from ^{3}He atoms close to the Fermi surface. If the component atoms are to couple to form pairs with angular momentum $\boldsymbol{L} = 1$ pointing in, say, the polar direction, then atoms with momenta lying in the equatorial plane can achieve this easily by mutually orbiting but atoms with momenta in the polar direction cannot mutually orbit to create an angular momentum also in this direction. In consequence this phase

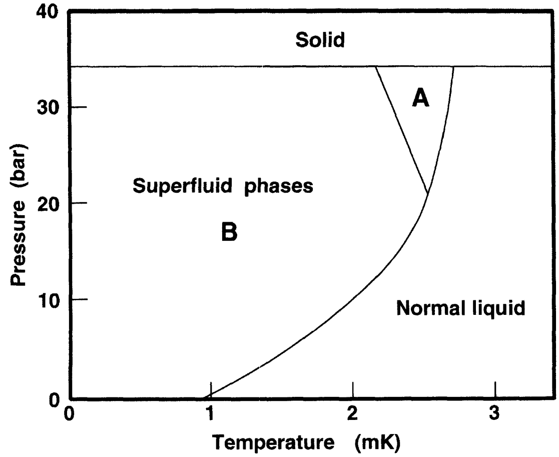

FIG. 16. Phase diagram of the superfluid phases of ^{3}He in zero magnetic field.

acts as an excellent superfluid for atoms with momenta in the equatorial plane but cannot at all form a superfluid for atoms with momenta along the polar direction. The superfluid energy gap Δ, which tells us the strength of the pairing, is thus anisotropic, vanishing along the $\boldsymbol{l}$ axis as shown in Fig. 17.

Since the pairs all orbit about a common axis, defined by the direction of the $\boldsymbol{l}$ vector, the nuclear magnetic moment associated with each ^{3}He nucleus experiences a changing magnetic field from its partner. This is equivalent to two parallel bar magnets orbiting about a common center. The magnetic (dipole–dipole) energy of such a system is reduced when the magnets are oriented perpendicular to the rotation axis. Therefore, in the absence of any other disturbing features such as walls or flow, this will align the spin perpendicular to the $\boldsymbol{l}$ vector.

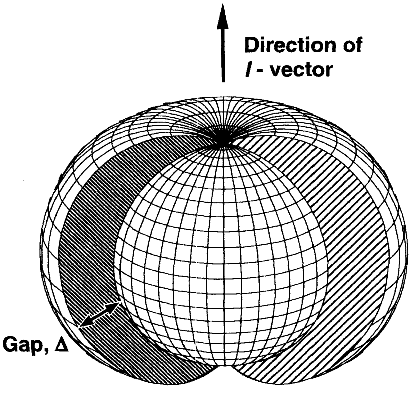

FIG. 17. The energy gap in the *A* phase. The gap is zero along the *l*-vector axis and is at its maximum in the perpendicular directions.

For an isolated pair this energy is miniscule and would not cause any orientation at millikelvin temperatures. However, all the pairs are in the same quantum ground state acting as a single entity such that all the spin vectors acting together are orienting themselves relative to all the orbital moments acting together. The net result is a greatly enhanced spin–orbit coupling. This demonstrates that indeed we are dealing with a coherent ground state.

3.2.2 The B Phase The structure of the *B* phase of superfluid ^{3}He is somewhat more subtle than that of the A phase. In low magnetic fields the system shows a superposition of all possible m_S values and all possible m_L values, with the result that there is no net preferred spin or angular momentum direction in the liquid. As a consequence of this apparent higher degree of symmetry, the B-phase energy gap is isotropic. To first order, each pair attempts to make its total angular momentum (spin plus orbital) zero, $\boldsymbol{J} = \boldsymbol{S} + \boldsymbol{L} = 0$. Therefore pairs consisting of ^{3}He atoms with momenta parallel to the field are in the $m_S = 0$ state. Those formed from atoms with momenta perpendicular to the field have $m_S = +1$ and -1, with all three states contributing for other angles. However, the same magnetic dipole forces that orient the A phase also act here, forcing the spin direction to be rotated with respect to the orbital direction. However, unlike in the A phase where the total spin system of the pairs is rotated with respect to the total orbital momentum, in the B phase the rotation takes place for each pair individually, but about an axis common for all pairs, specified by a vector ***n***. The dipole–dipole coupling energy is minimized when this rotation angle is 104° (known as the Leggett angle). This leads to quite a subtle structure but does have the effect of producing a simple isotropic energy gap, at least in low magnetic fields.

The B phase corresponds to the theoretical BW state first examined by Balian and Werthamer (1963), long before this behavior was realized in superfluid ^{3}He. The original BW state had Cooper pairs with total angular momentum $\boldsymbol{J} = \boldsymbol{L} + \boldsymbol{S} = 0$, but the relative population of the m_S states was distributed around the Fermi surface as described above.

3.3 Broken Symmetries of the Superfluid Phases

3.3.1 The A Phase In Sec. 3.3.1 we introduced the ***l*** vector, which defines the axis along which the energy gap vanishes in the A phase. In the absence of any external fields and "foreign" objects such as container walls, it is clear that the direction of ***l*** must be arbitrary. Above the transition the direction of the ***l*** vector has no meaning. Thus as we pass through the transition the symmetry of the liquid is reduced, as there is now a definite (but arbitrary) direction for ***l*** whereas above the transition all directions were equivalent. This behavior is known as spontaneous symmetry breaking. Conventional superconductors and superfluid ^{4}He also exhibit spontaneous symmetry breaking, although here a more abstract symmetry is broken, known as gauge symmetry, which leads to the definite (but again arbitrary) phase factor in the superfluid/superconductor wave function. Since spatial gradients of the ***l*** vector give rise to superflows in a similar manner as spatial gradients of the phase factor give rise to superflows in superfluid ^{4}He, the broken gauge and orbital symmetries are linked in the A phase. This is described as a broken relative gauge-orbit symmetry. In addition, the directionality of the spin part of the wave function leads to broken spin rotation symmetry in ^{3}He-A. The spin part of the wave function in the A phase is described by a vector ***d***, which is defined to point along the direction of zero spin projection. In other words the ***d*** vector points perpendicular to the spin ***S*** and is common for all pairs.

3.3.2 The B Phase In superfluid ^{3}He-B gauge symmetry is broken (*i.e.*, the phase of the wave function takes a particular value). As discussed in Sec. 3.2.2, there is no independent directionality for the spin and orbital parts of the wave function as in the A phase. However, the orbital and spin vectors are coupled for each pair such that all the spin vectors may be rotated with respect to all the orbital vectors around a common axis specified by the vector ***n***. Thus all the directionality of the B phase (in low magnetic fields) is specified by this spin–orbit rotation axis and therefore the B phase exhibits a broken relative spin–orbit rotation symmetry.

3.4 The Phase Diagram

The phase diagram of superfluid ^{3}He has already been introduced in Fig. 16. In low magnetic fields, the B phase covers the majority of the *P-T* space while the A phase is confined to a region of high pressure and temperature. The phase transition between the normal state and the superfluid state is second order with a discontinuity in the heat capacity (in this sense very similar to conventional superconductors).

The phase transition between the A and B phases is, however, first order, and very substantial supercooling of the A phase has been observed (Hakonen *et al.*, 1985). The mechanism for the nucleation of the B phase from the A phase has been a matter of much debate. The first theoretical estimates of the nucleation time for the B phase suggested that it should be of order the age of the universe. The precise nucleation mechanism is as yet still uncertain; however, there is strong evidence that cosmic rays may be playing an important role (Leggett, 1984).

The phase diagram is transformed by the application of a magnetic field. Another phase, called the A1 phase, appears in a narrow temperature range separating the normal state from the A phase. The A phase becomes stable over a wider range of temperatures and pressures. For magnetic fields larger than about 0.5 T, the B phase is removed completely from the phase diagram, and the A phase becomes the low-temperature superfluid phase. The A1 phase is very similar to the A phase, the main difference being that the A1 phase contains only $m_S = +1$ (up spin) pairs; that is, the A1 phase is a magnetic superfluid. The transition from the A1 phase to the A phase simply corresponds to the phase transition for the $m_S = -1$ (down spin) Cooper pairs. The A phase is often considered as consisting of two interpenetrating superfluids, one for the down-spin pairs and one for the up-spin pairs.

3.5 Properties of Superfluid ^{3}He

Not surprisingly, the high level of structure of the Cooper pairs in superfluid ^{3}He leads to rather unusual properties. In spite of the complexity of the superfluid wave function, many of the superfluid properties were found theoretically prior to their discovery. The reasons for this are that

1. the basic interactions between ^{3}He atoms are known rather precisely;
2. the entire superfluid sample (typically consisting of some 10^{23} atoms) is described by a single, albeit rather complicated, wave function with a well defined structure in each superfluid phase; and
3. there are virtually no impurities in liquid ^{3}He at low temperatures.

The only element that has appreciable solubility in ^{3}He is ^{4}He, and the extrapolated solubility of ^{4}He at sub-millikelvin temperatures is around one ^{4}He atom in an astronomical volume of liquid ^{3}He. Superfluid ^{3}He is therefore an exceptionally clean medium, for which theories should be applicable with extreme accuracy.

Nevertheless, there are still new phenomena being found in superfluid ^{3}He that have, as yet, no theoretical explanation. The reason for this is that the system is so complex that even though the fundamental equations are known, all the solutions are not.

3.5.1 Thermal Excitations and Superflow

In order to describe the thermal excitations in the superfluid phases, it is first necessary to describe those in the normal phase of liquid ^{3}He. The normal phase is described well by Landau's phenomonological Fermi-liquid theory (Landau, 1956). Here, the main effect of the interatomic forces can be simply accounted for by introducing an effective ^{3}He mass, m^*. The modified atoms, called quasiparticles, can then be considered to be almost noninteracting, with energy levels given by $E = p^2/2m^*$. The main thermal excitations of the system correspond to either the occupation of energy levels above the Fermi energy (quasiparticle excitations) or empty energy levels below the Fermi surface (quasihole excitations). The excitation energies, given by $\xi = |p^2/2m^* - E_F|$, are shown by the dashed line in Fig. 18.

At absolute zero temperature, all the ^{3}He quasiparticles are paired and can be described by the superfluid wave function. At finite temperatures, some of these pairs will be broken by thermal agitation. The unpaired quasiparticle excitations are still influenced by the pairing interaction and their energies are raised with respect to the normal-state excitations as shown by the solid line in Fig. 18. The minimum quasiparticle excitation energy is equal to the superfluid energy gap Δ, as shown in the figure. The Cooper pairs may be considered to lie at the origin in Fig. 18, and in order to break a pair, two excitations must be created, requiring a minimum of 2Δ of energy.

The arguments presented in Sec. 2.6 relating dissipationless flow with the excitation dispersion curve for superfluid ^{4}He are equally applicable to superfluid ^{3}He. The dispersion curve shown in Fig. 18 will clearly allow the existence of dissipationless superflow below the Landau critical velocity $v_L = \Delta/p_F$. In the B phase the measured critical velocity of the superfluid is indeed limited by the Landau velocity even in the presence of strong magnetic fields (Fisher *et al.*, 1991). (This is in contrast to the case of superfluid ^{4}He discussed in Sec. 2.6.) In the A phase the situation is far more complicated as a result of the extreme anisotropy of the energy gap. The Landau critical velocity for the A phase is dependent on direction, falling to zero for superflow along the **l** axis. The critical flow velocity for the A phase is in practice dependent on geo-

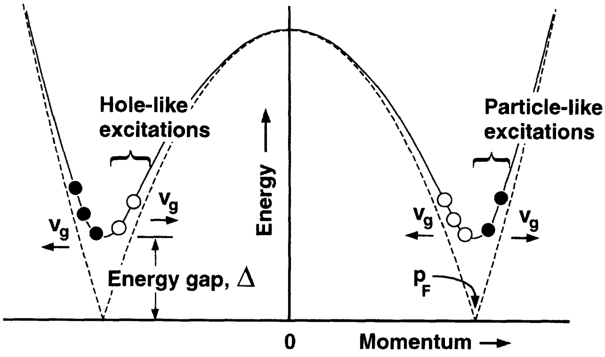

FIG. 18. The energy–momentum relations (dispersion curves) for the excitations in superfluid (solid line) and normal liquid ^{3}He (dashed line). The solid circles represent quasiparticles and the open circles quasiholes. The Fermi momentum p_F is indicated. The excitation energies plotted are measured from the Fermi energy.

metrical factors on account of the ***l*** textures which we describe in Sec. 3.5.3.

3.5.2 Thermal Properties of Superfluid ^{3}He The heat capacity of superfluid ^{3}He as measured by Greywall (1986) is shown in Fig. 19. The behavior at the transition is quite unlike that of ^{4}He. There is a clear second-order phase transition between the normal phase and the superfluid phases with no logarithmic singularity. The B-phase heat capacity is very similar to that of a conventional superconductor and is well described by the BCS theory with a slightly enhanced energy gap due to strong coupling corrections (the BCS theory is only applicable in the limit of weak pairing interactions). At low temperatures the heat capacity of the B phase falls exponentially with decreasing temperature because of the dominance of the Boltzmann factor $\exp(-\Delta/kT)$ governing the number of thermal quasiparticle excitations. The extremely small heat capacity of ^{3}He-B at temperatures of around 100 μK has been utilized in superfluid-^{3}He particle detectors (Bradley *et al.*, 1995) capable of measuring energy depositions of less than 1 keV.

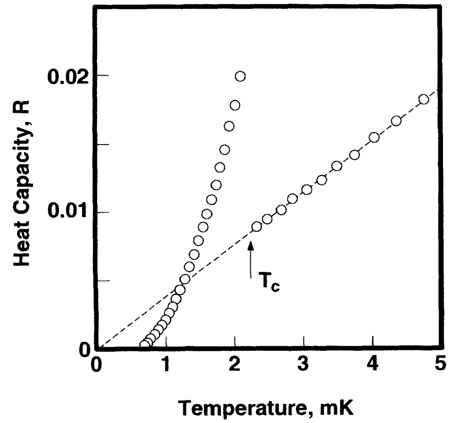

FIG. 19. The heat capacity of superfluid ^{3}He at 20.3 bar (after Greywall, 1986).

In contrast, the heat capacity of ^{3}He-A is expected to vary as T^3 at low temperatures on account of the nodes in the energy gap (see Sec. 3.3.1). However, as a significant field is needed to stabilize the A phase to low temperatures this behavior has not been experimentally verified.

The thermal transport properties of the superfluid phases are qualitatively similar to those of superfluid ^{4}He in that at high temperatures a counterflow of normal fluid and superfluid is set up by a temperature gradient and the thermal conductivity is very high. The situation is particularly interesting at very low temperatures where the normal-fluid density is very low, since the quasiparticle excitations making up the normal fluid travel ballistically. The theoretical mean free path of a quasiparticle in ^{3}He-B at a temperature of around $0.1\,T_c$ (the lowest temperature presently achievable) is about 1 km. This property has been utilized in quasiparticle beam experiments (Fisher *et al.*, 1992).

3.5.3 Textures The directional properties of the superfluid give rise to properties very reminiscent of those seen in liquid crystals. The directions of the ***l*** and ***d*** vectors in the A phase and the ***n*** vector in the B phase, which determine the dynamic behavior of the phases, are influenced both by external fields and by interfaces (including solid boundaries and superfluid phase boundaries). The arrangement of the various directionalities in a given situation is known as the texture.

In the A phase, a solid–superfluid boundary forces the ***l*** vector to lie normal to the surface. Put in simple terms, the pairs at the interface may orbit in the plane of the surface, whereas other directions will involve collisions of the component ^{3}He atoms with the boundary. In order to minimize bending energies, a slow variation in the direction of the ***l*** vector is preferable; however, in a simply connected volume this condition cannot be satisfied everywhere. There has to be at least one singularity (or textural defect). This is illustrated for a spherical cell in the first part of Fig. 20. If, on the other hand, we confine the A phase in a torus then the singularity can be avoided, as shown in the lower part of the figure. Since the spin direction can be influenced by a magnetic field, there is an interesting region near walls where there is a competition between the orienting effect of the wall on the orbital angular momentum and the orienting effect of the field on the spin angular momentum.

The effect of a solid boundary in the B phase is more complex. In the absence of walls the ***n*** vector prefers to lie parallel to the field. However, if we have a wall nearby, then the direction of ***n*** depends on the orientations of both the field and the wall.

Other orienting effects include electric fields, thermal conduction, and superflow. The combination of all these orienting effects in practice leads to very messy textures with many defects (somewhat in analogy with the structure of a deformed polycrystalline solid).

Textural effects in the A phase are obviously very strong as a result of the large anisotropy of the energy gap. In consequence virtually all the dynamic properties of the A phase (transport properties and NMR properties) are strongly affected by the texture. For example, at the lowest temperatures virtually all the quasiparticle excitations of the A phase have momenta along the ***l*** axis (where the energy gap is zero), so that in this sense the excitation gas is almost one dimensional. Spatial variations of the direction of ***l*** lead to confinement of the excitations, thus reducing all excitation transport properties by an enormous factor.

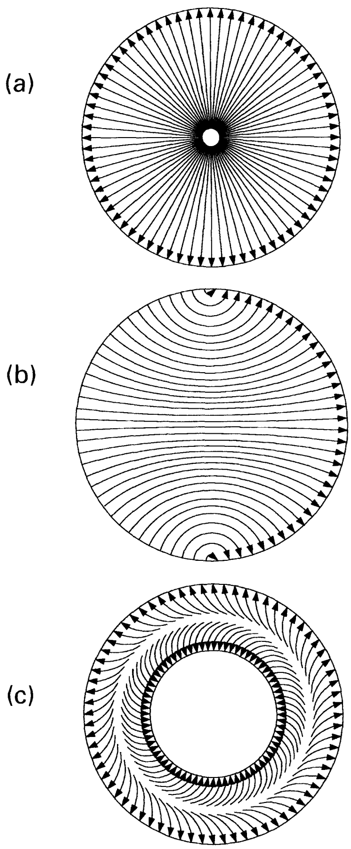

FIG. 20. (a), (b) The A-phase texture (the direction of the *l*-vector) in a spherical volume. As can be seen, for the direction of *l* to vary only slowly over the volume there must be either (a) a point singularity in the bulk or (b) a line singularity at the boundary. (c) The texture in a toroidal container can be accommodated with no singularities.

For low magnetic fields, the textures in the B phase are far weaker as far as excitations are concerned since the energy gap is isotropic. In higher magnetic fields (above 0.1 T, say) the energy gap becomes distorted thus strengthening the influence of the texture. The B-phase texture does, however, have an enormous effect on the NMR properties even in small magnetic fields (see Sec. 3.5.5.1).

3.5.4 Vortices The complexity of the superfluid ^{3}He wave function also reveals itself in the variety of superfluid ^{3}He vortices, which have been methodically studied and categorized by the Helsinki ultralow-temperature group (Krusius, 1993).

There is only one type of vortex possible in superfluid ^{4}He because of the simplicity of the wave function (which reflects the simplicity of the ordering). Put simply, in superfluid ^{4}He the phase of the wave function is allowed to change by a multiple of 2π around a vortex core. In superfluid ^{3}He, however, there are several properties that may change as we circle the core. The phase may change, but also the directions of the orbital and spin angular momentum vectors may change, and since the latter are coupled the number of possible structures is quite large.

The circulation κ of vortices in superfluid ^{4}He is quantized in units of h/m_4, as discussed in Sec. 2.9. Similarly, in superfluid ^{3}He vortices are quantized in units of $h/2m_3$ where m_3 is the bare ^{3}He atomic mass, the reason being that the superfluid is composed of Cooper-pair bosons consisting of two ^{3}He atoms (analogously, the flux carried by a flux-line vortex in a superconductor is quantized in units of $h/2e$).

In the B phase, the two most common types of vortex are the axisymmetric (V1) vortex and the nonaxisymmetric (V2 or dumbbell) vortex. Both of these are hard-core vortices, meaning that the structure of the wave function is modified within the vortex core over a length scale of the order of the superfluid coherence length $\xi \approx 10\text{–}100\,\text{nm}$. The V1 vortex occurs at higher temperatures and carries a single quantum of circulation. The B phase is gradually transformed into the A phase on approaching the vortex axis. The V2 vortex has an exotic double-core structure consisting of two topologically confined half-quantum vortex cores, so that the core carries, in total, a single quantum of circulation. Single half-quantum vortices are topologically forbidden; their confinement within the V2 core is analogous to the confinement of quarks within nucleons.

The predominant vortices in the A phase are soft-core vortices, meaning that the structure of the superfluid is unchanged in the vortex core. They are in fact textural vortices in the sense that they are defined by the $\boldsymbol{l}$ texture (as mentioned in Sec. 3.3.1, a spatially varying $\boldsymbol{l}$ texture produces superflow). The size of the soft core, typically a few micrometers, is much larger than that of hard cores, and they carry two quanta of circulation. Other vortex types in the A phase include hard-core vortices and, remarkably, a vortex sheet consisting of multiple soft-core vortices locked together side by side.

3.5.5 Magnetic Properties Since the Cooper pairs in superfluid ^{3}He have spin $S = 1$ arising from the nuclear spin of the constituent ^{3}He atoms, they have a magnetic moment. This is the only superfluid/superconducting system which is currently known to have magnetic Cooper pairs. The absence of electrical charge in the ^{3}He pairs makes certain types of measurements (such as the measurement of superflow) rather difficult as compared with a similar measurement in a superconductor. However, this is more than compensated by the magnetic moment of the pairs, which allows them to be probed using the powerful technique of NMR, which is unique in that the technique allows us to look very directly at the Cooper-pair wave function. A part of the wave function concerns the direction of the nuclear spin (or magnetic moment). Not only can we see what this part of the wave function is doing by NMR, but we can also use NMR to manipulate it. In consequence, new phenomena can be observed such as spin supercurrents, spin vortices and coherent excited states of the Cooper-pair condensate.

3.5.5.1 Nuclear Magnetic Resonance Historically, the discovery of superfluid ^{3}He was made using NMR techniques, and the A and B phases of the superfluid were identified and then associated with the theoretical ABM and BW states primarily because of their NMR signatures.

The magnetic susceptibility of normal liquid ^{3}He is temperature independent at millikelvin temperatures. Since the A-phase Cooper pairs are formed with parallel spins the A-phase susceptibility is identical to that of the normal state. However, as mentioned above in Sec. 3.2.1, the pairs have the lowest magnetic (dipole) energy when the orbital and spin directions are perpendicular. In NMR we apply a magnetic field and then with a perpendicular rf field tip the magnetization from the equilibrium direction and follow the precession by observing the voltage output of a surrounding pickup coil. In the normal phase, the spins precess with a frequency determined only by the field and the value of the nuclear moment. However, in the A phase, since the spin direction is influenced by the orbital moment, if we tip the spins from their equilibrium direction there is a restoring force from the Cooper pairs themselves trying to return the spin direction to the perpendicular state. This gives an extra restoring force above the "bare" magnetic value, which means that the precession frequency is greater than that for ^{3}He atoms in the normal liquid. This is a unique signature of the A phase. In contrast, the B phase shows no such effect in the absence of other textural orienting forces, and the NMR frequency is similar to that of the normal fluid. However the susceptibility falls rapidly with decreasing temperature close to T_c and reaches a low-temperature value equal to about a third of the normal-state susceptibility. This is because in the normal liquid all the atoms have spin $\frac{1}{2}$, whereas in the B-phase superfluid the pairs have $S = 1$, $S = -1$, and $S = 0$. The $S = 0$ pairs do not contribute to the susceptibility, which therefore falls with the increasing superfluid fraction.

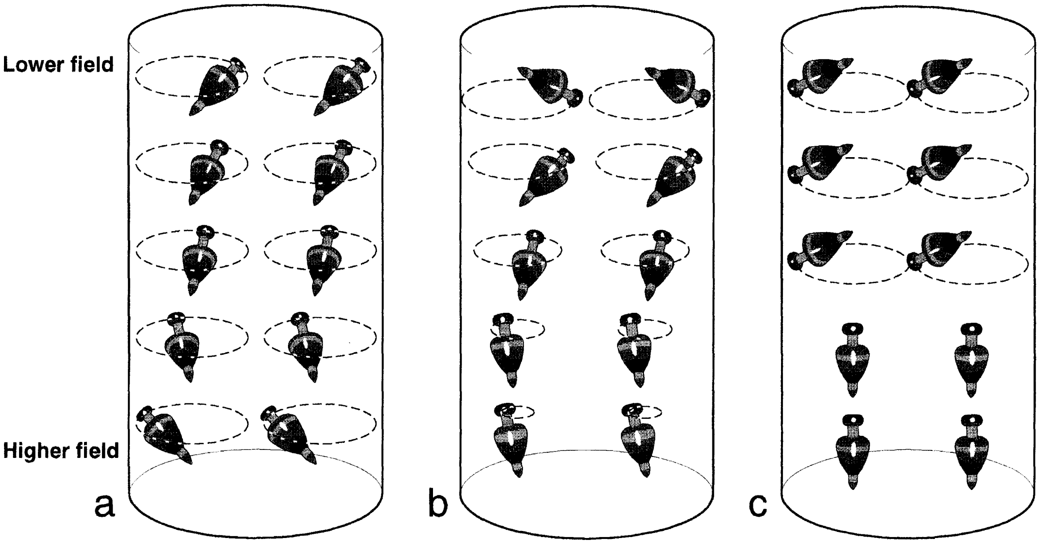
The dynamic magnetic properties of the superfluid phases are more interesting. Since the direction of the spins in the pairs is influenced not only by the magnetic forces but also the dipole–dipole interaction from the influence of the orbital moment, the spin dynamics becomes very complex. First, unlike the situation with free spins, we see the phenomenon of longitudinal NMR in which there are oscillations of the magnetization parallel to the steady field. The extra dipole–dipole restoring forces also give rise to subtle feedback mechanisms that lock the whole precessing system into one coherent state, as discussed in the next section.

3.5.5.2 Coherent Excited States in ^{3}He-B Any wave function has the property that a spatial gradient in any of its quantities is associated with an appropriate flow. Such gradients are responsible for some of the most fundamental properties of superfluids and superconductors. For example, gradients in the phase θ of the wave function in superfluid ^{4}He are associated with dissipationless mass flow (see Sec. 2.8). This can be thought of as the operation of Lenz's law. In an attempt to nullify the gradient the superfluid responds with a supercurrent. In superfluid ^{3}He-B we can set up (by NMR) gradients across a sample in the spin part of the wave function, by arranging for the spins to precess at different frequencies in different parts of the liquid. In this case the flow set up is a flow of spin, a spin supercurrent. Spin supercurrents are damped by thermal excitations (or the normal-fluid component), but nevertheless play a vital role in the spin dynamics and can give rise to extraordinary phenomena at very low temperatures where the normal-fluid damping becomes negligible.

The first coherent excited state discovered in ^{3}He-B is called the homogeneous precession domain (HPD) (Borovik-Romanov *et al.*, 1984; Fomin, 1984). It can be excited by both pulsed and continuous-wave (cw) NMR methods. The most striking property of the HPD, as observed with pulsed NMR, is that it is a very long-lived signal even in the presence of large gradients of the external field. In fact, a magnetic field gradient is required in order to stabilize the HPD signals.

The mechanism behind the HPD formation is illustrated in Fig. 21. Before the NMR tipping pulse, the net magnetization (spin) induced by the vertical magnetic field H is vertical throughout the whole volume. On application of a 90° NMR pulse, the net magnetization (spin) is tipped into the horizontal plane and then precesses around the steady field direction at the Larmor frequency $f_L = \gamma H/h$, where γ is the gyromagnetic ratio for ^{3}He and h is Planck's constant. If the cell is exposed to a vertical field gradient, the precession frequency is higher at the top of the cell than at the bottom. In normal liquid ^{3}He we would see the signal picked up by the NMR coil (reflecting the net transverse magnetization of the whole volume) rapidly decay as the spins precessing at different rates in different parts of the cell become out of phase. Under conditions we consider here this would limit the NMR signal time to about 1 ms.

In the superfluid B phase, however, the different precession frequencies of the spins in different parts of the cell leads to a gradient in the direction of the spin, which induces a spin supercurrent acting to counter the phase gradient. The vertical spin supercurrent so induced transports down-spin to the lower field regions and up-spin to the higher field regions.



Just after pulse, spins slowly get out of phase.

Spin supercurrent flows. Spins at top tip further over, spins at bottom straighten up.

Precessing domain is formed.

FIG. 21. Formation of the homogeneously precessing domain.

Thus the spin deflection gradually increases in the low-field region and decreases in the higher-field region. This continues until the angle of deflection reaches the critical deflection of 104°. Once this angle is exceeded the extra dipole–dipole restoring force cuts in. This has the effect of increasing the precession frequency above the local Larmor frequency.

Thus as the spin deflection in the low-field region (where the Larmor precession frequency is at its lowest) increases beyond 104°, the frequency increases. This then matches the frequency in the next highest field region; the gradient thus disappears, the supercurrent stops, and the two regions are locked together in frequency. After a short period all the spin deflection of the high-field region of the cell has been transported to the lower-field region and two domains remain, one with coherently precessing spins in the low-field region and the other of completely undeflected spin in the high-field region. This situation can be maintained for hundreds of milliseconds, and if the precessing domain can be trapped in a minimum in the texture away from the disturbing effect of walls, it can continue for tens of seconds (Bunkov *et al.*, 1992). This is in stark contrast to the 1-ms signal seen under the same conditions in the normal state.

The importance of these precessing states lies in the fact that they represent an excited but coherent state. The fact that we can study their evolution by NMR makes them not only interesting but very accessible to study.

4. OTHER SIMILAR SUPERFLUIDS

The superfluids are largely unique in that superfluidity is in general a low-temperature property and relies on the system being liquid. There are other potential superfluids, but phase transitions to solids intervene. However, superfluidity can occur in exotic circumstances. It is possible that some of the heavy-fermion metals that show superconductivity (see HEAVY-FERMION PHENOMENA) do so with Cooper pairs with spin 1. The exact structure of the pairs in high-temperature superconductors at present is a matter of conjecture.

The closest analogies to the helium superfluids may lie among the neutron and proton liquids that are believed to exist inside neutron stars. These exotic objects give rise to the very regular radio pulses that suggested the original name pulsars. They are the stellar bodies that remain after a supernova explosion. Although the temperature of these liquids in absolute terms is very high, they are actually low-temperature systems in the sense that the temperature is much lower than the appropriate Fermi temperatures ($T_F = E_F/k$). This suggests that the liquids are likely to be superfluid with neutron–neutron and proton–proton Cooper pairs as in superfluid ^{3}He. Since neutron stars rotate very rapidly, up to revolution rates approaching 1000 Hz, any internal superfluid must be traversed by a very dense lattice of vortices. It is possible that the starquakes observed when the very slowly decaying rotation rate makes very small (but easily detected) jumps are the result of sudden reorganizations of this vortex lattice.

The dilute gases of trapped cooled atoms in which Bose–Einstein condensations have recently been observed must also be superfluid below the condensation temperature. These systems are being intensively studied at present, and we expect a whole new range of superfluid phenomena to be observed. Superfluidity in these systems is quite different from that in a liquid in that the gas of particles is dilute and interactions are very small.

Finally, one further related system of great interest is provided by dilute solutions of ^{3}He in ^{4}He. At low temperatures, superfluid ^{4}He will dissolve ^{3}He up to around 10% depending on pressure. It is an intriguing thought to imagine what might happen if we took such a mixture to a temperature low enough for the dilute ^{3}He fraction to become superfluid while dissolved in an already superfluid ^{4}He. Such a mixture of two interpenetrating superfluids would certainly show unusual behavior. Interesting questions arise as, for example, in rotation how would the vortices in the two superfluids interact? Unfortunately, at the densities possible in the solution this ^{3}He transition may well need a temperature of fractions of a microkelvin, which is several orders of magnitude below our present capability.

GLOSSARY

Absolute Zero: The lowest possible temperature, at which the thermal energy and entropy are zero.

Adiabatic Demagnetization: Cooling method relying on the temperature reduction undergone by paramagnetic magnetic moments when the ambient magnetic field is reduced.

Boson: Any fundamental or composite particle whose total intrinsic spin is an even multiple of $\hbar/2$.

Bose–Einstein Condensation: The process which occurs at low temperatures in a collection of bosons when large numbers of the particles enter the ground state.

Circulation: The integrated scalar product of the velocity and distance around a closed loop.

Coherence Length: Minimum length scale on which the superfluid wave function may vary.

Cooper Pairs: The boson particles formed from a pair of fermions that allow fermion systems to become superfluid.

Dilution Refrigerator: Refrigerator operating in the millikelvin region, whose working fluid is ^{3}He dissolved in liquid ^{4}He.

Dipole–Dipole Interaction: The nonisotropic interaction between two magnetic moments. In superfluid ^{3}He this coupling determines the orientation of the (magnetic) nuclear spin relative to the (nonmagnetic) orbital angular momentum of the Cooper pairs.

Dispersion Relation: The relationship between the momentum and the energy of a particle.

Energy Gap: The minimum energy of a quasiparticle excitation in superfluid ^{3}He.

Fermion: Any fundamental or composite particle whose total intrinsic spin is an odd multiple of $\hbar/2$. Obeys Pauli's exclusion principle.

Fermi Momentum p_F, Fermi Energy E_F: Momentum and energy of a particle at the Fermi surface.

Fermi Surface: The surface marking the limit of filled states in momentum space for a system of fermions.

Gauge Symmetry: The invariance of a system in condensed matter physics under a global change of the phase of the wave function.

Homogeneous Precessing Domain: Domain that can be set up in superfluid ^{3}He in which the magnetizations of all the Cooper pairs precess coherently.

Landau Velocity: The critical velocity in a superfluid at which excitations may be freely created and the superfluidity breaks down.

Longitudinal NMR: Exotic nuclear magnetic resonance in which the exciting radiofrequency field is parallel to the static field.

Nuclear Cooling: Cooling method for the microkelvin region based on the adiabatic demagnetization of nuclear spins.

Persistent Current: A current in a superfluid that flows indefinitely because of the lack of dissipation.

Phonons, Rotons: Thermal excitations in superfluid ^{4}He.

Quasiparticle Excitations: Excited states of the system whose behavior is similar to propagating particles. These excitations may be either bosons or fermions. In the present article the term is used for the fermionic excitations, which may be particle-like or hole-like in superfluid ^{3}He.

Quantized Vortices: The vortices in a superfluid whose circulation is quantized since the wave function is limited to making a multiple of 2π change around the vortex axis.

Quantum Fluid: Fluid whose behavior is dominated on a macroscopic scale by quantum mechanics.

Spin Supercurrent: A flow of spin in superfluid ^{3}He in response to a gradient in the spin part of the wavefunction.

Spontaneous Symmetry Breaking: The lifting of a symmetry arising from ordering at a phase transition.

Superfluid: Fluid able to flow without dissipation; frictionless liquid.

Superleak: A restricted passage that allows the passage of superfluid but restricts the passage of normal fluid.

Texture: The "grain" in the structure of superfluid ^{3}He, governed ultimately by the directions of the orbital and spin angular momentum directions of the Cooper pairs.

Thermomechanical, Mechanothermal: Terms describing the linking of thermal and mechanical effects which occurs in superfluids.

INTRODUCTION

Among the properties of surfaces and interfaces, structure is fundamental, as it determines or influences chemical, electrical, mechanical, and even magnetic and optical behavior. In describing structure, it is essential that a scale length be defined. For example, a surface may feel smooth or rough or it may scatter light specularly or diffusely, which are clearly macroscopic or mesoscopic measures of surface structure. On the other extreme, the atomic structure of the surface describes where the atoms are located relative to their positions in the bulk of the crystal. In the past half century, remarkable progress has been made in determining the atomic structure of the surface, driven initially by the development of ultrahigh vacuum, which permitted the preparation of clean surfaces and maintenance of the cleanliness for sufficient time to make detailed structural measurements. quent invention of numerous structural characterization methods and the development of supercomputers and advanced computational algorithms have led to a broad understanding of surface atomic structure.

"Surface structure" is not just "where are the atoms". There are also larger-scale features for whose description the detailed positions of the atoms need not be known. These features are typically affected or determined by extended structural entities such as steps, terraces, dislocations, grain boundaries, and voids. The term "surface morphology" has come into use to describe such larger-range features. Their influence on surface properties can be significantly greater than that of the atomic structure. The analogous term for the bulk of materials is "microstructure". Looking down on a surface to observe its form and topology in the way one looks at the ground from an airplane illustrates why "morphology" is appropriate.

This article discusses surface atomic structure and surface morphology under the umbrella of "surface structure". It aims to provide an overview of basic concepts and fundamental principles related to structural properties of solid surfaces and interfaces and to illustrate systematic trends in structures of surfaces and interfaces in different classes of materials. Section 1 reviews surface thermodynamics, as a basis and a driving force for formation of surface structure. Section 2 introduces concepts and notations required to describe the structures of single-crystal surfaces. Section 3 overviews intrinsic structures of single-crystal surfaces and discusses surface relaxation and reconstruction, with examples chosen from semiconductor and metal surfaces. Section 4 deals with the morphology of real surfaces and interfaces, and the development of morphology through kinetic limitations or thermodynamic driving forces encountered during thin-film growth or surface treatment.

1. SURFACE THERMODYNAMICS

1.1 Gibbs Surface Model and Surface Tension

J. W. Gibbs (1928) laid the groundwork for surface thermodynamics. He introduced a notion of a *dividing surface* and derived all surface thermodynamic properties by an *excess procedure*. A real system consisting of two homogeneous phases separated by a finite inhomogeneous transition region [Fig. 1(a)] is idealized as two homogeneous phases separated by a hypothetical geometrical surface, the dividing surface [Fig. 1(b)]. The dividing surface is chosen to be near the macroscopic observable physical interface and everywhere parallel to it; different choices of dividing surface may be used that are parallel to each other but displaced from each other in the direction of the surface normal. The excess procedure expresses the thermodynamic properties of the real system in terms of the thermodynamic properties of the ideal system and excess properties, which define the difference between the real and ideal values. Thus, all extensive surface thermodynamic functions can be expressed in terms of the dividing surface through the excess procedure. For the two-phase system that is represented by two homogeneous phases, phases 1 and 2, and a dividing surface, as shown in Fig. 1(b), any extensive property can be divided unambiguously into contributions from phase 1, phase 2, and the surface as

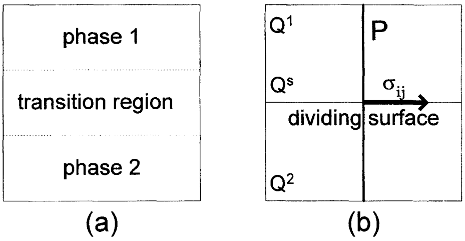

FIG. 1. The Gibbs surface model: (a) the real system; (b) the idealized system. The thin horizontal line in the middle marks the dividing surface; the thick vertical line marks the imaginary plane P used to derive the surface stress tensor σ_{ij}.

$$Q = Q^1 + Q^2 + Q^s, \qquad (1)$$

where Q is the extensive property of the whole system, which is the integration of the specific value of Q over the whole system including the inhomogeneous transition region; Q^1 and Q^2 are, respectively, the same extensive property for phases 1 and 2 that would apply as if they are homogeneous up to the (infinitely narrow) dividing surface; Q^s is the excess extensive property, *i.e.*, the difference between Q and $Q^1 + Q^2$, assigned to the surface. One intriguing problem with the excess extensive property is that it is usually not unique, depending on the choice (or location) of the dividing surface (see discussion below).

One defines surface tension γ as the reversible work required to create unit area of surface (by cleavage), at constant temperature (T) and pressure (p); this function is the partial derivative of Gibbs free energy (G) of the whole system with respect to area of surface formed (A), at constant T, p, and mole concentration of each component (n_i):

$$\gamma = \left(\frac{\partial G}{\partial A}\right)_{T,p,n_i}. \tag{2}$$

As $G = G(T, p, n_i, A)$, the differential of Gibbs free energy can be written as

$$dG = -S\,\mathrm{d}T + V\,\mathrm{d}p + \Sigma\mu_i\,\mathrm{d}n_i + \gamma\,\mathrm{d}A, \tag{3}$$

where S is the entropy, V the volume, and μ_i the chemical potential of molecular species i.

Alternatively, γ can be defined as the partial derivative of Helmholtz free energy (F) of the whole system with respect to A, at constant T, V, and n_i,

$$\gamma = \left(\frac{\partial F}{\partial A}\right)_{T,V,n_i}; \tag{4}$$

and the differential of Helmholtz free energy, $F = G - pV$, is

$$\mathrm{d}F = -S\,\mathrm{d}T - p\,\mathrm{d}V + \sum \mu_i\,\mathrm{d}n_i + \gamma\,\mathrm{d}A. \tag{5}$$

(Similarly, γ can be defined in terms of internal energy, $E = F + TS$, and grand canonical potential, $\Omega = F - \sum \mu_i n_i$.)

From Eqs. (1) and (3) and applying the first and second law of thermodynamics to the two homogeneous phases 1 and 2, the differential of surface Gibbs free energy is derived as

$$\mathrm{d}G^s = \sum \mu_i\,\mathrm{d}n_i{}^s + \gamma\,\mathrm{d}A. \tag{6}$$

Here $n_i{}^s$ is the excess mole concentration of the ith species assigned to the surface. According to Euler's theorem, the surface Gibbs free energy is

$$G^s = \sum \mu_i n_i{}^s + \gamma A, \tag{7}$$

and similarly, the surface Helmholtz free energy is

$$F^s = pV^s + \sum \mu_i n_i{}^s + \gamma A \approx \sum \mu_i n_i{}^s + \gamma A, \quad \text{for } V^s \to 0. \tag{8}$$

Equations (7) and (8) give another definition for surface tension:

$$\gamma = g^s - \sum \mu_i \Gamma_i{}^s \approx f^s - \sum \mu_i \Gamma_i{}^s, \tag{9}$$

where g^s (f^s) is the Gibbs (Helmholtz) free energy per unit area of surface, *i.e.*, the specific surface Gibbs (Helmholtz) free energy, and $\Gamma_i{}^s$ is the surface density $n_i{}^s/A$ of the ith species.

In general, surface tension γ, which measures the change in Gibbs or Helmholtz free energy for the whole system in creating the surface, has two contributions: the change in Gibbs or Helmholtz free energy per unit area for the surface "phase", g^s or f^s, and the change per unit area of surface formed for the surrounding bulk phases. Note that g^s, f^s, and $\Gamma_i{}^s$ are all *excess* surface properties that are dependent on the position of the dividing surface, but γ, a quantity associated with the whole system, is not, because the position of the dividing surface affects the Gibbs (or Helmholtz) free energy in such a way that the change in the surface term g^s (or f^s) is always balanced by the change in the bulk term $\Sigma\mu_i\Gamma_i{}^s$. For a one-component system, it is possible to choose the dividing surface so that $n_1{}^s$ and, hence, $\Gamma_1{}^s$ vanish; the specific surface Gibbs or Helmholtz free energy then becomes equal to surface tension. Consider a one-component system with solid and gas phases;

the atomic density assumes a constant value of n_{bulk} in the solid phase and a value of zero in the gas phase. In the interface (surface) region, the atomic density decreases gradually from the bulk value to zero as one goes from the bulk phase toward the gas phase. If the dividing surface is located inside the transition region, in the vicinity of the surface, there will be a thin region of "extra" atomic density (>0) in the gas phase and a thin region of "lost" atomic density ($<n_{\mathrm{bulk}}$) in the solid phase. By choosing the position of the dividing surface so that the extra density in the gas phase equals exactly the lost density in the solid phase, there will be no excess surface density, *i.e.*, n_1^{s} and hence Γ_1^{s} vanish. For a multi-component system, however, one choice of the dividing surface that makes n_i^{s} vanish will not make other $n_{j\neq 1}^{\mathrm{s}}$ vanish. Therefore, in general, surface tension γ should not be confused with the specific Gibbs (or Helmholtz) surface free energy, g^{s} (or f^{s}).

Surface tension is a very difficult quantity to measure experimentally, but it can in principle be calculated with a reliable energy functional, such as those based on first-principles (or *ab initio*) computational techniques. In an empirical way, surface tension (surface energy) of a solid surface has two contributions: the formation energy and the relaxation energy. The former reflects the breaking of bonds to make a solid surface (at the ideal bulk terminations); the latter reflects the tendency of a solid surface to distort because it is a quasi two-dimensional (2D) system and hence would like to assume an atomic structure and bonding configuration different from that of the bulk. To create a surface, it costs energy to break bonds, and the cost is partly recovered by the relaxation process involving rearrangement of atoms and bonds at the surface. The formation energy (positive) dominates the relaxation energy (negative). The energy of a single-crystal surface scales approximately with the cohesive energy of the bulk crystal. The greater the bulk cohesion, the stronger the interatomic bonds, the higher the surface energy. The weakly van der Waals–bonded rare-gas solids have the lowest surface energy; the strongly bonded semiconductors and metals have high surface energy. In contrast to that of an isotropic liquid surface, the energy of a solid surface is anisotropic, depending on the orientation of the surface, because a different number of bonds is broken to create different surface orientations.

1.2 Surface Stress and its Relation to Surface Tension

Imagine that there exists a plane P normal to the dividing surface [Fig. 1(b)]. One may derive the surface force acting on P by the same excess procedure discussed above. The total force acting across P, from the material on one side of P to the material on the other side, can be divided into contributions from the two homogeneous bulk phases and from the surface phase. The surface force per unit length of the line intersection of the plane P with the dividing surface plane is then defined as the surface stress.

Gibbs (1928) first pointed out the distinction, for the case of a solid, between surface tension and surface stress: the former measures the energy cost to create unit area of new surface; the latter measures the energy cost to deform the surface. The relationship between surface stress and surface tension can be derived as follows.

Suppose we deliberately deform the surface, at constant temperature and total amount of surface species, introducing an infinitesimal strain ε_{ij} to the surface. The work required to do so is

$$\delta W = A\sum \sigma_{ij}\varepsilon_{ij} \quad (i,j=1,2). \tag{10}$$

Here σ_{ij} denotes the surface stress tensor. This work is equal to the infinitesimal change of surface Gibbs or Helmholtz free energy, G^{s} or F^{s}, at constant T and n_i^{s},

$$\begin{aligned}\delta G^{\mathrm{s}} &= \delta F^{\mathrm{s}} = \delta(\gamma A) = \gamma\delta A + A\delta\gamma \\ &= \gamma A\sum \varepsilon_{ii} + A\sum \frac{\partial\gamma}{\partial\varepsilon_{ij}}\varepsilon_{ij} \quad (i,j=1,2).\end{aligned} \tag{11}$$

Combining Eqs. (10) and (11), we have

$$\sigma_{ij} = \gamma\delta_{ij} + \frac{\partial\gamma}{\partial\varepsilon_{ij}} \quad (i,j=1,2), \tag{12}$$

where the Kronecker delta $\delta_{ij} = 1$ if $i = j$ and $\delta_{ij} = 0$ if $i \neq j$. Surface stress, σ_{ij}, is independent of the location of dividing surface, although it is an excess surface property, as indicated by its relation to surface tension γ in Eq. (12).

Equation (12) also implies that the surface stress tensor σ_{ij} is defined as the derivative of surface Gibbs or Helmholtz free energy (G^s or F^s) with respect to surface strain ε_{ij}, at constant temperature and total amount of surface species,

$$\sigma_{ij} = \frac{1}{A}\left(\frac{\mathrm{d}G^s}{\mathrm{d}\varepsilon_{ij}}\right)_{T,n_i^s} = \frac{1}{A}\left(\frac{\mathrm{d}F^s}{\mathrm{d}\varepsilon_{ij}}\right)_{T,n_i^s} \quad (i,j = 1,2). \tag{13}$$

Equivalently, surface stress may be defined in terms of other thermodynamic energy functions.

For a liquid, surface stress is equal to surface tension because liquid is a purely plastic medium and its surface tension is independent of strain, *i.e.*, the second strain-derivative term on the right-hand side of Eq. (12) vanishes. (For a one-component liquid, surface tension also equals the specific Gibbs or Helmholtz surface free energy. So, for this special case, the values of all three quantities, surface stress, surface tension and specific surface free energy, are the same, which has often caused confusion.) When a liquid surface is stretched, atoms rapidly enter the surface from the bulk; the existing surface atoms stay where they are and the new surface is formed of atoms from the bulk now occupying surface positions. Thus, expanding a liquid surface is equivalent to creating a new liquid surface. In contrast, solids are a purely elastic medium, at least at low deformations. When a solid surface is stretched, surface atoms are displaced from their minimum-energy positions, sitting at new sites for which the surface as a whole has a different energy. Thus, the surface tension of a solid surface depends on surface strain. While a liquid surface is always under tensile stress for γ to be positive, a solid surface can be under an overall stress that is either tensile or compressive because the second term in Eq. (12), the strain derivative of tension, can be either positive or negative and may have a magnitude larger than the first term, the tension contribution. Also, the strain-derivative term often makes the surface stress of a solid surface anisotropic, while the surface stress of a liquid surface is always isotropic.

2. SURFACE CRYSTALLOGRAPHY

2.1 Orientation of Crystalline Surfaces

Given a single crystal of a particular Bravais lattice (see CRYSTALLOGRAPHY), a lattice plane is defined to be any plane containing at least three noncollinear Bravais lattice points; it is denoted by Miller indices, which are the coordinates of the shortest reciprocal-lattice vector normal to the plane. A common way of creating a crystalline surface is to cut a bulk single crystal parallel to one of its low-index atomic planes (*e.g.*, {100}, {110} or {111} planes in a cubic single crystal). An ideal surface (one that has all atoms in bulk positions) is made by removing all the atoms lying on one side of a chosen atomic plane and keeping the positions of all remaining atoms intact. The orientation of this surface is then well defined, with its surface normal specified by the directional indices, [*hkl*], defined in the conventional way with respect to the three-dimensional (3D) unit cell of the bulk crystal (Ashcroft and Mermin, 1976). The surface is denoted as an (*hkl*) surface, using the Miller indices of the corresponding parallel set of atomic planes in the bulk crystal. The notation {*hkl*} denotes a set of equivalent planes or surfaces.

Low–Miller-index surfaces are widely used in surface science research and epitaxial growth of thin films because of their relatively greater stability and high symmetry. A real surface generally consists of a number of terraces of low-index surface planes of the same orientation separated by steps. In *nominal* {*hkl*} surfaces the normal to the average surface orientation coincides with the normal to the *singular* {*hkl*} terraces that constitute the surface. To achieve this condition, there must be on the average an equal number of "up" steps and "down" steps in a nominal {*hkl*} surface [see

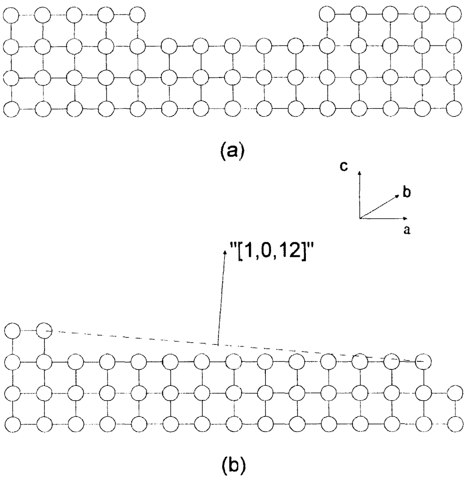

FIG. 2. Side views ([0$\bar{1}$0] projection) of (001) surfaces of a simple cubic lattice. (a) A nominal surface consisting of three singular (001) terraces separated by one up and one down single-atomic-height step. (b) A vicinal surface miscut by ≈4.8° toward [100]. The normal (arrow) to the average surface orientation (dashed line) is [1 0 12].

Fig. 2(a)]. In practice, it is very difficult to cut a crystal exactly parallel to a chosen low-index plane. Even if there is no average miscut, the uncertainties in cutting and polishing lead to a wavy surface, giving only a nominally low-index surface. A vicinal surface is made by a deliberate cut up to a few degrees away from a low-index plane toward a specific direction. For example, Fig. 2(b) shows a vicinal surface of a simple cubic lattice formed by a miscut $\approx 4.8^0$ away from [001] toward [100]. A vicinal surface may be specified either by the normal to its average surface orientation, which generally produces unreasonably large Miller indices [*e.g.*, the surface in Fig. 2(b) would be labeled as (1 0 12)], or by the indices of the constituent terraces plus the miscut angle and miscut orientation {*e.g.*, Si(001) miscut 2^0 toward [110]}. The latter choice makes it convenient to understand and discuss the properties of a small-miscut vicinal surface in terms of its low-index singular terraces and the effects of defects (steps). If the miscut angle is not too small and the index of the normal to the average surface orientation does not contain numbers that are too large, the surface is named with its appropriate Miller indices.

2.2 Surface Periodicity and Symmetry

The structure of a single-crystal solid is uniquely defined by its intrinsic symmetry (Ashcroft and Mermin, 1976), which includes translational symmetry (periodicity), symmetry of the Bravais lattice (primitive unit cell), and symmetry of the unit cell basis (atoms or molecules) in the unit cell. The translational symmetry in 3D is realized by 7 different *crystal systems*: cubic, tetragonal, orthorhombic, monoclinic, triclinic, trigonal, and hexagonal. Allowing more than one grid point per unit cell leads to 14 *Bravais lattices*, including types of primitive (p), body-centered (bc), face-centered (fc), and base-centered unit cells. Each lattice point may have more than one atom associated with it, reducing the symmetry of the original crystal system. There are 32 *crystallographic point groups* that a crystal structure can have, covering symmetry operations of rotation, reflection, and inversion, and combinations of them. The full symmetry of the crystal (including atomic arrangement) is described completely by 230 *crystallographic space groups*, with the addition of symmetry operations of screw axes and glide planes.

As a crystalline solid is truncated to make a surface, the translational symmetry of the solid perpendicular to the surface is removed, while the periodicity parallel to the surface remains. Because in the surface region each atom layer becomes intrinsically inequivalent to other layers, all the symmetry properties of a solid surface are two-dimensional. Consequently, surface structures, in analogy to 3D crystal structures, are classified by the 2D Bravais lattice (net) and symmetry groups of the net and of the atomic basis associated with the net. There are five different 2D Bravais nets: oblique, primitive (p) rectangle, centered (c) rectangle, square, and hexagonal, as depicted in Fig. 3; ten 2D point groups; and seventeen possible 2D space groups (Woodruff, 1981).

The 2D Bravais net consists of a grid of equivalent points; the atomic basis represents the arrangements of atoms at each net point. The translational symmetry of a real surface usually differs from that of an ideal bulk termination of the solid, *i.e.*, that of the corresponding atomic plane in the bulk, because of surface reconstruction (see discussion below). If $(\boldsymbol{a}_s, \boldsymbol{b}_s)$ and $(\boldsymbol{a}_i, \boldsymbol{b}_i)$ are the unit net vectors

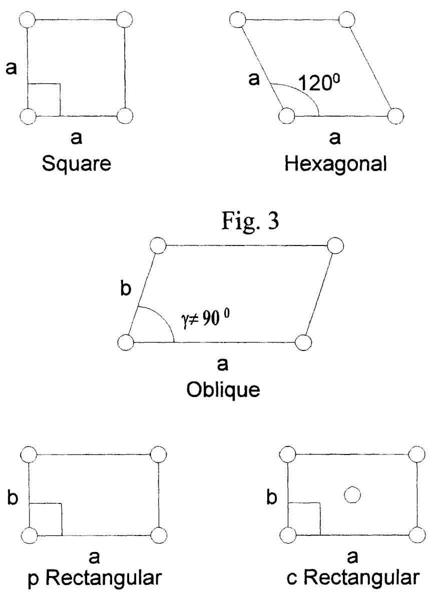

FIG. 3. The five two-dimensional Bravais nets: oblique, square, hexagonal, and primitive (p) or centered (c) rectangle.

(the primitive translational vectors) of the real surface and of the ideal surface, respectively, the general translational vectors are

$$\boldsymbol{T}_s = n\boldsymbol{a}_s + m\boldsymbol{b}_s \tag{14}$$

in the real surface and

$$\boldsymbol{T}_i = n\boldsymbol{a}_i + m\boldsymbol{b}_i \tag{15}$$

in the ideal surface. Here n and m are integers. The relationship between the real surface net and ideal surface net is uniquely defined by a (2 × 2) matrix, $\boldsymbol{G}$ (Park and Madden, 1968),

$$\begin{pmatrix} \boldsymbol{a}_s \\ \boldsymbol{b}_s \end{pmatrix} = \boldsymbol{G}\begin{pmatrix} \boldsymbol{a}_i \\ \boldsymbol{b}_i \end{pmatrix}. \tag{16}$$

The determinant of $\boldsymbol{G}$, $|\boldsymbol{G}|$, equals the ratio of the areas of the real unit net and the ideal unit net. If $|\boldsymbol{G}|$ is an integer, the nets are *simply* related; if $|\boldsymbol{G}|$ is a rational number, the two nets are *rationally* related. When $|\boldsymbol{G}|$ is irrational, the real surface has an incommensurate structure relative to the ideal surface (substrate).

Although the matrix notation is exact, it is seldom used. Instead, a notation introduced by

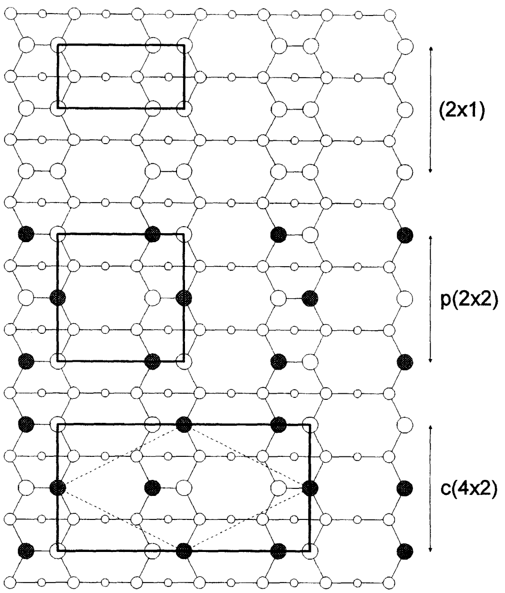

FIG. 4. Schematic top view of three possible reconstructions on Si(001). Top region: (2 × 1); middle: p(2 × 2); bottom: c(4 × 2). Open and solid circles mark atom positions; their size indicates different layers of atoms, with the largest circles in the outermost layer. In the middle and bottom regions, the slightly different heights of the two atoms in a dimer due to buckling are indicated by solid and open circles. The unit mesh of each reconstruction is depicted by a dark rectangle. For the c(4 × 2) structure, the primitive unit mesh is depicted by a dashed-line rhombus.

Wood (1964) has been widely adopted and is convenient for small commensurate unit meshes. This simple notation uses the ratio of the lengths of the real primitive net vectors to those of ideal primitive vectors plus an angle through which the real net is rotated with respect to the ideal net. Figure 4 illustrates the use of this notation to describe several possible reconstructions on Si(001). A detailed discussion of these reconstructions will be presented later.

2.3 Reciprocal-Space Representation and Diffraction

Conventionally, surface structures are detected through their representation in reciprocal space using diffraction-based surface probes. An important consequence of periodicity is the modification of the law of momentum conservation. As a wave (*e.g.*, electrons or photons) interacts with a periodic structure, its momentum is conserved plus or minus any reciprocal-lattice vector (lattice momentum). For a surface, the periodicity only exists parallel to the surface, so the modified law of momentum conservation applies only to the components of the wave vectors parallel to the surface,

$$\boldsymbol{k}_{\|} = \boldsymbol{k}_{0\|} + \boldsymbol{g}_{hk}. \tag{17}$$

$\boldsymbol{k}_{0\|}$ and $\boldsymbol{k}_{\|}$ are parallel to surface components of incident and diffracted-wave vectors. $\boldsymbol{g}_{hk}$ is a surface reciprocal-net vector (*i.e.*, a general translational vector in $\boldsymbol{k}$ space), which is expressed as

$$\boldsymbol{g}_{hk} = h\boldsymbol{a}^* + k\boldsymbol{b}^*, \tag{18}$$

where h and k are integers; $\boldsymbol{a}^*$ and $\boldsymbol{b}^*$ are primitive unit vectors of the reciprocal net, defined relative to the real-space net as

$$\boldsymbol{a}^* = (2\pi\boldsymbol{b}_s \times \boldsymbol{n})/A, \quad \boldsymbol{b}^* = (2\pi\boldsymbol{a}_s \times \boldsymbol{n})/A,$$

$$A = \boldsymbol{a}_s \cdot \boldsymbol{b}_s \times \boldsymbol{n}, \tag{19}$$

where $\boldsymbol{n}$ is the unit vector normal to the surface.

The conditions for diffraction are totally defined by the momentum conservation expressed in Eq. (17) together with an energy conservation equation,

$$k^2 = k_0{}^2 \text{ or } k_{\|}{}^2 + k_{\perp}{}^2 = k_{0\|}{}^2 + k_{0\perp}{}^2. \tag{20}$$

These conditions can be conveniently visualized using the Ewald sphere construction in $\boldsymbol{k}$ space, as illustrated in Fig. 5. One first draws a vector of the incident wave, $\boldsymbol{k}_0$, to the origin of the reciprocal space, and then draws a sphere of radius k_0 about the tail of the vector $\boldsymbol{k}_0$. In three dimensions, this (Ewald) sphere passes through certain reciprocal-lattice points in addition to the origin, and the diffracted beam $\boldsymbol{k}$ is simply given by a vector from the tail of $\boldsymbol{k}_0$ to those reciprocal-lattice points lying on the Ewald sphere. A surface can be approximated by a 2D net. It is straightforward to show that for a 2D net, the complete reciprocal space consists of a set of lines or "rods" that are infinite in extent, are perpendicular to the 2D net, and pass through the reciprocal-net points. Because those rods inside the Ewald sphere will always intersect the sphere, the conditions for the appearance of diffracted beams are greatly relaxed, relative to those for a 3D crystal, for which the reciprocal lattice consists of points. Therefore, a small change in energy of the incident wave, *i.e.*, in the length of $\boldsymbol{k}_0$ and the radius of Ewald sphere, will totally extinguish one set of diffracted beams in three dimensions. The same change for a surface will only shift slightly the direction of the diffracted beams.

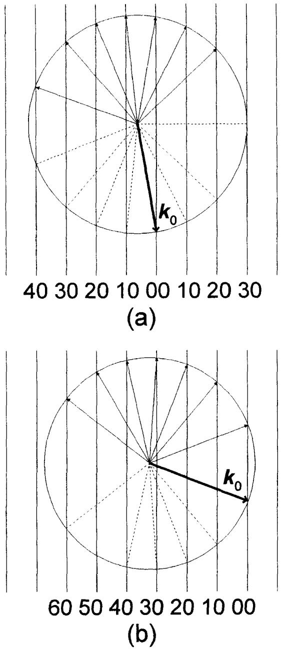

FIG. 5. Ewald sphere construction for a two-dimensional system, *e.g.*, a single layer. The incident beam is denoted by the vector k_0 and all other radial vectors ending on the Ewald sphere correspond to diffracted beams, k. (a) Near-normal incidence for LEED; (b) low-angle incidence for RHEED. Dashed lines indicate those diffracted beams penetrating into the bulk. For RHEED, k_0 is generally much larger, relative to the spacing of the reciprocal-lattice rods, than is shown in (b); for LEED, the relative magnitudes shown in (a) are appropriate.

Electron beams and x rays are typically used in diffraction-based surface probes. Figure 5 illustrates two common setups for electron diffraction: low-energy electron diffraction (LEED), generally performed at near-normal incidence, and reflection high-energy electron diffraction (RHEED), at glancing incidence. Most forms of radiation used for diffraction (electrons, x rays) have a mean free path in solids sufficiently large to penetrate some distance into the crystal. For example, for electrons this mean free path varies from approximately 5 Å up to thousands of ångströms, as the energy is changed. The actual penetration into the crystal can be limited by changing the angle of incidence (compare LEED and RHEED). The finite penetration of radiation into the crystal implies that a 2D net and perfect reciprocal-lattice rods to describe scattering from a surface form only a limiting approximation, *i.e.*, there is some 3D character to the reciprocal lattice. Thermal He and other noble-gas atoms, on the other hand, are scattered above the surface without penetrating the crystal because the energies for the wavelengths appropriate for crystal diffraction are much lower. For He scattering, a 2D net and pure reciprocal-lattice rods are a good approximation; consequently, of course, only the structure of the outer surface layer can be detected. Helium scattering is also very useful in studying "unstable" surface structures such as adsorbate layers because of the very low energy of the probe.

In addition to determining the periodicity (*i.e.*, long-range order) of the surface structure, diffraction can in principle also determine the positions of the atoms in the structure. This sensitivity to the atomic basis associated with the lattice occurs through the intensities of the diffracted beams. For electron diffraction, determination of atomic positions is complicated by the strong interaction of electrons with atoms, causing multiple scattering. The use, for example, of x rays (for which the interaction is much weaker) at grazing incidence avoids this problem.

As real-space surface structures are derived indirectly from their representations in reciprocal space with diffraction techniques, controversies often arise when different structural models are fitted to the diffraction data, especially when a large atomic basis is involved or when the relaxation from the ideal (bulk-termination) surface is small. The advance of a new generation of surface probes using scanning tunneling and force microscopies has allowed the direct observation of surfaces in real space, often with atomic resolution. In many ways, the "old" diffraction probes and the new scanned probes compensate each other: the former, working in reciprocal space, are sensitive to the long-range order, and the latter, working in real space, give local order with atomic detail. It is frequently much easier to construct a correct model to fit the diffraction data using scanned-probe real-space images as input. In modern laboratories, diffraction and real-space techniques are often combined to monitor and determine surface structures *in situ* and in real time.

3. SURFACE RELAXATION AND SURFACE RECONSTRUCTION

3.1 A General Discussion

Real surfaces do not retain the ideal bulk termination. Atoms of surface and near-surface layers are generally displaced from their ideal bulk positions, residing at new positions of minimum energy in response to a change of atomic and electronic environments in the surface regions. The atomic rearrangements can take place a few layers deep into the bulk, but the most dramatic structural changes usually occur at only the true surface layer. The structure of this outer layer dominates most surface properties. Surface *relaxation* involves only atomic displacements that do not change the translational symmetry of the surface (*i.e.*, the periodicity of the surface), *e.g.*, collective equal displacements of all atoms in the surface layer; surface *reconstruction* describes atomic displacements that change the periodicity of the surface. Surface relaxation should not be confused with atomic relaxations at defects (vacancies, adatoms, steps, *etc.*), at which the periodicity is already disturbed. A change in surface periodicity can also be caused by a change of atom number density in the surface layers. Because atoms in the surface layer are undercoordinated, missing all neighbors on the vacuum side of the surface, atoms may be added or deleted from the top layer in order to minimize the surface free energy, as has been discussed in Sec. 1.

The driving force for surface relaxation and reconstruction is minimization of surface (free) energy. Surfaces with high surface energy have a stronger tendency to relax and/or reconstruct than surfaces with low surface energy. For a given solid, higher-energy (generally higher-index) orientations of a surface usually relax and/or reconstruct more than lower-energy (lower-index) orientations [see, *e.g.*, the discussion in Sec. 3.3 of fcc metal (110), (100), and (111) surfaces]. It is, however, the reduction of surface energy rather than the surface energy itself that controls the tendency for a surface to relax and/or reconstruct. The nature of interatomic interactions in different classes of solids is the key factor controlling their respective surface structural properties. The surfaces of rare-gas solids, in which atoms are bonded with the weak van der Waals interaction, are most inert, exhibiting only small relaxations perpendicular to the surface; surfaces of metals that have isotropic metallic bonds most often do not reconstruct but display large relaxations; semiconductor surfaces with broken highly directional covalent bonds have the strongest tendency to reconstruct.

The lowering of surface energy can be achieved by reducing surface chemical energy and/or surface strain energy; the two often compete. The reduction of chemical energy, which dominates at the atomic level by optimizing bonding and/or electron density, often occurs at the expense of strain energy, which is caused by bond distortion [see, *e.g.*, the discussion of reconstruction on Si(001) in Sec. 3.2]. The reduction of strain energy becomes dominant in determining morphologies at the mesoscopic scale because elastic interactions extend to a much longer range than do chemical interactions.

The fundamental mechanisms for reducing surface chemical energy through surface relaxation/reconstruction depend strongly on the nature of chemical bonding in the underlying solid. In semiconductors, atoms bond with each other by sharing electron pairs in covalent bonds. The major effect of creating a surface is to break covalent bonds, introducing a large number of dangling bonds in the surface. Consequently, there exists a strong driving force for reconstructing semiconductor surfaces to remove dangling bonds on surface atoms. In metals, atoms bond with each other through the effective medium of an electron gas, and the major effect of creating a surface is the depletion of electron density in the vicinity of the surface. Surface atoms tend to rearrange themselves to reoptimize their surrounding electron density. Such atomic rearrangement in both semiconductor and metal surfaces involves, inevitably, changes of interatomic spacings and distortion of bond angles, so that the gain in chemical energy is usually achieved at the expense of strain energy.

The surface strain energy can be reduced by morphological changes at the mesoscopic scale, such as creation and modulation of steps and dislocations (see Sec. 4.2). Such structural and morphological changes give rise to a variation of surface stress over the surface, which generates a distribution of elastic force density. The strain relaxation energy equals the integral of force density times displacement over the whole surface area. Thus, the strain relaxation process is always accompanied by a redistribution of the surface stress field.

A large portion of research in surface science, especially in earlier years, focused on determination of the intrinsic surface structure—in particular, surface relaxation and surface reconstruction of clean crystalline solid surfaces. In the following we discuss some general features of relaxation and reconstruction in semiconductor and metal surfaces and present a few typical examples.

3.2 Semiconductor Surfaces

Semiconductors are generally made of atoms with s and p valence orbitals each containing on average two electrons (the half-filled s and p shells of an average atomic configuration yield the filled valence band and empty conduction band of the semiconducting bulk). In those semiconductors that crystallize in diamond (elemental semiconductors) and zincblende (binary compound semiconductors) structures, the s and p orbitals at each atomic site hybridize into an sp^3 configuration, which is characterized by four equivalent hybrid orbitals pointing to the corners of a tetrahedron with the atom at the center. Therefore, each atom is tetrahedrally coordinated, forming four covalent bonds with its four nearest neighbors, and each bond shares an electron pair, amounting effectively to a total of eight electrons, a very stable closed s and p shell, on each atom. In a Group-IV elemental semiconductor, each atom contributes one electron per covalent bond. In a binary compound semiconductor, each atom contributes $f = n_V/4$ electrons per covalent bond, where n_V is the number of valence electrons in a single atom; $f_c + f_a = 2$, where subscripts c and a denote cations and anions, respectively.

In creating a surface, some covalent bonds must be broken, leaving behind dangling bonds, hybrid orbitals with a single electron. Because of the high energy cost of dangling bonds, the surface energy of semiconductor surfaces is usually high, and there exists a strong tendency for semiconductor surfaces to relax and/or to reconstruct to reduce the number of dangling bonds or to reconfigure the dangling bonds into a lower-energy state.

3.2.1 The {100} Surfaces The {100}-oriented surfaces of elemental and compound semiconductors have been the most extensively studied surfaces because of their technological importance. In particular, the Si(100) surface serves as the foundation of modern semiconductor technology. In an ideal {100} surface of a diamond or zincblende structure, each atom has two dangling bonds, caused by the loss of two of its nearest neighbors [see Fig. 6(a)]. The primary feature of a reconstructed {100} surface is dimerization, the rebonding of two neighboring surface atoms to form a dimer to eliminate one dangling bond per atom [Fig. 6(b)]. The rebonding, which bonds two second-nearest-neighbor atoms into a distance almost equal to the first-nearest-neighbor separation, requires a rather large distortion of bond angles. Thus, the decrease in electronic energy by rebonding is partly offset by an increase in strain energy. The minimization of strain energy drives the dimers to order into parallel rows, leading to a (2 × 1) reconstruction (see top region of Fig. 4). The dimerization of Si(001) and Ge(001) was first proposed by Schlier and Farnsworth (1959) as an explanation of their (2 × 1) LEED patterns observed at room temperature. The dimer rows have been "seen" directly by scanning tunneling microscopy (STM) on both Si(001) (Tromp *et al.*, 1985, Hamers *et al.*, 1986a) and Ge(001) (Kubby *et al.*, 1987), as well as on (001) surfaces of compound semiconductors, such as GaAs(001) (Biegelsen *et al.*, 1990a, 1990b).

Using a typical dimer bond length of 2.5 Å, it is estimated that the gain in electronic energy is about 4 eV per dimer, based on a tight-binding model (Harrison, 1981), and the cost in strain energy is about 2 eV per dimer, based on the Keating model (Keating, 1966); so, overall, the dimerization, or more precisely the (2 × 1) reconstruction, lowers the surface energy by ≈2 eV per dimer. This estimate is roughly the same for all the elemental and binary compound semiconductor {100} surfaces, and it is in very good agreement with *ab initio* calculations (Ramstad *et al.*, 1995) for Si(001).

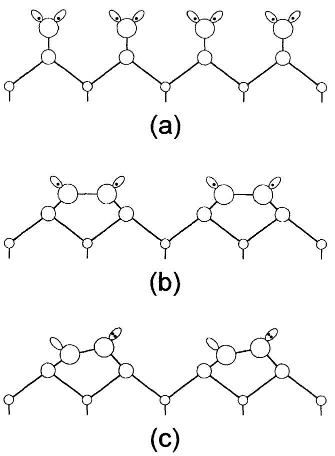

FIG. 6. Dangling-bond configurations on {100} surfaces of elemental semiconductors: (a) two dangling bonds (hybrids with a single electron) on each surface atom in an ideal bulk-terminated surface; (b) one dangling bond on each atom in a dimer. Each dangling bond is half-filled, leading to a metallic surface layer. (c) Charge transfer from downward atom to upward atom in a tilted ("buckled") dimer. The dangling bond on the lower atom is empty and the one on the higher atom is filled, leading to a semiconducting surface layer.

3.2.1.1 Dimer Buckling in the {100} Surfaces of Elemental Semiconductors The energies of two dangling bonds are degenerate in a dimer reconstruction if the dimers consist of two identical atoms in identical positions. Such dimers are called symmetric or "unbuckled" dimers. In the symmetric configuration, the two degenerate dangling bonds are both half-filled, resulting in a metallic surface. Because such energy degeneracy is not a spin degeneracy, the symmetric structure is unstable against Jahn–Teller distortion, which will lower the free energy by lowering the symmetry of the dimer, *i.e.*, by removing the degeneracy of the dangling bonds in the dimer and changing the surface from metallic to semiconducting. An asymmetric dimer can be most easily achieved by a simple tilt, or buckling, as shown in Fig. 6(c).

The buckling of dimers induces rehybridization of surface bonds: the atom moving downward changes its back bonds more to an sp^2-like bonding (about equally bonded to its three nearest neighbors within a plane) and hence its dangling bond to more p-like; the atom moving upward changes its back bonds to more p-like (bond angles are reduced toward 90°) and its dangling bonds to more s-like. The two reconfigured dangling-bond states result in a charge transfer from the downward atom to the upward atom and a lowering of electronic energy. In other words, the buckling of a dimer splits two degenerate dangling-bond energy levels. The dangling-bond bonding level, of s character, lies below the maximum of the bulk valence band and will then be occupied; the dangling-bond anti-bonding level, of p character, lies above the maximum of the valence band and will be empty, making a metallic surface layer semiconducting. Chadi (1979), using tight-binding calculations, first showed that the symmetric dimers are unstable against buckling on Si(001). *Ab initio* calculations (for a list of these calculations, see, *e.g.*, Ramstad *et al.*, 1995) later confirmed this conclusion. The energy gain from buckling is $\approx 0.2\,\text{eV}$ per dimer (Ramstad *et al.*, 1995). Similar results are obtained for Ge(001) (Needels *et al.*, 1987).

The buckling, like the dimerization, decreases electronic energy at the expense of increasing strain energy. The minimization of strain energy causes periodic arrays of buckling patterns that give rise to $c(4 \times 2)$ and $p(2 \times 2)$ reconstructions, which have been observed at low temperatures on Si(001) and Ge(001) by LEED (Kevan and Stoffel, 1984; Tabata *et al.*, 1987) and by x-ray diffraction (Lucas *et al.*, 1993). Low-temperature STM (Wolkow, 1992) of Si(001) shows that surface dimer buckling begins to "lock in" below $\approx 200\,\text{K}$, the number of buckled dimers that are locked into the buckled position increases with decreasing temperature, and the ordering of buckled dimers forms local $c(4 \times 2)$ and $p(2 \times 2)$ domains, with the $c(4 \times 2)$ domains dominating.

Although buckled (tilted) dimers are more stable than unbuckled (untilted) dimers, there seems to be a rather low energy (kinetic) barrier for a buckled dimer to switch from one buckling configuration (*e.g.*, with the left-side atom up) to another (with the left-side atom down). At sufficiently high temperature, surface dimers can switch their orientations so rapidly and independently of each other that the buckling configurations are in a dynamic disorder, leading to an averaged symmetric appearance in STM and to a (2×1) diffraction pattern. LEED (Kevan and Stoffel, 1984; Tabata *et al.*, 1987) and x-ray diffraction (Lucas *et al.*, 1993) have revealed a structural phase transition from the (2×1) to the $c(4 \times 2)$ phase as the temperature is decreased, corresponding to the freezing in of rocking dimers, in the temperature range between 150 and 250 K. Theoretical calculations (Ihm *et al.*, 1983; Saxena *et al.*, 1985; Zubkus *et al.*, 1991) predict a second-order phase transition from an ordered $c(4 \times 2)$ or $p(2 \times 2)$ structure to a disordered (2×1) structure at approximately 200–250 K, in good agreement with experiments.

3.2.1.2 The {100} Surfaces of Binary Compound Semiconductors and Electron Counting Covalent bonds in a binary compound semiconductor are partially ionic because the electronegativities are smaller for the metal atoms (cations) than for the nonmetal atoms (anions). In a zincblende structure, bulk {100} planes are alternately occupied by cations and anions, and so an ideal {001} surface will be completely terminated by either cations or anions, leading to a polar surface. Polar surfaces, especially the {100}-oriented ones, have been widely used in homo- and hetero-epitaxial growth of compound semiconductors because the sticking coefficient of anion molecules depends strongly on the cation surface concentration. For example, the sticking coefficient of As_2 molecules on a GaAs(001) surface is unity if the surface is Ga-terminated but zero if it is As-terminated (Arthur, 1974; Foxon and Joyce, 1977). During MBE growth, the surface composition can be controlled from anion- to cation-rich by adjusting growth conditions, *e.g.*, the substrate temperature, the growth rate, and the ratio of the respective fluxes. All

{100} surfaces of III–V and II–VI compound semiconductors display reconstructions depending on surface composition.

The GaAs(001) surface has attracted much attention because of its potential importance in optoelectronic devices. As the As-rich GaAs(001) surface is heated from room temperature to above 450 °C, the following sequence of reconstructions is observed (Cho, 1971; Drathen *et al.* 1978; Massies *et al.*, 1980):

$$\begin{aligned} \mathrm{c}(2\times 8) &\xrightarrow{\approx 475\,^{\circ}\mathrm{C}} 1\times 6 \longrightarrow \mathrm{c}(6\times 4) \\ &\xrightarrow{\approx 575\,^{\circ}\mathrm{C}} 3\times 1 \longrightarrow 4\times 1 \\ &\xrightarrow{\approx 650\,^{\circ}\mathrm{C}} \mathrm{c}(8\times 2). \end{aligned} \tag{21}$$

The sequence is correlated with the continuous decrease of the As concentration in the surface due to thermal desorption of As_2 molecules without evaporation of Ga (Arthur, 1974). A reverse sequence is observed (van Bommel *et al.*, 1978) when cooling down the Ga-rich surface:

$$\mathrm{c}(8\times 2) \xrightarrow{\approx 450\,^{\circ}\mathrm{C}} \mathrm{c}(6\times 4) \xrightarrow{\approx 350\,^{\circ}\mathrm{C}} \mathrm{c}(2\times 8), \tag{22}$$

which is attributed to surface segregation of As from inside the bulk (Arthur, 1974; Neave and Joyce, 1978). In the As-rich surfaces, three different forms of (2 × 4) and/or c(2 × 8) reconstructions may occur depending on growth conditions, and they are denoted as (2 × 4)-α, -β, and -γ structures (Farrell and Palmstrøm, 1990). If an excess amount of As is present on the surface beyond one monolayer (ML) coverage, the surface displays a c(4 × 4) reconstruction (Neave and Joyce, 1978) and eventually becomes (1 × 1) when a thin film of As of a few monolayers thick is formed. All {100} surfaces of III–V and most of the II–VI compound semiconductors except ZnSe behave like GaAs(001) (Cornelissen *et al.*, 1988).

STM images of As-rich GaAs(001) surfaces (Biegelsen *et al.*, 1990a, 1990b) reveal that the basic features of the surface reconstructions are dimers and dimer vacancies (missing dimers). At different coverages, different reconstructions arise from the specific density, the arrangement, and the orientation of dimers and dimer vacancies. The three forms of (2 × 4)/c(2 × 8) reconstruction on the As-rich surface correspond to coverages of 0.5, 0.75, and 1 ML of As, respectively; the c(4 × 4) reconstruction corresponds to a As coverage of 1.75 ML.

The formation of dimers and dimer vacancies, and hence the reconstructions, can be understood by an electron-counting model (Chadi, 1987a; Pashley, 1989). As for elemental semiconductors, the dimerization on {100} surfaces of compound semiconductors reduces the number of dangling bonds. The energy of dangling-bond states can be reduced by charge transfer between two dangling bonds to fill one dangling bond with a lone electron pair while emptying the other one. On elemental {100} surfaces, this energy redistribution is achieved by intra-dimer charge transfer through dimer buckling, while on compound {100} surfaces, it is achieved by charge transfer between the second-layer atoms and surface dimers through the formation of dimer vacancy rows. Because dangling-bond energies are lower on anions than on cations, charge transfer from dangling bonds on cations to those on anions is greatly favored over the reverse. On a cation-terminated surface, all the dangling bonds on surface cation dimers can be emptied by transferring their electrons to the second-layer anions that are exposed at the dimer-vacancy sites; on an anion-terminated surface, all the dangling bonds on surface anion dimers can be filled by obtaining extra electrons from the second-layer cations that are exposed at the dimer-vacancy sites. Consequently, all compound-semiconductor {100} surfaces exhibit a general (2 × N) reconstruction; the twofold periodicity results from the dimerization, and the N-fold periodicity results from the dimer vacancy row formation. The periodicity N defining the optimal density of dimer vacancies is determined by an electron-counting rule (Mönch, 1995).

Consider an anion-stabilized (2 × N) structure with M_a anion dimers and $N - M_a$ missing dimers per unit mesh. Each dimer will contain six electrons: two in the dimer bond itself and two each in the dangling bonds at each of the dimer atoms. These electrons are supplied by the surface anions as well as by the second-layer cations that are exposed to the surface at the vacancy sites. Because each cation and anion contributes, respectively, f_c and f_a electrons per bond, counting the total number of electrons in the unit mesh, we have

$$6M_a = 4M_a f_a + 4(N - M_a)f_c. \tag{23}$$

Since $f_c = 3/4$ and $f_a = 5/4$ for III–V semiconductors, and $f_c = 2/4$ and $f_a = 6/4$ for II–VI semiconductors, we obtain from Eq. (23)

$$M_a(\text{III–V}) = 3N/4; \quad M_a(\text{II–VI}) = N. \tag{24}$$

Because the value of M_a, *i.e.*, the number of dimers in the unit cell, must be an integer, the relations in Eq. (24) predict that the smallest unit mesh on anion-stabilized {100} surfaces is (2 × 4) for III–V systems and (2 × 1) for II–VI systems. Figure 7 shows a schematic diagram of the (2 × 4) reconstruction on As-terminated GaAs(001). Similarly, for a cation-stabilized ($N \times 2$) structure with M_c cation dimers, we have

$$2M_c + 8(N - M_c) = 4M_c f_c + 4(N - M_c)f_a, \tag{25}$$

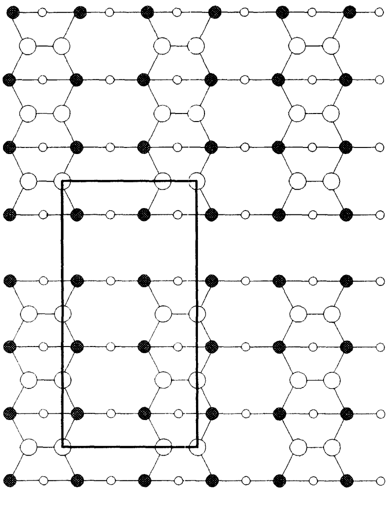

FIG. 7. Schematic top view of the (2 × 4)-β reconstruction on As-stabilized GaAs(001), induced by As vacancies. The large and small open circles denote As atoms in the first and third layers, respectively. The solid circles denote Ga atoms in the second layer. The solid rectangle marks the unit mesh.

and

$$M_c(\text{III–V}) = 3N/4; \quad M_c(\text{II–VI}) = N. \tag{26}$$

The smallest unit mesh on cation-stabilized {100} surfaces is (4 × 2) for III–V systems and (1 × 2) for II–VI systems. The acceptable values of N clearly depend on surface composition, which alters the number of electrons in the surface. So far, all the known reconstructions on the {100} surfaces of binary compound semiconductors satisfy the electron-counting rule (Mönch, 1995).

3.2.2 The {111} Surfaces The {111} surfaces of semiconductors, like the {100} surfaces, have also attracted much attention, the interest stemming from their complex structures, such as the well-known Si(111)-(7 × 7) reconstruction. In an ideally bulk-terminated {111} surface of diamond or zincblende structures, surface atoms have three nearest neighbors in the second layer and one half-filled dangling bond perpendicular to the surface [see Fig. 8(a)]. The elemental semiconductors Si and Ge cleave along {111} planes, and both as-cleaved surfaces exhibit a metastable (2 × 1) reconstruction. The ground-state structure of Si(111) is a (7 × 7) reconstruction and that of Ge(111) is a c(2 × 8) reconstruction. A simple rebonding (dimerization) mechanism like the one on Si(001) to reduce the number of dangling bonds is unlikely here because there is no easy direction for surface bonds to rotate. However, an adatom can effectively reduce the number of dangling bonds, two per adatom, by saturating three dangling bonds but introducing only one, a key ingredient on both the Si(111)-(7 × 7) and Ge(111)-c(2 × 8) reconstructions. For binary compound semiconductors, the {111} surfaces are fully terminated by either cations or anions, and the same (2 × 2) reconstructions are observed on different terminations, but with different structural origins.

3.2.2.1 The (2 × 1) Reconstruction on Cleaved Si(111) and Ge(111) and on Clean C(111) Both Si{111} and Ge{111} display a (2 × 1) reconstruction upon cleavage. The doubling of surface periodicity relative to the ideal surface (bulk {111} planes) occurs in

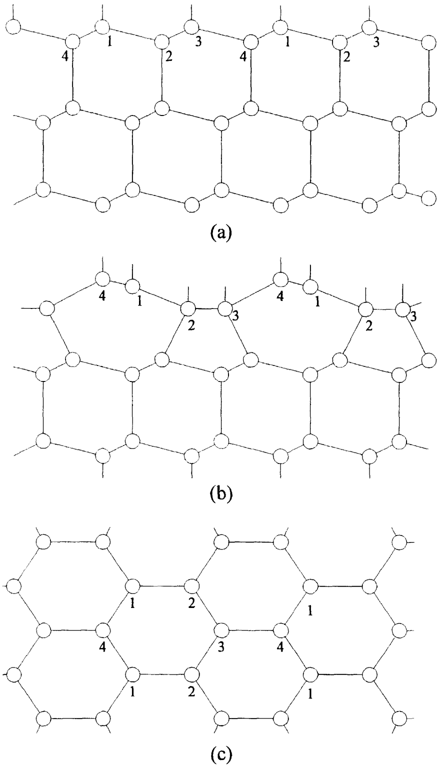

FIG. 8. π-bonded chain model of the (2 × 1) reconstruction on {111} surfaces of solids with the diamond structure. (a) Side view of ideally terminated surface. (b) Side view of the reconstructed surface. (c) Top view of the reconstructed surface.

⟨211⟩ directions, and the three equivalent ⟨211⟩ directions in the diamond lattice may give rise to three different orientations of (2 × 1) domains. In an early model (Haneman, 1961), the doubling of periodicity was thought to result from alternating rows of depressed and raised surface atoms, which was expected to lower surface energy by rehybridization of sp^3 orbitals on the surface atoms, inducing a charge transfer from the downward atoms with p-like dangling bonds to the upward atoms with s-like dangling bonds. This simple model, accepted until 1980, was found to be inconsistent with the measurements of surface electronic properties—in particular, the core-level shifts of surface atoms measured by photoemission (Himpsel *et al.*, 1980; Brennan *et al.*, 1980). A model proposed by Pandey (1982), which consists of zigzag π-bonded chains along ⟨110⟩ directions [Figs. 8(b) and 8(c)], was found to be consistent with these data. These chains are joined to the underlying bulk by five- and seven-member rings instead of the six-member rings that are characteristic of the diamond structure [see Fig. 8(b)]. The arrangement of surface atoms into such zigzag chains reduces surface energy because it conserves the total number of dangling bonds in the surface but makes them nearest neighbors and hence promotes some π-bonding among them rather than having them as second-nearest neighbors, as in the ideal or the earlier model surfaces. Surface energy is further reduced by tilting (or buckling) of chains, similar to buckling of dimers on Si(001) and Ge(001), as shown by both *ab initio* theories and various experiments (for a collection of theories and experiments, see e.g., Schlüter, 1988; Mönch, 1995).

The chains can be easily formed by simultaneously depressing a surface atom [atom 3 in Fig. 8(b)] into the second layer and raising a second-layer atom [atom 4 in Fig. 8(b)] into the surface layer, with a very small barrier of $\leq 0.03\,\text{eV}$ (Northrup and Cohen, 1982). The reconstructed surface is about 0.3–0.4 eV per atom more stable than the ideal surface (Pandey, 1982; Northrup and Cohen, 1982). The small formation barrier explains why the chain structure can be readily formed during cleavage. The formation process may be mediated by generation of stacking faults that involves formation of five- and seven-member rings (Reichardt, 1991).

Clean diamond {111} surfaces, which are prepared by annealing polished samples in ultrahigh vacuum in the temperature range of 950–1200 °C, show a (2 × 2) LEED pattern (Marsh and Farnsworth, 1964; Lander and Morrison, 1966). The (2 × 2) pattern is interpreted as the superposition of diffraction patterns from more than one of the three possible (2 × 1) domains present in the surface. [Occasionally, a (2 × 2) pattern also occurs on Si(111) and Ge(111).] So, similar to the {111} surfaces of Si and Ge, the {111} surfaces of C display a (2 × 1) reconstruction, which can be explained by Pandey's chain model (Pandey, 1982). However, differences exist between the {111} surfaces of C and those of Si or Ge. In C(111), the chains are flat, as shown by total-energy calculations (for a list of theories, see

Mönch, 1995), and are purely stabilized by strong π-bonding between C dangling bonds. In Si(111) [or Ge(111)], however, the π-bonding between dangling bonds is much weaker, and it alone is not sufficient to stabilize the chain structure. Consequently, the chains are buckled and the structure is primarily stabilized by the buckling-induced charge transfer between surface atoms rather than by π-bonding (Badziag and Verwoerd, 1988).

3.2.2.2 The Si(111)-(7 × 7) and Ge(111)-c(2 × 8) Reconstructions The (2 × 1) reconstructions on the as-cleaved Si(111) and Ge(111) surfaces transform irreversibly into (7 × 7) and c(2 × 8) structures, respectively, after annealing at elevated temperature (Lander *et al.*, 1963), confirming the metastability of the (2 × 1) reconstruction. The calculated surface energy of Si(111)-(7 × 7) is indeed lower than that of Si(111)-(2 × 1) (Brommer *et al.*, 1992). The determination of atomic structure involving large surface unit meshes is generally difficult. It took almost thirty years to solve the Si(111)-(7 × 7) reconstruction after it was first observed (Schlier and Farnsworth, 1959). After many different experimental techniques had been applied and a variety of models had been proposed, a complete description of the structure was finally achieved by Takayanagi *et al.* (1985a,b), who used a comprehensive analysis of transmission electron-diffraction patterns and all the prior knowledge developed for this surface. They introduced the dimer–adatom–stacking fault (DAS) model, showing how three key ingredients involved in the reconstruction that had each been independently suggested earlier, the adatom, the stacking fault, and the dimer, contribute to the overall structure shown in Fig. 9.

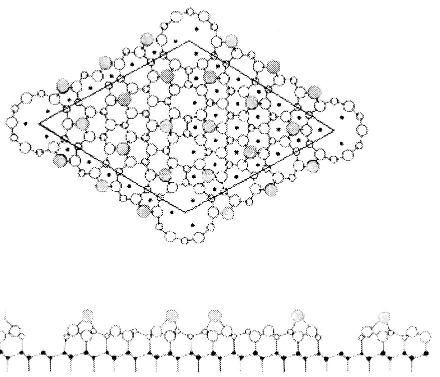

FIG. 9. (Top) Top view and (bottom) side view, taken along the long diagonal of the unit cell, of the dimer–adatom–stacking fault (DAS) model of the Si(111)-(7 × 7) reconstruction. The adatom layer (large shaded circles) and two double layers (open and solid circles) are indicated. The stacking fault is in the left half of the unit cell. (After Takayanagi *et al.*, 1985b.)

The (7 × 7) unit cell consists of two triangular subunits; one of them (the left half in Fig. 9) contains a stacking fault, producing wurtzite-type stacking of the outermost two double layers. There are six adatoms in each of the two subunits, in a (2 × 2) arrangement. They are located directly over the second-layer atoms and bind to three first-layer atoms. The faulted and unfaulted subunits are separated by a triangular network of partial dislocations, and dangling bonds along these dislocations are partially saturated by the formation of dimers (three dimers at each triangle edge), which are linked by eight-member rings. At the corners of the unit cell, *i.e.*, the crossing points of the dislocations, there are holes (corner holes) exposing large portions of the second double layer. Around the corner holes, atoms are connected by twelve-member rings.

The DAS model combines all the structural ingredients that had emerged from previous experimental studies. The adatom is the most effective way to reduce the dangling-bond density on a {111} surface of diamond structures (Harrison, 1976). However, incorporation of adatoms also introduces large strain in the surface. *Ab initio* theories (Northrup and Cohen, 1984; Northrup, 1986; Meade and Vanderbilt, 1989) show that the balance between the gain in electronic energy and the cost in strain energy produces, as the most stable arrangement of adatoms on Si(111), a (2 × 2) lattice in which adatoms sit on top of the second-layer atoms (in T_4 sites), with one rest atom (unsaturated surface atom) per (2 × 2) unit mesh. This arrangement has been seen directly by STM (Binnig *et al.*, 1983a; Becker *et al.*, 1985a; Hamers *et al.*, 1986b) in both triangle subunits of the (7 × 7) unit cell of Si(111). However, for Si(111), adatoms alone are unable to stabilize the surface. Additional structural changes must be incorporated; in particular, stacking faults (Bennett *et al.*, 1983) are introduced to create dimers at

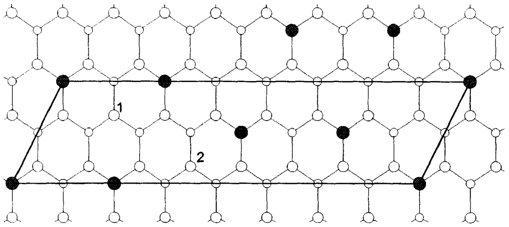

FIG. 10. Adatom model of the Ge(111)-c(2 × 8) reconstruction. Large and small open circles mark the first-layer and second-layer atoms, respectively. Shaded circles are Ge adatoms sitting on top of the second-layer atoms. Numbers 1 and 2 denote two inequivalent sites of rest atoms in the first layer. (After Becker *et al.*, 1989.)

the boundaries between faulted and unfaulted subunits (McRae, 1983; Himpsel, 1983) to reduce the dangling-bond density further. STM, equipped with spectroscopy (Tromp *et al.*, 1986), also reveals details of other structural features, such as the rest atoms, the corner holes, and the asymmetry between the two triangle subunits. Consequently, in the (7 × 7) structure, the overall electronic-energy gain (from the reduction of dangling bonds by a factor of 2.6 by creation of adatoms and dimers) offsets the strain-energy cost associated with creation of adatoms and with the formation of dimers and stacking faults, as shown by theoretical calculations (Qian and Chadi, 1987; Štich *et al.*, 1992; Brommer *et al.*, 1992).

The structure of the Ge(111)-c(2 × 8) surface, which involves only adatoms, is much simpler than that of the Si(111)-(7 × 7) surface. STM images (Becker *et al.*, 1985b, 1989) show that there are four adatoms and four rest atoms in the unit cell, as shown in Fig. 10. All adatoms are located at T_4 sites (van Silfhout *et al.*, 1990) while the rest atoms occupy two inequivalent positions (Hirschorn *et al.*, 1991). There is one dangling bond on each adatom and on each rest atom. The dangling bonds on adatoms are empty while those on rest atoms are filled (Becker *et al.*, 1989), indicating charge transfer from adatoms to rest atoms to reduce surface energy. The Ge dangling-bond energy is lower than that of Si. Also, Ge adatoms introduce less surface strain on Ge(111) than do Si adatoms on Si(111) because Ge is softer than Si (the elastic constants are approximately 40% larger for Si than for Ge). Consequently, for Ge(111), the introduction of adatoms alone is energetically favorable because the energy gain by reducing dangling-bond density by a factor of 2 more than offsets the adatom-induced energy cost in strain. The balance between the electronic-energy gain and the strain-energy cost is rather delicate in the (7 × 7) and c(2 × 8) reconstructions. Applying a compressive strain to a Ge(111) surface will convert the c(2 × 8) structure into the (7 × 7) structure, as demonstrated by the growth of thin Ge films on Si(111) (Gossmann *et al.*, 1985). Also, there exists a family of $[(2n-1)\times(2n-1)]$ DAS structures that employ the same underlying principle of energy balance as in the (7 × 7) structure. Depending on sample conditions and annealing temperatures, different domains with (5 × 5), (7 × 7), and (9 × 9) unit cells may appear on Si(111) (Becker *et al.*, 1986). The detailed mode of reconstruction can be controlled by varying the lateral stress (strain) in the surface. For example, the (5 × 5) reconstruction appears in the SiGe alloy surface under compressive stress as a thin SiGe alloy film is grown on a Si(111)-(7 × 7) substrate (Gossmann *et al.*, 1984), as well as in the Si(111) surface under tensile stress, obtained from a Si–Ge thin-film sandwich structures (Ourmazd *et al.*, 1986).

3.2.2.3 The {111} Surfaces of Compound Semiconductors The ideal {111}-(1 × 1) surfaces of binary compound semiconductors terminated by either cations or anions are conventionally denoted as (111) and $(\bar{1}\bar{1}\bar{1})$ surfaces, respectively. For III–V as well as II–VI compound semiconductors, both cation-terminated (111) and anion-terminated $(\bar{1}\bar{1}\bar{1})$ surfaces exhibit a (2 × 2) reconstruction (Ebina and Takahashi, 1982), but with different structural origins. The (2 × 2) structure of (111) surfaces arises from the formation of cation vacancies while that of $(\bar{1}\bar{1}\bar{1})$ surfaces arises from the formation of a regular array of anion trimers on top of the anion termination layer.

Most studies have been carried out on GaAs (111) and $(\bar{1}\bar{1}\bar{1})$ surfaces. In GaAs(111), each (2 × 2) unit mesh contains one Ga vacancy, exposing three As atoms in the second layer below the surface. Consequently, there are equal numbers (three) of Ga and As atoms in the unit mesh, and Ga dangling bonds are empty and As ones are filled as a result of the charge transfer from Ga to As. This structural and electronic configuration has been directly seen by STM (Haberern and Pashley, 1990). A LEED study (Tong *et al.*, 1984) shows that the exposed second-layer As atoms relax toward the center of Ga vacancies, leading to almost planar (on Ga atoms) and pyramidal (on As atoms) surface bonding configurations. The resultant atomic arrangement becomes similar to the tilted chains on nonpolar (110) surfaces of compound semiconductors (see discussion below). Total-energy calculations (Chadi, 1984) reveal that the formation of Ga vacancies on GaAs(111) is exothermic but the formation of As vacancies on GaAs($\bar{1}\bar{1}\bar{1}$) is endothermic. The vacancy-induced (2×2) reconstruction is also observed on similar systems, such as GaP(111), InSb(111) and GaSb(111) (Xu *et al.*, 1985; Bohr *et al.*, 1985; Feidenhans'l *et al.*, 1987).

Different models have been proposed for the GaAs($\bar{1}\bar{1}\bar{1}$)-(2×2) reconstruction. It cannot originate from As vacancies because of their large positive formation energy (Chadi, 1984). An anion-cluster model that consists of As trimers sitting on top of a complete terminating As layer was suggested from STM (Biegelsen *et al.*, 1990c). This structural model satisfies the electron-counting rule (Pashley, 1989) discussed in Sec. 3.2.1.2, and it possesses a lower surface energy than many other proposed models, as shown by an *ab initio* calculation (Kaxiras *et al.*, 1986). The anion trimer model is also supported by a TEM study of InSb($\bar{1}\bar{1}\bar{1}$) (Nakada and Osaka, 1991).

3.2.3 The {110} Surfaces The {110} surfaces of elemental semiconductors have complex structures, most notably superstructures involving steps. For example, a (16×2) reconstruction, which consists of 25-Å-wide stripes of singular terraces separated by up and down monatomic-height steps running along ⟨112⟩ directions, has been observed on both Si(110) (Yamamoto, 1994) and Ge(110) (Ichikawa *et al.*, 1995). A similar reconstruction with all the steps in the same sense (*i.e.*, all steps up or down) also forms on Si(110) (Yamamoto, 1994), leading to a vicinal facet of (17, 15, 1) structure.

Both III–V and II–VI semiconductors that crystallize in the zincblende structure cleave naturally along {110} planes, because these planes contain an equal number of cations and anions and thus are intrinsically neutral. The ideal surface consists of planar zigzag chains of alternating cations and anions along the [$\bar{1}$10] direction; each surface atom remains threefold coordinated, with one dangling bond [Fig. 11(a)]. The surface displays no reconstruction but sizable relaxations. The simplest relaxation at the {110} surfaces of a zincblende crystal is the tilting (buckling) of the zigzag chains (MacRae and Gobeli, 1966; Levine and Freeman, 1970), as shown in Fig. 11(b). Because bond energies change less with changing bond angle than with changing bond length, the buckling of the chain involves mainly bond rotations with bond length being approximately conserved, as shown by a collection of experimental results on {110} surfaces of III–V, II–VI, and even I–VII compounds (Mönch, 1995). Similar to buckled dimers on Si(100) or Ge(100), the buckled chains reduce surface energy by charge transfer from the downward atoms to the upward atoms because the dangling bond on the lower atoms becomes more p-like (with backbonds more sp^2-like) while that on the upper atoms becomes more s-like (with backbonds more p-like). Also, the dan-

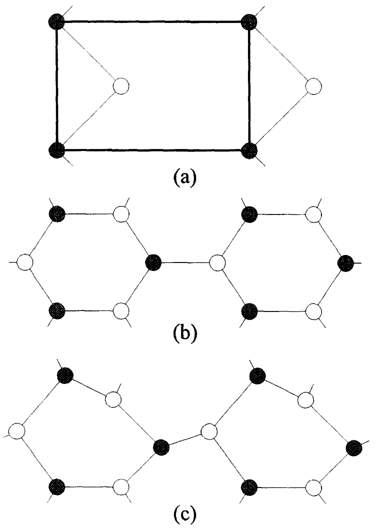

FIG. 11. Schematic atomic arrangements at {110} surfaces of zincblende-structure compound semiconductors. Open and shaded circles denote cations and anions, respectively. (a) Top view. (b) Side view of ideal bulk-terminated surface. (c) Side view of the relaxed surface.

gling-bond energy is lower on anions than on cations (see Sec. 3.2.2.3), so that all the cations on the {110} surfaces of compound semiconductors move downward and all the anions move upward [Fig. 11(b)], leading consistently to a charge transfer from the downward cations to upward anions. A correlation exists between buckling angle and ionicity of the underlying compound. For compounds with large ionicity, substantial charge transfer can be induced by the large difference in electronegativities between surface cations and anions, without a need for much buckling of chains. Thus, in general, the angle of buckling is found to decrease with increasing ionicity (Mönch, 1995).

3.3 Metal Surfaces

The nature of chemical bonding in metals differs from that in semiconductors. Covalent bonds are directional, while metallic bonds are more or less isotropic. Consequently, atoms in a semiconductor have to bond with each other in specific orientations, leading to a tetrahedral network and the diamond and zincblende structures; atoms in a metal, in contrast, bond as much as possible closely packed, forming face-centered cubic (fcc), hexagonal close-packed (hcp), or body-centered cubic (bcc) crystal structures, the three simple 3D lattices with highest atom number density. The fcc and hcp structures represent the closest packing of spheres in three dimensions, both having twelve nearest neighbors, while the bcc structure has eight nearest neighbors but six nearly as close second-nearest neighbors, with a separation only slightly larger than the first-nearest-neighbor distance. Such close packing maximizes the electron-density overlap. Different packing sequences result from different electronic structures of the constituent metal atoms.

The difference in bonding between semiconductors and metals also strongly influences the structural properties of the respective surfaces. As just described, in semiconductor surfaces, removal of atoms at the vacuum side produces a great number of dangling bonds, and thus a strong tendency for reconstruction to reduce their number. This driving force for reconstruction disappears in metal surfaces because there are no dangling bonds. Metal surfaces generally exhibit less tendency to reconstruct than semiconductor surfaces.

An empirical estimate of the magnitude of surface relaxation and the tendency to reconstruct for systems of close-packed spheres can be obtained by comparing the interatomic spacing to the diameter of a free atom. For example, rare-gas crystals can be approximated as the close packing of 'hard' spheres. The atoms bond with each other *via* the weak van der Waals interaction, and the atomic radii hardly change in the solid. Consequently, there is very little relaxation (less than a few percent) and no reconstruction of rare-gas crystal surfaces. Metallic bonds are much stronger than the van der Waals interaction; consequently interatomic spacings in a metal are less than the diameters of free metal atoms and metal surfaces have a stronger tendency to relax. Some metal surfaces also reconstruct, optimizing the interatomic spacings and/or the coordination numbers of surface atoms in order to minimize the surface free energy.

A more detailed understanding of the structure of metal surfaces than the sphere packing model requires knowledge of the electronic properties of metals. They can be described in the simplest limit by a jellium model, in which a periodic array of positive ions is embedded in the uniform density of a free-electron gas. Two theoretical approaches in the spirit of the jellium model, the embedded-atom method (EAM; see, *e.g.*, Foiles, 1987) and the effective-medium theory (EMT; see, *e.g.*, Jacobson and Nørskov, 1988) have been widely used to determine many properties of metals and metal surfaces. At equilibrium, metal atoms are located at sites of most favorable electron density to minimize their free energy. At the surface the electron density is reduced because of the removal of neighbors on the vacuum side. The most intuitive (but not always correct) conclusion one draws is that the atoms in the outermost surface layer can reduce their energy by relaxing inward to a higher electron density. Such inward relaxation frequently does occur. For example, the spacing of the two outermost layers of unreconstructed fcc (110) metal surfaces is reduced between 5.1% in Pd(110) (Schottke *et al.*, 1987) and 17.1% in Pb(110) (Breuer *et al.*, 1990) relative to the bulk value.

A relaxation in the opposite direction, *i.e.*, an increase in the separation of the two outer layers, is also possible, as observed, *e.g.*, in the Pt(111) surface (Materer *et al.*, 1995). Metals are frequently not well described by a jellium model, *i.e.*, the electron density does not decrease uniformly at the surface. Electronic surface states can introduce a local maximum in the electron density at a position outside the regular 3D lattice position of the outermost layer of atoms. The lowest-energy state of the surface may then involve an outward relaxation.

The electron density at the surface can also be optimized by reducing the interatomic spacing within the surface layer or by increasing the coordination number of the surface atoms, either by incorporating extra atoms into the surface layer or by rearrangement of the atoms. These effects produce reconstructions. A reconstruction may be caused by large atomic displacements or by atomic displacements so small that the reconstruction is difficult to observe. We restrict ourselves here to reconstructions that are unambiguously identified.

The desire of the surface atoms to reduce their lateral spacing leads to tensile stress in not yet reconstructed surfaces (this means that the surface energy would be reduced if the crystal were compressed). For example, *ab initio* calculations (Feibelman, 1995) have shown an excess surface stress in Pt(111) of about $0.25\,\mathrm{eV}\,\mathrm{\AA}^{-2}$. Whether the excess surface stress is strong enough to induce a reconstruction depends on its value and on the energy cost in creating the reconstruction. For example, atomic rearrangement, including the incorporation of additional atoms within the surface layer, displaces surface atoms from their regular lattice positions. Because atoms in the topmost layer will lose some of their nearest neighbors in the second layer, the interaction between the topmost layer and the second layer is weakened. Whether the surface shows a reconstruction depends on the balance between the energy gain from increasing the atom number density in the topmost layer and the energy loss from weakening of the interaction between the topmost and second layer.

Most metal surfaces exhibit large relaxation but only some surfaces, including some orientations of the bcc metals W and Mo and of the fcc metals Au, Pt, and Ir, reconstruct. Intuitively, the higher the atom number density in a surface layer, the lower is the tendency for the surface to reconstruct, because a higher coordination implies a more bulk-like environment. The atom number density of a surface plane depends on the surface orientation (see Fig. 12). Nevertheless, there are surfaces with highest atom number densities [*e.g.*, Au(111)] that do reconstruct.

Among bcc metals, the W(100) surface is unreconstructed at room temperature, but during cooling to 250 K W(100) reconstructs spontaneously to a $\sqrt{2} \times \sqrt{2}$ R45° structure (Fig. 13) (see, *e.g.*, Pendry *et al.*, 1988). Figure 13(b) shows that the lateral displacement of the atoms in the first layer leads to zigzag chains. The atoms in the second layer are also slightly displaced, by about 20% of the displacement of the atoms in the topmost layer (Altmann *et al.*, 1988). Additionally the topmost layer shows an inward relaxation of about 6%. *Ab initio* calculations (Singh and Krakauer, 1988) have identified the gain in energy due to an increase in the effective coordination of the surface atoms as the driving force towards the reconstruction. Mo(100) exhibits a similar reconstruction at lower temperatures, but with a seven times larger unit cell (Daley *et al.*, 1993).

The fcc 5d transition metals (Au, Pt, Ir) display a variety of reconstructions on different low-index surfaces. In the following we discuss, as an example, the general trend of surface relaxation and reconstruction on these 5d metals.

3.3.1 The fcc (110) Surface

Many experiments (for a list of these experiments, see, *e.g.*, Rous, 1995) have shown that the (110) surface of fcc 5d metals has a strong tendency to reconstruct. Figure 14(a) shows a schematic diagram of the unreconstructed surface. Atoms in the topmost layer have only seven nearest neighbors, a great reduction from the bulk value of twelve. Atoms in the second layer also are missing one nearest neighbor, which would sit on top of them. Even more importantly, an atom located in the (110) plane has only two in-plane nearest neighbors along the [110] direction. In the perpendicular direction there are no in-plane nearest neighbors, leading to a very weak interaction between atoms in different [110] chains. Chains of atoms in such a configuration can be rearranged easily without losing nearest-neighbor bonds.

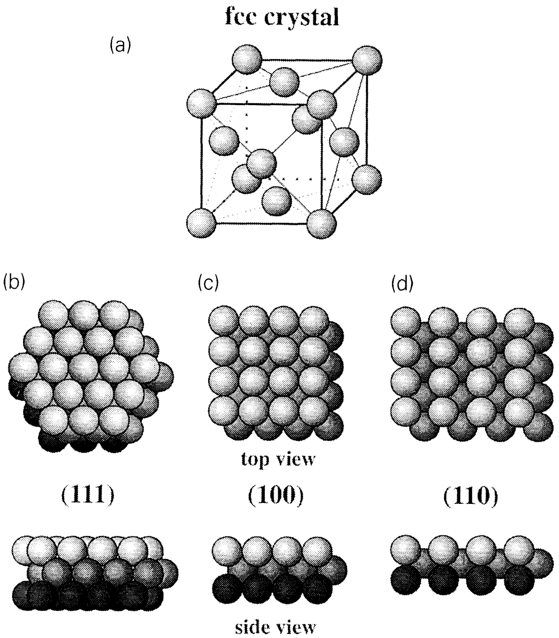

FIG. 12. Surfaces of fcc crystals. (a) Model of the fcc crystal. (b)–(d) Top and side views of the (111), (100), and (110) surfaces, respectively.

The large potential for reconstruction leads to the missing-row structure, observed, *e.g.*, on Au(110) and Pt(110). Figure 14(c) shows a schematic view of the missing-row reconstruction. Counting all atoms exposed to vacuum in the top, second, and third layers as surface atoms, the reconstruction changes neither the average coordination of surface atoms nor the surface atom-number density. However, the distribution of coordination of surface atoms has changed. In the unreconstructed surface [Fig. 14(b)], half of the surface atoms (in the topmost layer) lose five neighbors, and the other half (in the second layer) lose one neighbor; in the reconstructed surface [Fig. 14(d)], a fourth of the surface atoms (in the topmost layer) lose five neighbors, one half (in the second layer) lose three neighbors, and another fourth (in the third layer) lose one neighbor. The missing-row reconstruction transforms half of the atoms missing five or one neighbors into ones missing three neighbors by breaking some second-nearest-neighbor bonds between rows. Calculations have shown that this more uniform coordination leads to a reduction in free energy. The free-energy reduction for the missing-row reconstruction can be visualized by recognizing that the reconstruction is equivalent to forming small (111) facets (Binnig *et al.*, 1983b), the most stable surface of fcc crystals.

Surfaces of fcc (110) metals exhibit a systematic correlation between formation of a missing-row reconstruction and electronic properties. Whereas all 5d fcc transition metals reconstruct, the 4d fcc metals and the 3d transition metals show no tendency to reconstruct. The trend can be understood by comparing the energy cost of forming the missing-row reconstruction with the energy gain. The cost of

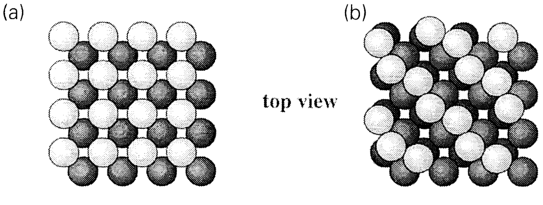

FIG. 13. Top view of the W(100) surface: (a) unreconstructed and (b) $\sqrt{2} \times \sqrt{2}$ reconstructed.

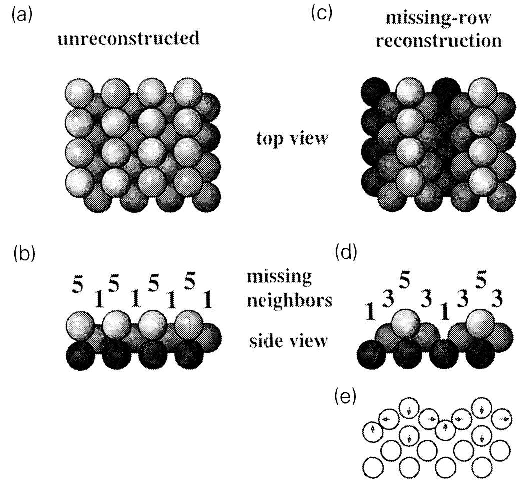

FIG. 14. Reconstruction of fcc (110) surfaces. (a), (b) Top and side views of the unreconstructed surface same as Fig. 12(d). (c), (d) Top and side views of the 2×1 missing-row reconstructed surface. (e) A schematic side view of the relaxation of the Au(110)-(2×1) missing-row reconstruction as proposed by Moritz and Wolf (1985).

breaking the second-nearest-neighbor bonds between neighboring rows is balanced by the gain produced by a more uniform distribution of the number of nearest neighbors. Thus, the gain is related to a more localized effect (the nearest-neighbor bonds) than is the cost (the second-nearest-neighbor bonds). The electrons of the 5d metals are very localized, so that the first-nearest-neighbor effect dominates over the second-nearest-neighbor effect, favoring the reconstruction. As one moves from 5d to 4d and 3d metals, electrons become less and less localized. As a result, the second-nearest-neighbor effect becomes dominant, preempting the reconstruction. This trend is reproduced qualitatively by many calculations (see Woodruff, 1994, for a selection of theoretical publications).

An interesting question is why the (110) surface does not form larger (111) facets, leading to ($N \times 1$) ($N > 2$) instead of (2×1) missing-row reconstructions. The simple model described above would lead to larger facets because the energy gain would be greater. The cause lies in the atomic relaxation. As shown in Fig. 14(e), the relaxation involves atomic displacements both perpendicular and parallel to the surface (Fery *et al.*, 1988). For larger (111) facets the relaxation would have to be mainly a uniform displacement of atoms perpendicular to the (111) facet. In certain cases, such as Au(110), calculations have shown that there is only a slight energy advantage for the 2×1 missing-row reconstruction relative to ($N \times 1$) structures with larger (111) facets [about 10 meV per atom (Ho and Bohnen, 1987)]. In agreement with these calculations, the Au(110) surface has an intrinsic amount of disorder involving (3×1) and (4×1) reconstructed regions (Binnig *et al.*, 1983b; Gritsch *et al.*, 1991). On Ir(110) a (3×1) reconstruction has been observed (Naumovets *et al.*, 1975).

3.3.2 The fcc (100) Surface In the (100) surface, atoms have eight nearest neighbors, four of them within the surface plane. The (100) surface of metal crystals is expected to have a smaller tendency to reconstruct than the (110) surface. Nevertheless all three 5d transition metals have reconstructed (100) surfaces (for a list of relevant experiments, see, *e.g.*, Rous, 1995). In contrast to the reconstruction of the (110) surface, the reconstruction of the (100) surface is controlled by gain and cost both related to nearest-neighbor bonds. The details of the underlying mechanisms are not yet known.

Both Pt(100) and Au(100) form a hexagonal surface layer on top of the square (100) lattice (Fig. 15) (Abernathy *et al.*, 1992). The

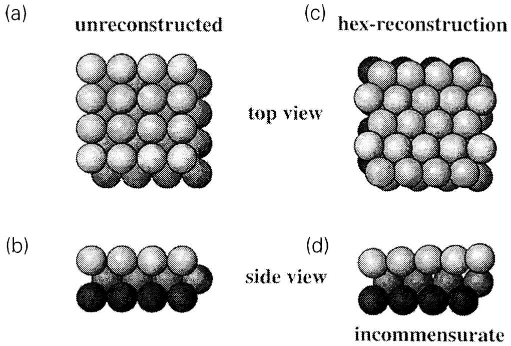

FIG. 15. Reconstruction of fcc (100) surfaces. (a), (b) Top and side views of the unreconstructed surface same as Fig. 12(c). (c), (d) Top and side views of the hexagonally reconstructed surface. The hexagonal layer has a periodicity incommensurate with that of the substrate lattice.

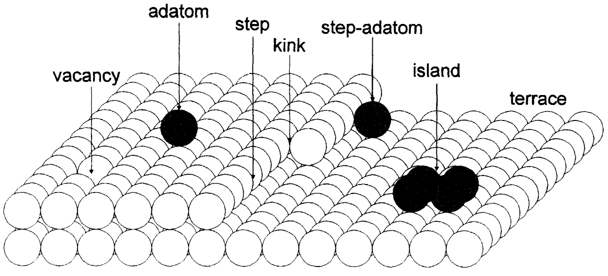

FIG. 16. The TSK model of a surface defined for a simple cubic crystal. Open circles are substrate atoms. Shaded circles are adatoms deposited on the substrate. There are two terraces (the upper terrace is on the left) separated by a step containing a single-atom kink.

atom number density in this hexagonal outermost layer is 8% higher than in a regular (111) plane. This enhanced atom number density lowers the surface free energy. Such a layer is generally higher-order commensurate or incommensurate with the underlying bulk. The energy cost of this type of reconstruction is the reduced interaction with the second layer, because the incommensuration leads to a lower average coordination with the second layer.

Ir(100) reconstructs by forming a quasihexagonal (1×5) reconstruction (Lang *et al.*, 1983). In one close-packed direction, $\langle 110 \rangle$, the interatomic spacing remains unchanged, whereas along the other direction the structure is highly compressed. The surface layer remains commensurate with the second layer. Because more atoms are located at (or near) their regular lattice sites, the weakening of interactions between the topmost layer and the second layer is not as great as in the incommensurate structures of Pt(100) and Au(100). On the other hand, the bonds within the outermost layer are not as optimized as those in an incommensurate structure.

3.3.3 The fcc (111) Surface The (111) surface is the most stable and inert surface of fcc crystals, in which surface atoms have nine nearest neighbors, three fewer than in the bulk. The reconstructions on Au(100) and Pt(100), with their hexagonal outer layers having about 8% higher atom number density than a regular (111) plane, suggest that a (111) surface reconstruction that increases the outer-layer atom number density would lower the free energy.

Au(111) reconstructs by forming the $(22 \times \sqrt{3})$ herringbone structure that allows the surface to increase the atom number density by about 5% (Perderau *et al.*, 1974; Barth *et al.*, 1990). Pt(111) reconstructs by forming a similar structure in equilibrium at high temperatures (≈ 1300 K) (Sandy *et al.*, 1992). The reconstruction of Pt(111) is also observed during homoepitaxial growth at lower temperatures (Hohage *et al.*, 1995). Calculations (Needs *et al.*, 1991) show that the excess surface stress causes a general tendency for the fcc 5d metals to reconstruct in this manner.

4. MORPHOLOGICAL FEATURES OF REAL SURFACES, INTERFACES AND THIN FILMS

4.1 The Terrace–Step–Kink (TSK) Model

Real surfaces are not perfect but contain defects, such as steps, kinks at steps, adatoms, and vacancies, which are generally described in terms of the terrace–step–kink (TSK) model (Burton *et al.*, 1951), as shown in Fig. 16. These morphological features not only influence surface properties but also play a fundamental role in thin-film growth (see THIN-FILM DEPOSITION). The STM has allowed the direct visualization of the TSK model (Swartzentruber *et al.*, 1990; Wang *et al.*, 1990) and has made possible the quantitative determination of kinetic and thermodynamic properties of morphological features ranging from a single adatom to micrometer-sized terraces.

At thermal equilibrium, the concentration of surface defects is determined by minimization of free energy, *i.e.*, the competition between their formation energy and their configurational entropy. The formation energy of a particular type of defect can be determined by measuring its concentration as a function of temperature. For example, surface steps meander by forming kinks. Step energies and kink energies on Si(001) have been determined by STM from the distribution function of kinks along the steps (Swartzentruber *et al.*, 1990). Beyond a critical temperature, the surface roughening temperature, surface steps form spontaneously, as the entropy term, which increases linearly with temperature, becomes equal to the step formation energy.

Surface defects may induce both local structural and long-range morphological changes. For example, steps and dimer vacancies on Si(001) "freeze" the motion of buckled dimers (see Sec. 3.2.1.1) between the two equivalent positions at room temperature, as a means to release surface strain energy (Wolkow, 1992). Step–step interactions (*e.g.*, entropic repulsion) influences kink formation on steps; the meandering of an individual step is independent of that of other steps only when steps are far separated (Swartzentruber *et al.*, 1990; Wang *et al.*, 1990; Zandvliet *et al.*, 1992). The kinetics of step motion (Kitamura *et al.*, 1993a) and vacancy diffusion (Kitamura *et al.*, 1993b) have also been measured with STM at high temperatures. A novel mechanism for the vacancy diffusion, involving a rolling motion at surface and subsurface atoms, has been proposed (Zhang *et al.*, 1993).

4.2 Equilibrium Step Configurations

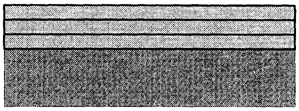
4.2.1 Stress-Domain Structure Surface stress plays an important role in determining surface structure and morphology. Theories (Marchenko, 1981; Alerhand *et al.*, 1988) predict that if the intrinsic surface stress is anisotropic, a single-domain surface is unstable against formation of alternating degenerate stress domains. For example, the (2×1) reconstruction of Si(001) introduces a highly anisotropic surface stress: the stress $\sigma_{||}$ along the dimer bond is tensile (*i.e.*, surface atoms would like to be closer together along this direction than they are); the stress $\sigma_{\perp}$ along the dimer row is consequently compressive (or at least less tensile than $\sigma_{||}$). Because of the tetrahedral bonding configuration in the diamond structure, the dimer directions are orthogonal on terraces separated by monatomic steps, giving rise to orthogonal (2×1) domains on adjacent terraces, which are referred to as (2×1) and (1×2). The intrinsic stress anisotropy, $F = \sigma_{||} - \sigma_{\perp}$, causes a morphological instability (Marchenko, 1981; Alerhand *et al.*, 1988): a flat Si(001) surface is unstable against formation of monatomic steps as domain boundaries separating alternating (2×1) and (1×2) domains. Such stress domains are quite generally possible in systems that lower their surface energy by reconstruction.

The discontinuity of stress at the step introduces a force monopole, giving rise to an elastic step–step interaction that lowers the surface energy with a logarithmic dependence on step separation (terrace width, L) (Marchenko, 1981; Alerhand *et al.*, 1988), $E_s = C_1 - C_2 \ln(L/a)$, where C_1 denotes the step-formation energy per unit length, C_2 reflects the strength of the interaction, which is related to the stress anisotropy and elastic constants, and a is a microscopic cutoff length on the order of a lattice constant. The surface assumes the lowest-energy configuration with an optimal step separation of $L_0 = \pi a \exp(C_1/C_2 + 1)$. Therefore, a surface with sufficiently low step density could reduce its energy by introducing extra steps. However, the spontaneous formation of extra steps to reduce the size of the stress domain predicted by theory is not observed on nominally singular Si(001). Instead, the existing steps are observed to become wavy in the low–step-density regions (Tromp and Reuter, 1992). Step undulations lower the surface energy, just as creation of new steps does, by effectively reducing the size of the stress domains (Tersoff and Pehlke, 1992). Step undulations preempt the formation of extra steps because the undulations are kinetically preferred and are compatible with step flow.

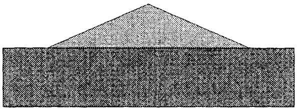
4.2.2 Steps on Vicinal Surfaces Vicinal surfaces—in particular, vicinal Si(001)—play important roles in epitaxial growth and device fabrication, as templates for growing smooth thin films. The step morphology is frequently related to the vicinality of the surface. The behavior of steps on vicinal Si(001) demonstrates the range of morphological phenomena related to steps that can be encountered. Most effort has been dedicated to surfaces miscut toward a $\langle 110 \rangle$ direction, because in these directions, the dimer rows on the surface are either parallel or perpendicular to the steps. On vicinal

Si(001) surfaces with a small miscut ($<1.5°$) toward $\langle 110 \rangle$, the misorientation produces only monatomic steps, which separate alternating (2×1) and (1×2) domains constituting the stress-domain structure. By convention, the (2×1) notation is chosen to describe the domains that have the dimer rows perpendicular to the steps. If the surface is nominally singular (miscut by less than a few tenths of a degree), the equilibrium populations of these two domains are about equal (Men *et al.*, 1988). When an external stress is applied to such a surface, the relative populations of the two domains can be changed by straining the surface at a temperature sufficiently high so that the step mobility is high (Men *et al.*, 1988). The domain compressed along the dimer bond is favored. The experiment is well understood by the theoretical model (Alerhand *et al.*, 1988) mentioned in the last section. The response of the relative domain population to an external stress provides a unique way to determine the intrinsic surface stress anisotropy (Webb *et al.*, 1990, 1991). For Si(001), the anisotropy is $0.07 \pm 0.01\,\mathrm{eV\,Å^{-1}}$, as obtained from LEED and STM measurements (Webb *et al.*, 1990, 1991). *Ab initio* calculations (Garcia and Northrup, 1993; Dabrowski *et al.*, 1994) have produced a value in good agreement with the experiment.

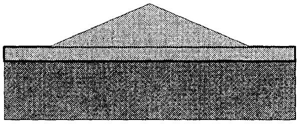
Step configurations on high-miscut vicinal Si(001) surfaces are more complicated and their behavior is less well understood. As the miscut angle toward $\langle 110 \rangle$ increases, the populations of (2×1) and (1×2) domains begin to differ, with the population of (2×1) domains increasing gradually with increasing miscut angle (Tong and Bennett, 1991; Pehlke and Tersoff, 1991; Swartzentruber *et al.*, 1992). At sufficiently high miscut ($\approx 4°$) double-atomic-height steps start to form (Wierenga *et al.*, 1987; Swartzentruber *et al.*, 1992). The formation energy of double-atomic-height steps is lower than that of the monolayer-high steps (Chadi, 1987b), but, at a sufficiently small miscut angle, single-atomic-height steps may be stabilized by their elastic step–step interactions (Vanderbilt *et al.*, 1989). Several model calculations (Alerhand *et al.*, 1990; Poon *et al.*, 1990; Pehlke and Tersoff, 1991) predict the existence of a first-order phase transition from the single-atomic-height-step surface to the double-atomic-height-step surface as the miscut angle increases. Experimentally, however, no indication of a first-order phase transition has been observed. Instead, the step concentration changes continuously with both miscut angle (Swartzentruber *et al.*, 1992) and temperature (de Miguel *et al.*, 1991). Experiments (de Miguel *et al.*, 1992) also indicate that at high temperatures and/or large miscut angles, a simple 1D elastic model becomes unsatisfactory.



Frank-van der Merwe



Volmer-Weber



Stranski-Krastanov

FIG. 17. Three equilibrium growth modes in heteroepitaxy.

4.3 Surface/Interface Morphology of Epitaxial Thin Films

4.3.1 Equilibrium Growth Modes The surface morphology of a thin film grown on a substrate by vapor deposition is described, at thermal equilibrium, by three different growth modes, as depicted in Fig. 17. In the Frank–van der Merwe mode, growth proceeds layer by layer, maintaining a smooth film; in the Volmer–Weber mode, 3D islands form immediately and the film does not cover the whole substrate surface; in the Stranski–Krastanov mode, the film first grows layer by layer—*i.e.*, "wets" the surface—followed by the formation of 3D islands. The realization of different growth modes, and hence different thin-film morphologies, is determined again by minimization of surface free energy, in this case for the combined substrate/film system. The surface energy of the substrate ($\gamma_{\mathrm{substrate}}$), the surface energy of the film (γ_{film}), and the interface energy between the film and substrate ($\gamma_{\text{interface}}$) (Bauer, 1958) enter into this minimization. For heteroepitaxy, *i.e.*, the growth of material A on a different substrate B, the surface energy of the film (A) will differ from that of the substrate (B). If $\gamma_{\text{substrate}} < \gamma_{\text{film}} + \gamma_{\text{interface}}$, the deposited film tends to nucleate 3D islands, leaving the low-energy substrate exposed (the Volmer–Weber mode). The condition of $\gamma_{\text{substrate}} > \gamma_{\text{film}} + \gamma_{\text{interface}}$ defines the layer-by-layer or Frank–van der Merwe growth mode. However, γ_{film} increases with increasing film thickness because of misfit strain, which leads to Stranski–Krastanov growth: the film first grows layer by layer as long as $\gamma_{\text{substrate}} > \gamma_{\text{film}} + \gamma_{\text{interface}}$, forming a finite thickness of wetting layer, followed by formation of 3D islands as $\gamma_{\text{substrate}} < \gamma_{\text{film}} + \gamma_{\text{interface}}$ to relieve the misfit strain built up in the film. In general, if A wets B, then B will not wet A. For homoepitaxy, *i.e.*, the growth of material A on a substrate of the same material A, $\gamma_{\text{substrate}} = \gamma_{\text{film}} + \gamma_{\text{interface}}$. The equilibrium film grows layer by layer in the Frank–van der Merwe mode.

Stranski–Krastanov growth has attracted considerable interest recently because of its potential for fabricating 3D spatially confined structures (Liu and Lagally, 1997a). One typical example is the growth of Ge or SiGe alloy on Si. Because Ge has a lower surface energy than Si, Ge initially grows layer by layer, wetting the Si substrate. As the film gets thicker, the strain energy in the film increases, and eventually 3D islands start to form to relieve the 4% lattice mismatch between Ge and Si. The equilibrium surface morphology of a thin Ge film grown on Si(001) is rather complex (Liu *et al.*, 1997). For pure Ge films grown on Si(001), the thickness of the wetting layer is extended up to 3 ML by strain-relaxation mechanisms involving only 2D surface roughening processes before 3D islanding takes place (Mo *et al.*, 1990; Tersoff, 1991). The misfit strain is partially relaxed by the formation of dimer vacancy lines, the $(2 \times N)$ reconstruction (Chen *et al.*, 1994). The reconstruction also induces changes in surface (step) morphology and stress field, reversing the relative roughness of the two types of steps on the surface (Wu *et al.*, 1995) as well as the surface stress anisotropy (Wu and Lagally, 1995; Liu and Lagally, 1996; Liu *et al.*, 1997). The 3D islands form in two stages. Initial islands are small and coherent with the substrate lattice, *i.e.*, without dislocations (Eaglesham and Cerullo, 1990; Mo *et al.*, 1990). Larger dislocated islands form later.

4.3.2 Kinetics-Limited Growth Morphology

Equilibrium thin-film morphologies for different film systems can be achieved by growth at high temperature and low deposition rate. Very often, growth is carried out far from equilibrium, and consequently, the evolving surface morphology during thin-film growth is kinetically limited (Liu and Lagally, 1997b). The ability to control kinetic parameters to manipulate thin-film morphology allows us to grow novel artificial film structures with desirable properties. Surface diffusion is the most important kinetic parameter controlling growth morphology. Because the rate of diffusion is an exponential function of temperature, different regimes of growth that lead to different thin-film morphologies can be achieved by tuning the growth temperature, even for systems that belong to the Frank–van der Merwe growth mode, e.g., homoepitaxial growth.

Real surfaces have imperfections such as steps. As adatoms are deposited onto a surface, they are preferentially incorporated at steps, particularly at kink sites where they can bind to the most neighbors (Burton *et al.*, 1951). If all deposited adatoms are attached at steps, growth will proceed with advancement of steps, so called step-flow growth. Step-flow growth requires a high mobility of the adatoms so that they reach the existing steps before meeting with each other to nucleate islands. It is achieved, in homoepitaxy, by growing at high temperature, at low deposition rates, or on high–step-density surfaces. Step-flow growth, representing a situation close to thermal equilibrium, produces smooth films for homoepitaxial film growth. However, morphological instabilities, *e.g.*, the bunching of substrate steps, may arise from the additional kinetic barrier for adatoms crossing the steps (Ehrlich and Hudda, 1966; Schwoebel and Shipsey, 1966) or from complex dynamics of step flow (Mullins and Hirth, 1963; Kandel and Weeks, 1995). For step-flow growth of a strained film, a step-bunching instability caused by the elastic attractions between steps (Tersoff *et al.*, 1995) or by strain-modified adatom diffusion (Duport *et al.*, 1995) can occur.

At lower temperature, at high deposition rates, or on surfaces with a low step density, adatoms may meet each other in the middle of terraces before reaching the existing steps and nucleate stable 2D islands. As the deposition continues, the nucleated islands grow by incorporating new arriving adatoms, and more islands form by new nucleation events. Eventually, the 2D islands meet and coalesce. This regime is referred to as two-dimensional island growth. The 2D island growth mode is used for fundamental studies of kinetic mechanisms of homoepitaxial growth and to calibrate deposition rates in layer-by-layer growth, but serves little technological function.

The nucleation and growth of 2D islands can be described by phenomenological rate equations (Venables *et al.*, 1984). The properties of islands (*e.g.*, island number density, island compactness, and island shape) are largely determined by surface diffusion. The surface diffusion coefficient can be quantitatively determined by STM measurement of the island number density as a function of temperature at the initial stage of island growth (Mo *et al.*, 1991; Bott *et al.*, 1996; Liu and Lagally, 1997b). The compactness of islands (fractal-like versus close-packed) is controlled by how fast an adatom diffuses along island edges and crosses corners where two edges meet (Zhang, *et al.*, 1994; Hohage *et al.*, 1996; Zhang and Lagally, 1997). In general, growth at relatively lower temperatures produces less compact (more fractal-like) islands, because adatoms diffuse more slowly and thus do not reach their equilibrium positions before they become trapped by newly arriving atoms. On reconstructed surfaces, 2D island growth becomes more complex. For example, on (2×1) reconstructed Si(001), the large anisotropy in adatom sticking coefficients to two different edges (steps) of an island creates kinetics-limited islands with long and thin shapes. Reconstruction can also introduce additional roughness to the growth front. Two islands nucleating at different locations in the same terrace can form antiphase domain boundaries when they meet. For example, in Si(001) islands have a 50% chance to align their dimer rows out of phase (Hamers *et al.*, 1989), roughening the growth front. The GaAs(001) (4×2) structure has four different possibilities of island positions with only 1/4 of the islands meeting without antiphase boundaries. The larger the unit mesh, the more possibilities that exist.

Islands may nucleate not only on terraces but also on top of those islands that are already formed, when these become large enough so that atoms falling on them can no longer reach the edge. In addition to surface diffusion, the barrier for an adatom to jump off an island (*i.e.*, crossing a step) now becomes a key kinetic parameter in determining the film roughness, even for homoepitaxial films. The roughness of the film increases as the film grows thicker if atoms cannot cross the steps.

In heteroepitaxy, misfit strain can lead to various 2D morphological instabilities that roughen the surface, even in the absence of kinetic roughening, and are due to energetic (thermodynamic) driving forces. For example, as Ge is deposited on Si(001), the surface first roughens by formation of dimer vacancies, giving rise to the $(2 \times N)$ reconstruction. The dimer vacancy lines reduce adatom diffusion (Lagally, 1993), leading subsequently to additional roughness induced by new kinetic limitations (Mo and Lagally, 1991; Lagally, 1993; Wu and Lagally, 1996).

4.3.3 Interface Morphology The quality of the interface—in particular, the smoothness of the interface of a thin-film structure—frequently influences other properties, and may determine the usefulness of the film, for example, for electronic and magnetic applications. A strained film is inherently unstable; strain energy increases as the film grows thicker. Upon reaching the "equilibrium critical thickness" (van der Merwe, 1963; Matthews and Blakeslee, 1976), a strained film will relax back to its equilibrium lattice constant, forming dislocations at the interface, if the kinetics permit it. Films can be grown beyond the equilibrium critical thickness by growing at low enough temperatures so that the kinetics are so small that dislocation formation is suppressed. For homogeneous nucleation of dislocations, the kinetic barrier for nucleating a dislocation decreases with increasing strain (LeGoues *et al.*, 1993), so that eventually, as the misfit strain increases, dislocations always will form. A structural defect at the surface or interface may activate the nucleation of dislocations.

It is difficult to create a smooth interface, even without forming dislocations. Interdiffusion roughens the interface by creating a transition region in which a compositional gradient exists. In general, interdiffusion lowers the interface energy by increasing the configurational entropy. In those cases when $2E_{A-\mathrm{B}} > E_{A-A} + E_{\mathrm{B-B}}$, where E denotes the bond energy, there will also be a strong tendency for interdiffusion to form interface alloy compounds. Substantial interdiffusion can occur even at relatively low temperatures, at which bulk diffusion is negligible, through surface diffusion-assisted atom place exchange in the outer few layers, driven by surface segregation of the thermodynamically more stable component and/or by preferential occupation of different components at different lattice sites induced by surface reconstruction. For example, Ge surface segregation causes a decrease of Ge concentration at the interface when a SiGe alloy film is grown on Si and a nonabrupt interface when Si is grown on Ge. The (2 × 1) reconstruction on Si(001) introduces a nonuniform stress distribution in the surface layers (LeGoues *et al.*, 1990; Liu and Lagally, 1996), leading to preferential occupations of Si or Ge at different sites and formation of an ordered SiGe phase at the interface when SiGe alloy is deposited on Si(001) (LeGoues *et al.*, 1990).

Pre-existing surface roughness generally remains at the interface after overgrowth. In the growth of a multilayer thin film, the situation is more complex because the growth of B on A can be quite different from that of A on B. As stated earlier, if B wets A, A will not wet B. In general, the roughness of a surface or interface can be quantitatively characterized by its rms roughness, lateral correlation length, and fractal exponent (Sinha *et al.*, 1988). An x-ray diffraction technique has been developed to measure the magnitude and correlation of interfacial roughness in a multilayer film (Savage *et al.*, 1991; Phang *et al.*, 1994). The interfacial roughness is frequently correlated among different layers (Savage *et al.*, 1991; Phang *et al.*, 1994). In particular, strain-induced interaction between islands in different layers leads to a self-organization of islands, with progressively improved uniformity in island size, shape, and spacing, as the multilayer thickness increases (Tersoff *et al.*, 1996; Teichert *et al.*, 1996; Liu *et al.*, 1999), which provides an attractive route to fabricating arrays and superlattices of quantum dots (Liu and Lagally, 1997a).

GLOSSARY

Adatom: A single atom adsorbed on a surface (terrace) bonded only to the surface atoms.

Basis: A group of atoms, molecules, or ions that constitute a single lattice point of the Bravais lattice.

Bravais Lattice: An infinite array of discrete points with an arrangement and orientation that appears the same from whichever of the points the array is viewed.

Crystal Systems: Point groups of the Bravais lattice (the symmetry of the basis is excluded).

Crystallographic Point Groups: Point groups of the general crystal structure including the symmetry of the basis.

Crystallographic Space Groups: Space groups of the general crystal structure.

Dangling Bond: A hybridized electron orbital on an atom without bonding on account of missing neighbors.

Dislocation: An extended line defect resulting from missing half of an atomic plane in the solid or from missing half of an atomic row in the surface.

Dividing Surface: A hypothetical geometrical surface separating two homogeneous phases to replace the real physical transition region between the two phases.

Epitaxial Growth: Growth of a film on a substrate with lattice structure of the film confined to that of the substrate.

Excess Surface Properties: The difference between the extensive thermodynamic property of a real system and that of an ideal system consisting of two homogeneous phases separated by the dividing surface.

Heteroepitaxy: Epitaxial growth of a material A on a substrate of different material B.

Homoepitaxy: Epitaxial growth of a material A on a substrate of the same material A.

Jahn–Teller Distortion: Lattice distortion that lowers the symmetry, removing the degeneracy in electronic levels and hence lowering the total energy.

Kink: A jog of any length in a step terminated by one inside corner and one outside corner.

Miller Indices: The indices of an atomic (lattice) plane that are coordinates of the shortest reciprocal lattice vector normal to the plane.

Misfit Strain: Strain induced by different equilibrium lattice constants (misfit) between the film and the substrate during heteroepitaxial growth.

Primitive Unit Cell: A volume (area) of space that, when translated through all the vectors in a Bravais lattice, just fills all the space without either overlapping itself or leaving a void.

Reciprocal Lattice: The set of all wave vectors $\boldsymbol{K}$ that yield plane waves with the periodicity of a given Bravais lattice.

Stacking Fault: A single plane where the stacking differs from the usual stacking sequence of atomic planes inside the crystal.

Stacking-Fault Region: A finite region of a stacking sequence of atomic planes different from that in the surrounding lattice.

Surface Reconstruction: Atomic displacements at a surface that change the surface periodicity relative to that of an ideally bulk-terminated surface.

Surface Relaxation: Atomic displacements at a surface that do not change the surface periodicity relative to that of an ideally bulk-terminated surface.

Surface Stress: (I) The reversible work per unit area required to deform a surface. (II) The force per unit length on a line cut in the surface.

Surface Tension: The reversible work required to create a new unit area of surface.

Vicinal Surface: A crystal surface formed by a miscut a few degrees away from a low-index atomic plane.

The original article ATMOSPHERIC STRUCTURE describes the basic vertical structure of the Earth's atmosphere, with a brief description of latitudinal and seasonal variation and the response of the atmosphere to solar variability. This Addendum describes new insights into the atmospheric structure in regions that were poorly known when the original article was written but have been measured recently by new satellite- and ground-based instruments. A brief summary of the nature of the variability found in each atmospheric layer is also given, starting from the upper atmosphere downward to the Earth's surface.

1. THERMOSPHERE AND IONOSPHERE

Within the thermosphere and ionosphere most of the variability about the basic state is controlled by the solar radiative and plasma outputs. Since the original article was written there have been only a few new measurements of the sun's spectral irradiance in the extreme ultraviolet portion of the spectrum (10 to 120 nm), primarily from rockets. However, there have been extensive measurements of the solar UV spectrum (120 to 400 nm) and total solar irradiance that have been made from various satellites. These measurements have defined the range of variability of the solar radiative output over a solar cycle and also have shown variability associated with the 27-d solar rotation period, and shorter-term variability, such as during solar flares. In general, the solar radiative output over a solar cycle varies by about 10% near 200 nm, 1% near 300 nm, and 0.1% for the total solar irradiance. The older solar EUV measurements show considerable day-to-day variability that influences the basic temperature and compositional structure of the thermosphere and ionosphere as discussed in the original article.

There have also been new measurements from satellites and new analysis techniques that better define the energy and momentum inputs into the thermosphere and ionosphere from the aurora. The aurora is driven by the interaction of the solar-wind plasma with the Earth's magnetic field, and images of the aurora made by the NASA POLAR satellite in the UV and visible range have observed a tremendous source of variability introduced into the Earth's atmosphere especially during geomagnetic storms. During these storms the energy and momentum inputs into the Earth's upper atmosphere can vary by over two orders of magnitude. As a result, the high-latitude thermosphere and ionosphere are subjected to a wide range of dynamic phenomena such as large horizontal scale waves that travel globally, circulation changes to the basic wind structure, temperature and compositional perturbations that occur at high latitudes and propagate equatorward, and many others. Schematics showing the response to the aurora have been presented in the original article, and the new data have helped to better define the forcing that drive the variability and the small-scale structure.

In addition to the variability introduced into the thermosphere and ionosphere by solar and auroral variability, numerical models that couple the lower and upper atmosphere show

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

that another important source of variability in the thermosphere and ionosphere consists of gravity waves, tides, and other large-scale disturbances generated by weather systems in the lower atmosphere. These waves and disturbances propagate upward and deposit their energy and momentum in the thermosphere and are a major source of variability, especially during quiet auroral conditions and steady solar EUV output. During these conditions waves from the lower atmosphere are the major source of day-to-day variability that has been observed over a given station or by a satellite in orbit.

2. LOWER THERMOSPHERE AND MESOSPHERE

For many years the atmospheric structure and dynamics in the upper mesosphere and lower thermosphere between about 60 and 200 km altitude has not been measured on a global basis. Most data came from rockets and remote sensing from ground stations. The Upper Atmosphere Research Satellite (UARS) that was launched in 1991 had instruments on board that could measure the global temperature and winds between 30 and 500 km altitude. These measurements not only defined the basic structure of the region, but also illustrated the range of variability that exists in the upper atmosphere. Analysis of the data indicated that the equatorial upper atmosphere below about 110 km is strongly influenced by the diurnal tide that is forced by solar radiation being absorbed by water vapor in the troposphere and propagating upward to the 100-km altitude region before dissipating by molecular viscosity. At mid and high latitudes the tidal structure is dominated by a semidiurnal tide that is excited not only in the troposphere but also by *in situ* absorption of solar radiation primarily by ozone in the middle atmosphere near 50 km. During the summer months a strong signature of an intermittent two-day wave was found to dominate the winds in the upper mesosphere and lower thermosphere between 70 and 100 km altitude. The UARS satellite also found equatorially trapped fast Kelvin waves with periods of 3 to 5 d and regions of strong atmospheric gravity-wave activity that influenced the basic wind, temperature, and compositional structure of the upper mesosphere and lower thermosphere profoundly. In fact, the gravity-wave activity in this region of the upper atmosphere is so strong that it primarily controls the temperature and dynamic structure and drives it away from a radiative equilibrium structure that would result if only absorption of solar radiation acted upon the region. An example of the complex wind structure observed by the UARS satellite is shown in Fig. 1, which illustrates the zonal (positive eastward) and meridional (positive northward) winds for March equinox and December solstice at 1200 local time. These are the first global observations of the wind structure between 60 and 200 km, and they shown that the diurnal tide propagates to about 110 km at low latitudes and that there is a major transition in the dynamic structure above 110 km. This structural change occurs because the atmosphere is so thin above 100 km that the waves in the lower atmosphere are damped and strong solar EUV forcing in the thermosphere gives rise to a different circulation pattern. These figures show the changing wind structure for both equinox and solstice conditions near 100 km altitude. These data filled a critical gap in our knowledge of the wind structure in the region between 60 and 200 km altitude. These data, with the additional new data from ground stations such as LIDARs, radars, and airglow instruments, are greatly improving our understanding of the upper-atmosphere structure and dynamics.

In addition to the wind and temperature measurements, there have been composition measurements of the upper atmosphere. Briefly, the new measurements indicate that current aeronomical theory predicts too much hydroxyl, OH, that catalytically destroys ozone in the mesosphere. The ozone presently calculated by upper-atmosphere models is about 20% to 30% lower than measurements indicate. It is important to resolve this discrepancy because ozone is such an important constituent for absorbing damaging solar UV radiation before it reaches the Earth's surface. The current problem suggests that the laboratory rate coefficients for certain chemical reactions need to be re-evaluated because they may be different for upper-atmosphere environmental conditions. There are also problems

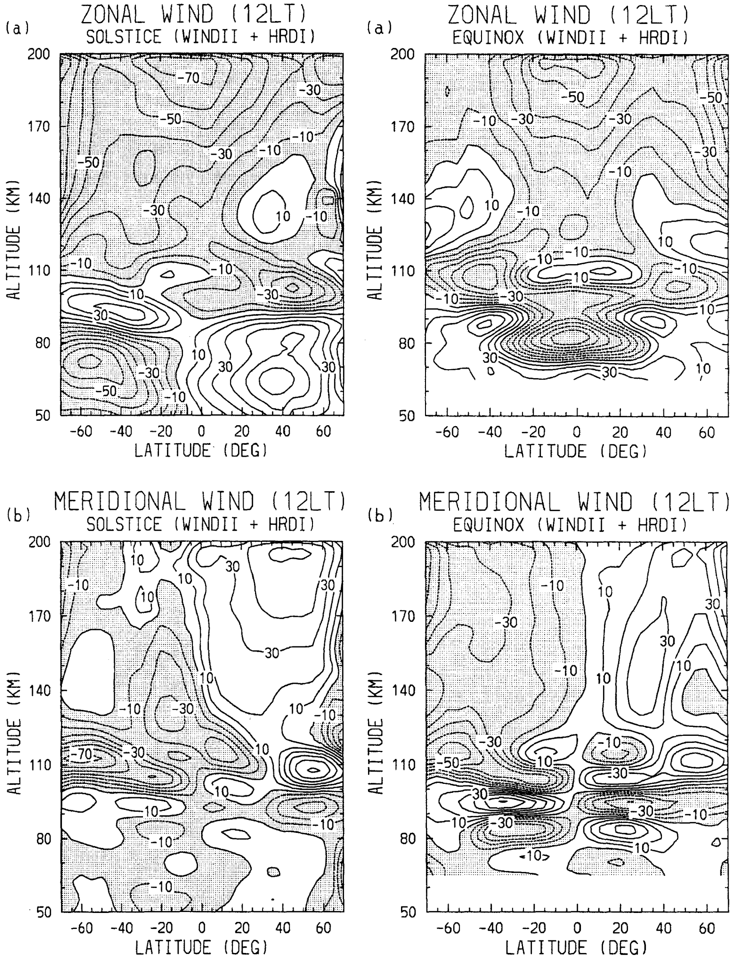

FIG. 1. Combined zonally averaged mesospheric and thermospheric winds for December solstice period (left panels) and March equinox period (right panels) at 1200 h local time measured by the Upper Atmosphere Research satellite. The upper frames are the zonal and the lower frames are the meridional components of the wind. A 10-m/s contour interval is employed. Shading is used for westward winds in the upper panels and for southward winds in the lower panels (McLandress *et al.*, 1996). The acronym WINDII represents the WIND Imaging Interferometer, and HRDI, the High Resolution Doppler Imager, instruments used to measure the winds from the Upper Atmosphere Research Satellite (UARS).

between theory and observations for other chemical species such as nitric oxide and carbon monoxide, indicating that there is still considerable work needed before we are able to understand the current compositional structure of the upper atmosphere.

A very important problem that governs the temperature structure of the upper mesosphere and lower thermosphere between 80 and 150 km altitude is the magnitude of the O–CO_2 vibrational exchange coefficient. This coefficient governs the infrared radiative cooling of the upper atmosphere. Current theory, laboratory measurements, and observational analysis of satellite infrared emissions indicate a factor of 6 uncertainty in the magnitude of this important rate coefficient, which governs the temperature structure of the upper atmosphere. Not only does this problem need to be resolved for understanding current-day atmospheric structure, but it is important for determining the magnitude of possible future global change.

There have been observations that suggest that the upper atmosphere above about 50 km altitude has been cooling during the last decade. This secular trend has been identified in satellite, LIDAR, and rocket data, but the cause of the cooling is not known. Studies of the upper-atmosphere response to global change and a CO_2 doubling from present-day levels indicate that the upper atmosphere will cool because of increased infrared radiation to space. But the major cooling is expected to occur slowly during the next century, and it is generally believed to be too small at the present time to account for the observed cooling. Another possible cause may be an association with the observed ozone decrease caused by chlorofluorocarbons (CFC's) affecting the ozone layer, or it may be a natural variability of the ocean–atmosphere system that is not well understood.

3. STRATOSPHERE

Ozone is one of the greenhouse gases that modify the radiative structure of our atmosphere. A change in ozone amount and distribution can influence climate. In addition, ozone protects the biosphere from harmful solar ultraviolet radiation. Ozone is continually being produced and destroyed by solar ultraviolet radiation. Additionally ozone is destroyed by catalytic reactions of nitrogen, hydrogen, chlorine, and bromine oxides. In the early 1970s it was predicted that human activity will lead to a diminishing ozone layer; and since the detection of the Antarctic ozone hole, the downward trends in the column total ozone have been well documented for the regions both inside and outside Antarctica by satellite, ground-based, and aircraft observations. Decadal trends have been observed, with the greatest ozone loss occurring in the Antarctic and the smallest in the equatorial region. Rates as large as −3%/yr have been observed in spring over Antarctica and −0.8%/yr in northern-hemisphere spring at mid-latitudes (Stolarski *et al.*, 1991). The ozone loss has also been linked to an observed cooling of the lower stratosphere. These observations all indicate that the basic structure described in the original article is subject to considerable variability and that these changes may be caused by a combination of natural variability, man's activities, changes in the solar radiative and plasma output, and changes associated with atmosphere–ocean and atmosphere–biosphere interactions. These complex interactions all contribute to a possible change in the vertical structure of the atmosphere.

Some of the major sources of atmospheric variability in the stratosphere are global oscillations associated with the quasi-biennial oscillation (QBO), an oscillation with an irregular period of about 26 months where the equatorial winds in the stratosphere oscillate in an easterly/westerly direction. A seasonal variation occurs with interannual variability superimposed and there are solar-cycle variations that have been detected within the stratosphere.

4. TROPOSPHERE WEATHER AND CLIMATE

It is well known that the Earth's climate has undergone considerable change over geologic history. In its early history the atmosphere was much warmer because of higher CO_2 levels. There were also ice ages and interglacial periods, all indicating that the basic structure of the atmosphere has undergone considerable change with time. Not only have the surface temperatures changed with time but most likely the entire atmospheric vertical structure has changed.

Variability in the lower atmosphere is governed by many factors. The most prominent that has emerged in recent years consists of the major changes to the climatological structure caused by El Niño. The period 1991 to 1995 was one of the longest El Niño events in recent times, and the major event that is presently underway in 1997 is expected to cause major changes in weather patterns. It is well documented that El Niño can affect the weather near the surface, but it is not clear whether there are associated changes that occur in the upper atmosphere. Interannual variability in the lower atmosphere is large and the major causes of this variability are uncertain but are subject to intensive study. Much of the variability is associated with atmosphere–ocean interactions, but there is also considerable variability introduced by nonlinear interactions of the large-scale dynamical processes.

Atmospheric chemistry is also having a strong influence on regional climate. The atmosphere is not only subjected to increasing amounts of important atmospheric trace gases such as CO_2, CH_4, and NO_x, but aerosol-forming gases give rise to cloud seeding and aerosol layers that affect the solar radiative balance of the lower atmosphere. All of these chemical processes exert some influence on the climatological balance within the lower atmosphere that in turn influences the structure of the entire atmosphere.

The limits of variability in the lower atmosphere have been quantified by use of historical records, but each year the record highs or lows for an individual station may be broken, indicating that the true range of atmospheric variability has not been determined. With possible global change occurring in the next century, computer models are suggesting that the range of variability may increase, with periods of prolonged drought and intense storms occurring in future climate scenarios. There is considerable effort being expended to identify and understand possible global change caused by increasing CO_2 concentrations and other greenhouse gases.

INTRODUCTION

It is impossible to review here all new developments that took place after the publication of the original article, and so an admittedly subjective choice was made. Quite a few larger publications appeared, the most important being the 1990 recommendations of the International Commission for Radiological Protection (ICRP) (ICRP 60, 1991), a new report of the UN Scientific Committee on the Effects of Atomic Radiations (UNSCEAR) (UNSCEAR, 1994) and the proceedings of the 10th International Congress of Radiation Research (Hagen *et al.*, 1995). Particularly the last volume is a valuable source to be consulted for an overview of the present state of the art in the field.

1. DEPOSITION OF ENERGY

Energy deposition plays an important role in the understanding of the action of ionizing radiations; with non-ionizing radiations the actual spatial pattern depends more on the structure of the target than on the property of the radiation. These questions have so far received less attention and will not be treated here. Classical microdosimetry is limited to micrometer dimensions. For even smaller sizes one has to recur to Monte-Carlo calculations. They have now been performed for protons and alpha particles. Presently it is attempted to determine energy deposition in molecules of biological interest, particularly DNA, to understand the initial processes of lesion formation and link them to the biological effective-

ness of different radiations. It has been found that the yield of DNA double-strand breaks as measured by conventional techniques does not depend to a great extent on radiation type. Chromosomal aberrations, cell killing, and mutation induction, on the other hand, show a clear dependence. This is interpreted by assuming that the interaction between primary lesions and their proximity plays an important role. Densely ionizing particles produce strand breaks close to each other forming "clusters" not resolvable by the usual experimental approaches. They presumably give rise to errors in repair. An understanding of this phenomenon is essential to assessment of the risk of, e.g., neutrons and alpha particles (Rossi and Zaider, 1996).

2. CELLULAR EFFECTS

2.1 Delayed Reproductive Death, Apoptosis, Genomic Instability, and Low-Dose Responses

If surviving cells as defined by the colony-forming assay are further cultivated, they display a decrease in plating efficiency that depends on the dose originally given. It appears that they retain some kind of "cryptic" damage expressed at later stages. In many cases these cells die in a characteristic manner that has been termed *apoptosis* and constitutes some kind of a cellular "suicide program". The cells do not just disintegrate as in necrosis but follow a given scheme of interphase death: At first the cells shrink and their mean density increases; this is followed by changes in their morphological appearance. Most characteristically the chromatin is fragmented into nucleosome sizes, i.e., about 200 nucleotide pairs. Apoptosis is an active cellular process requiring active protein synthesis, mediated by enzymes and under genetical control. It can also be directly triggered by ionizing radiation and seems to play an important role particularly at low doses (Hendry *et al.*, 1995).

Cells surviving the exposure to ionizing radiation display also a phenomenon called *genomic instability*, which was first demonstrated after alpha-particle irradiation: As discussed in the original article, dicentric chromosomal aberrations can be scored after one or two replication rounds. Their number decreases with time because the affected cells die. After several generations there is another increase that is due to newly formed aberrations, indicating fragility of the genome caused by the previous irradiation. At the same time, mutations may arise that were not present in the population before. All these findings have an important bearing on the understanding of radiocarcinogenesis: it is now well established that it proceeds in a multistage fashion, and that more than one (presumably around 5) mutational events are required. It is extremely unlikely that they are all caused directly by radiation; more probably genomic instability is responsible for the later steps (Little, 1994).

The response of cells to low doses of ionizing radiation has received increased attention. It is now clear that gene activity and its regulation can be influenced by x rays as well as by UV. Studies using single-cell observations suggest that mammalian cells may be more sensitive to killing by low doses of x rays than anticipated from an extrapolation from the overall survival curve. At the same time it has been reported by several groups that the yield of chromosomal aberration after high doses is reduced if the cell received "priming doses" in the order of a few hundred milligrays several hours before. This "adaptive response" depends on an active cellular metabolism and may be related to inducible repair processes, but there is presently no proof for this supposition. Studies related to these questions can be found in a special issue of *Radiation Research* (Skov and Marples, 1994) and is also summarized in UNSCEAR (1994).

2.2 Repair Processes

The last years have brought impressive progress in the understanding of cellular repair of radiation-induced damage (Friedberg *et al.*, 1995). Most of the relevant genes have been cloned, both in microorganisms and in mammalian cells. Excision repair was shown to work preferentially in active genes via a coupling with transcription. Apart from this, "general" excision can also be found. A number of genes responsible for the repair of radiation-induced double-strand breaks (DSB) in mammalian cells could be identified. It is now clear that DSB repair in mammalian cells operates through an "end joining" mechanism, in contrast to the case in yeast where homologous recombination plays the most important role. A major breakthrough was the cloning of the *Ataxia telangiectasia* (AT) gene, although its role remains still elusive.

2.3 Radiofrequency Electromagnetic Radiation

Because of the wide-spread public interest in the possible adverse effects of power lines, e.g., the induction or promotion of cancer (see below), effects on the cell and tissue level have to be analyzed. There are a number of mechanisms that could be invoked: The quantum energy of rf (radio-frequency) electromagnetic radiation is much too low to cause any direct damage at the molecular level and also well below the "thermal noise": it is 2.5×10^{-13} eV at 60 Hz while the mean molecular kinetic energy ($\frac{3}{2}kT$) is 0.04 eV. Forces on charged particles by a field of an electric field of 1000 V/m or a magnetic field of 0.1 mT, ranging between 10^{-7} and 10^{-10} pN, are even smaller than those generated when a single hair cell in the inner cochlea of the ear is activated (about 1 pN), the most sensitive interaction known in biological systems. An interaction with isolated components can thus be ruled out and some kind of cooperative mechanism has to be invoked. Electromagnetic fields may alter the lifetime of radicals, which could cause biological effects, but the levels required are much larger than created from external electricity. Resonance phenomena have frequently been suggested, but a careful analysis reveals that they are not plausible in real biological systems. The main argument is that the medium causes rapid damping so that with the external fields applied resonance cannot build up. The sensitivity to the pickup of even very weak signals might be increased if a number of sensors cooperate in a coherent way. This has been found, e.g., in sharks, who are able to sense even 10^{-5} V/m, but no such arrangement has ever been found or even suggested in higher mammals; and it would also be extremely difficult to link it with carcinogenesis. The authors of a very careful and rigorous study (Valberg *et al.*, 1997) come to the conclusion that there is no plausible mechanism to invoke a harmful action of rf electromagnetic radiation on biological systems; and, particularly, no clue to support either tumour induction or tumour promotion can be provided (see also Malyapa, 1997a, 1997b).

3. ORGAN AND WHOLE-BODY EFFECTS: CANCEROGENESIS

UNSCEAR (1994) has reviewed the available epidemiological data concerning cancer induction by ionizing radiations by exposure both from external and from internal sources. The most important information still stems from the survivors of the atomic bombs in Hiroshima and Nagasaki, which is also the core of the new ICRP recommendations (see below). They are supported by quite a number of studies with medical radiation applications and occupational exposures. On the basis of the available data risk estimates for various cancer sites were computed; these are summarized in Table 1.

A new dosimetry system for the atomic bomb survivors was introduced in 1986 (Roesch, 1987), which resulted in a significant reduction of the neutron component compared to the older estimates. In the meantime new figures based on measurements of isotopes produced by neutron reactions became available, casting some doubt on the correct assessment of thermal neutrons. A compilation of the data (Straume *et al.*, 1992) suggests that particularly at larger distances from the epi-

Table 1. Risk of exposure-induced deaths for various cancer sites, estimated on the basis of data for the bomb survivors and cancer incidences in the Japanese population (UNSCEAR 1994). Figures are given in %/Sv and relate to a single acute exposure.

Cancer site	Male	Female	Both
Leukemia	1.3	0.9	1.1
Esophagus	0.3	0.7	0.5
Stomach	0.9	2.0	1.4
Colon	0.5	0.6	0.6
Liver	2.2	0.3	1.2
Bladder	0.4	0.2	0.3
Lung	1.8	3.1.	2.5
Breast	—	2.0	2.0
Ovary	—	0.5	0.3
Others	4.3	2.0	3.1
Total	**11.7**	**12.3**	**12.0**

centre the dose by thermal neutrons is underestimated by factors between at least 2 to 10. This does not drastically change the overall risk factor but may have implications for neutron weighting factors (see below).

4. APPLIED RADIOBIOLOGY

4.1 New Developments in Biodosimetry

4.1.1 Fluorescence *in Situ* Hybridization for Chromosomal Translocations (FISH). Chromosomal aberrations were discussed in the original article. Apart from their fundamental relevance they are an important tool of biodosimetry. If lymphocytes taken from exposed individuals are cultivated *in vitro*, aberrations can be scored and used as an indicator of dose. Classically, dicentric chromosomes ("dics") are used for this purpose since they are comparatively easy to recognize. The lowest dose limit resolvable is about 0.1 Gy with x or gamma rays. Dics interfere with further cellular proliferation; 50% of the cells carrying them will die at every division. This means that these "unstable" aberrations will rapidly fade out so that reliable dose estimates are impossible after months or years. Translocations, on the other hand, are stably transmitted to the progeny, allowing in principle biodosimetry at any time, even after decades. Technical problems of their scoring prevented the use until recently. The introduction of the so-called FISH technique has now led to an improvement: Monoclonal antibodies coupled to fluorescent dyes can be raised against human chromosomes so that every chromosome can be selectively "painted". Translocations are then visualized by colour changes along the chromosomal structures. Studies have shown that they persist indeed much longer than dics. Their dose dependence is similar to that of dics, and their detection limit lies in the same range (about 100 mGy for gamma rays). Developments for automatic scoring are already well under way (Lucas *et al.*, 1992; Yang, 1997).

4.1.2 ESR Dosimetry. Ionizing radiation induces the formation of free radicals in the exposed tissue, but their lifetime is usually very short. This is not the case if they are created in a solid matrix where their movability is severely restricted. In this case they may persist for very long periods and may thus be detected by electron spin resonance (ESR), e.g., in teeth or bone. The method has practical applications both in radiation protections and in radiotherapy (Kudynski *et al.*, 1993).

4.2 Developments in Radiation Therapy

The "classical" radiation therapy of tumours uses quantum or electron radiation provided commonly by linear accelerators. The energy is adjusted in such a way that the dose maximum lies at the tumour site. By careful treatment planning using multiple beams and beam shaping by custom-made absorbers, the tumour volume can be delineated and the healthy tissue spared to a great extent. This technique has now reached a high degree of sophistication. More recently particle therapy has also gained some importance. The most important is based on protons. Since they deliver most of their energy just before the end of their range, a very good dose discrimination can be achieved. There is typically a dose factor of 5 between the so-called "plateau" and the "peak" regions. As the dose maximum is very sharp, small tumours can be very effectively treated with an optimal sparing of the surrounding areas. This technique has been applied especially to ocular melanomas; several thousand patients have so far been treated with excellent results. Not only could the tumour be locally cured, but also eyesight could be saved to a large extent in most cases. While in the beginning treatments were performed at accelerators built for research in physics (the forerunner being Boston, Massachusetts, U.S.A.), more recently "dedicated" machines have been established in specialized hospitals. The largest is situated in Loma Linda, California, U.S.A., commissioned in 1990; others are located in Boston, Massachusetts, U.S.A., Nice, France, and Villigen, near Zürich, Switzerland. Also more deep-seated tumours are now treated, which requires, of course, higher proton energies, which now go up to about 250 MeV (Miller, 1995).

Protons possess a very favourable dose distribution, but their biological effectiveness is not much different from that of gamma or x rays in consequence of their comparably low linear energy transfer (LET). In order to deliver an even higher "biological" dose and

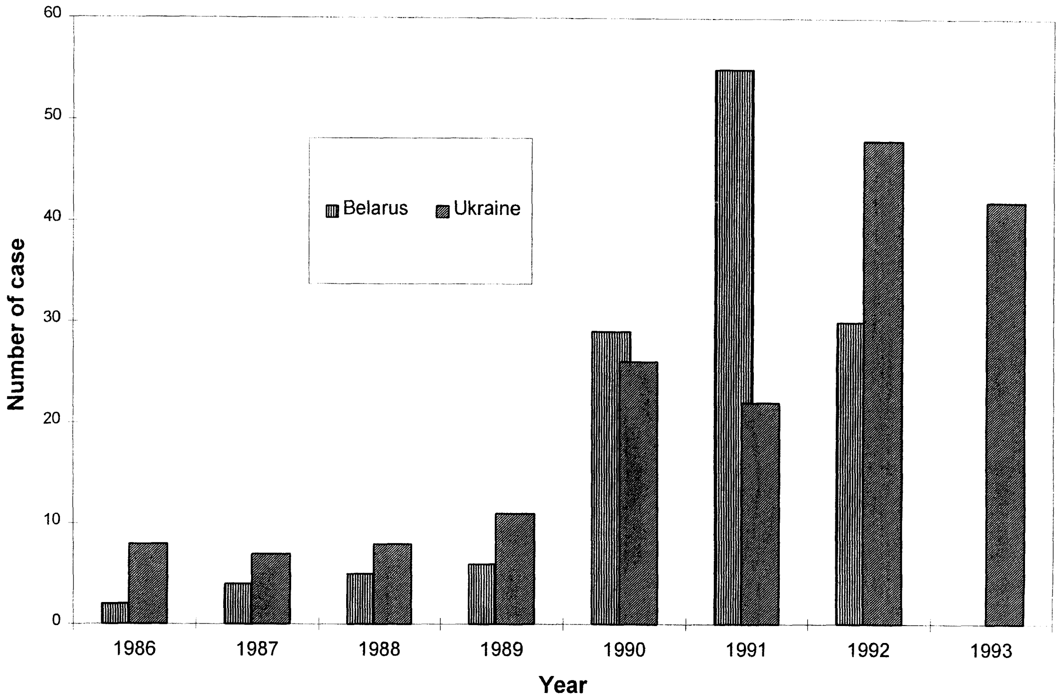

FIG. 1. Thyroid cancers in children up to age 14 in Belarus (Kazakov *et al.*, 1992) and Ukraine (Likhtarev *et al.*, 1995) as a consequence of the Chernobyl disaster. The 1992 value for Belarus is only for half a year.

overcome complications like the "oxygen effect" (see the original article), heavier ions are required. Studies along this line started many years ago in Berkeley, California, U.S.A., but had to be terminated because of the shutdown of the accelerator. Meanwhile two new studies were started, one in Chiba, Japan, where a dedicated heavy-ion accelerator was built, and in Darmstadt, Germany, which makes use of the existing heavy-ion accelerator and is still in the preclinical study phase. A new method for treatment planning has here been developed where the beam energy is modulated in such a way that the treatment volume matches as closely as possible the tumour ("raster scan") (Amaldi and Larsson, 1994).

5. RADIOECOLOGY, RADIATION PROTECTION, AND GUIDELINES

5.1 Effects of the Chernobyl Accident

The 1986 accident in the Soviet reactor in Chernobyl created a widespread radioactive contamination affecting more than 100 000 people. Because of uncertain dose assessment, firm epidemiological data are not readily available, but a few conclusions can now be drawn:

1. Contrary to common perceptions, there is **no** increase in childhood leukaemia, both in the Ukraine and in Belarus (Ivanov *et al.*, 1996; Drozdova *et al.*, 1996).
2. A dramatic increase in thyroid cancers was found in children up to age 14, as shown in Fig. 1.

5.2 Ultraviolet Radiation

All types of skin cancer show a world-wide dramatic increase. This is not only the case for the comparatively harmless basal- and squamous-cell carcinoma but also for the very aggressive melanoma. Figure 2 summarizes data obtained in British Columbia illustrating this alarming development. It is certainly not due to the reduction in stratospheric ozone but

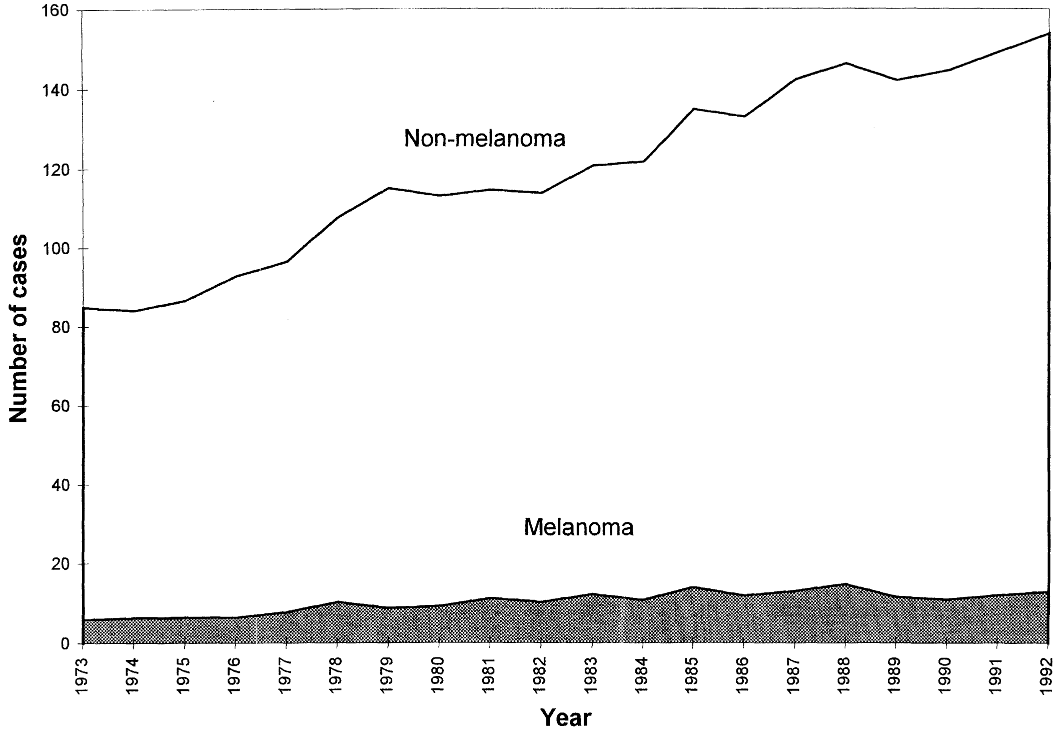

FIG. 2. Increase in non-melanoma and melanoma skin cancer in British Columbia from 1973 to 1992 (Philips *et al.*, 1996).

presumably to changed leisure habits and possibly also the increased use of sunbeds and other tanning devices.

There is a still on-going debate whether near UV (UV-A) has a carcinogenic action. Unfortunately there is not yet an action spectrum available for melanomas in mammals, but action spectra for other types of skin cancer obtained in hairless mice strongly indicate that also long-wavelength UV has clearly a carcinogenic activity.

Ozone depletion will add to this situation. Evidence is mounting that this is not only a theoretical possibility. It can now be seen world-wide, although the most dramatic effect has been registered in Antarctica. Future trends are difficult to predict and depend essentially on the use of chlorofluorocarbon compounds. It has to be kept in mind, however, that atmospheric chemistry operates at long time scales. A comprehensive review of all problems involved can be found in SSK (1996).

5.3 Radiofrequency Electromagnetic Radiation

The US National Research Council (NRC, 1997) has reviewed in a careful and comprehensive study all reports dealing with the question of a possible relationship between power lines and cancer. The result is best summarized by a sentence taken from the Executive Summary:

> *"Specifically, no conclusive and consistent evidence shows that exposures to residential electric and magnetic fields produce cancer, adverse neurobehavourial effects, or reproductive and developmental effects."*

The stress is on "conclusive and consistent," which does not rule out single, as-yet-unexplained findings. Taken together with biophysical considerations reviewed above it may be safely stated that scientific judgement does not provide any possibility for a link between normal environmental levels of electric and magnetic fields and human diseases.

Table 2. Radiation weighting factors (ICRP 60, 1991).

Type and energy range	Radiation weighting factor w_R
Photons, all energies	1
Electrons and muons, all energies	1
Neutrons, energy < 10 keV	5
10–100 keV	10
100 keV–2 MeV	20
2–20 MeV	10
>20 MeV	5
Protons, other than recoil, energy >2 MeV	5
Alpha particles, fission fragments, heavy nuclei	20

5.4 Principles and Fundamentals of Radiation Protection

The International Commission on Radiological Protection (ICRP) issued in 1990 a new set of fundamental recommendations (ICRP 60, 1991) that are likely to have also considerable impact on national legislation. More formally, the term "dose equivalent" has been changed to "equivalent dose" but also to some extent redefined. It is given by the product of dose and radiation weighting factors that replace the "quality factor". Radiation weighting factors are listed in Table 2.

A functional relationship with LET is no longer recommended, to avoid the impression of an accuracy that is inherently not possible. The step function for neutrons is somewhat artificial and commonly replaced by a smooth approximation.

Equivalent dose is measured over a tissue or an organ. To estimate a whole-body equivalent it has to be multiplied by "tissue weighting factors" w_T. This concept had already been used before but the actual values and organs to be considered have been altered, taking into account new medical results from the atomic-bomb survivors.

It has to be emphasized that the system described is only devised for application in occupational radiation protection. Its value in assessing the risk of medical radiation usage is obviously limited.

The ICRP has again reviewed all available evidence for the quantification of radiation carcinogenesis and models for risk projection. As a result new estimates for the expected occurrence of fatal cancer were produced, which must not be taken as firm evidence but rather as upper limits in order to limit possible risks. The numbers have increased considerably over the years, essentially as a result of the application of altered projection models. Consequently also new upper limits are recommended (Table 3). The data from the survivors of Hiroshima and Nagasaki are still the main source of information. Since they received acute doses in a short time, and as there is evidence that lowering the dose rate reduces the effect level, the ICRP introduced a "Dose and Dose Rate Effectiveness Factor" (DDREF) of 2 that is applicable in the common occupational situation. Extended studies with nuclear workers that became recently available are not at variance with the ICPR estimates.

Table 3. Recommended dose limits (ICRP 60, 1991).

	Occupational	Public
Effective dose (Whole body)	20 mSv/year averaged over 5 years	1 mSv/year
Eye lens (Equivalent tissue dose ETD)	150 mSv/year	15 mSv/year
Skin (ETD)	500 mSv/year	50 mSv/year
Hands or feet (ETD)	500 mSv/year	

ETD: Equivalent tissue dose

GLOSSARY

Apoptosis: "Programmed cell death": disintegration of a dying cell characterized by a sequence of distinct metabolic processes.

***Ataxia telangiectasia*:** Recessive hereditary disease in humans characterized by extreme sensitivity to ionizing radiations.

Chromosomal Aberrations: Change in the number of chromosomes (numerical aberration) or in their structure (structural aberrations). Radiation produces mainly the latter.

Dicentric Chromosomes: Chromosomal aberration where two chromosomes are joined in such a way that there are two centromeres (attachment sites for the spindle during mitosis).

DNA: Abbreviation for *deoxyribonucleic acid*, the macromolecule that carries the genetic information in cells.

Dose Equivalent: Formerly, the product of the (physical) dose and the quality factor for different radiation types. It is now replaced by "equivalent dose," which is the product of dose and the newly introduced "radiation weighting factor". If dose is measured in grays (Gy), the equivalent dose is given in sieverts (Sv). The old unit was "rem" with 100 rem = 1 Sv.

Double Strand Breaks (DSB): Rupture of the phosphate–sugar backbone of DNA in both strands opposite to each other. DSB are assumed to be the most important lesions caused by ionizing radiations.

ICRP: International Commission on Radiological Protection, an international non-government organisation that reviews the scientific literature and issues recommendations for radiation protection.

Linear Energy Transfer (LET): Energy imparted per unit path length by a charged particle.

Necrosis: Disintegration of a dying cell.

Recombination: Exchange of parts of genetic material between DNA molecules or chromosomes.

Translocations: Exchange of parts between different chromosomes without loss of genetic material.

INTRODUCTION

Since the original article (hereafter cited as A) was prepared, there has been considerable research activity into biological effects of sound, especially ultrasound, and its applications. Much of this has been motivated by medical applications, both to diagnosis, for which safety guidelines are desired, and to therapy, where the goal is to optimize treatment conditions. For either medical purpose, and for other applications, it is recognized as advantageous to know the mechanisms for the biological effects, whether they are adverse or beneficial. This brief review of selected findings and developments in the past six years is organized according to the mechanisms, both thermal and nonthermal, that are believed responsible for the various kinds of effects under consideration.

Theory for these mechanisms was discussed in A, and is not repeated here. In this Addendum the emphasis is on advances in experimental findings and applications. References are made to the literature for recent developments in theory.

1. BIOLOGICAL EFFECTS OF THERMAL ORIGIN

1.1 Safety Concerns

At frequencies in the megahertz range used in most medical ultrasound, acoustic absorption coefficients for mammalian tissues are high enough to allow temperature elevations produced in medical applications to be significant, even in some applications of diagnostic ultrasound. In tissues where cells divide rapidly, as in the mammalian embryo or fetus, a temperature rise of 2 °C or less can produce damage if prolonged sufficiently. For a wide range of teratogenic effects, the time t in minutes required for exposure to temperature T (in degrees Celsius) to produce the effect has been equated, approximately, to

$$t = 4^{43-T}, \qquad (1)$$

when T is not greater than 43 °C (Miller and Ziskin, 1989; NCRP, 1992); Eq. (1) was

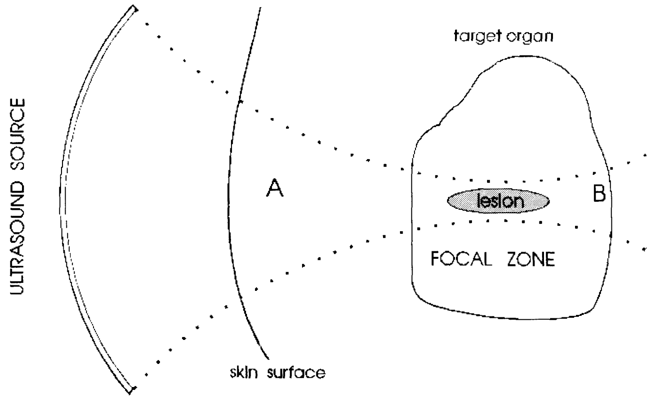

FIG. 1. Schematic diagram of arrangement used in surgical applications of focused ultrasound. A lesion (a region of severely damaged tissue that the body will remove by natural physiological processes) is produced in the focal region, while microscopic examination reveals no damage to tissue lying between the source and the target volume (A) or beyond it (B). Adapted from ter Haar (1995).

adapted from a more general equation given by Sapareto and Dewey (1984). According to Eq. (1), damage may occur after 4 min of exposure to a temperature of 42 °C, and after 16 min of exposure to 41 °C.

Among fetal tissues, the absorption coefficient is highest in bone, and the potential for heating increases with gestational age. Safety criteria derived from algorithms for calculating estimates of the maximum temperature rise that would be produced by ultrasonic exposure of bone and other tissues have been formulated during the past few years (NCRP, 1992; AIUM/NEMA, 1992). These criteria are expressed in terms of *thermal indices*, which are becoming familiar to users of diagnostic ultrasound equipment; many manufacturers of such equipment (in satisfying U.S. regulatory requirements) now display on the imaging screen a "real-time thermal index", i.e., an indicator of the maximum temperature rise being produced in the body of a patient during an ultrasound examination with current instrument settings.

Investigations of the accuracy of algorithms for temperature estimation, while not extensive, have included experimental measurements using special phantoms, as well as measurements made in living animals. The general conclusion is that the thermal indices, while based on estimates of temperature elevation that are subject to error, provide the user with information that is much more relevant to patient safety than was available before the indices were available; errors are usually in the direction of overestimating the temperature rise. It is hoped that in the future the accuracy of the indices can be improved, especially for the more critical situations.

1.2 Thermal Therapy Using Ultrasound

First introduced in the 1940's and 1950's, focused ultrasound has received increasing attention in recent years as a mean of modifying tissue in selected parts of the body; special emphasis has been given to its capability for elevating tissue temperature in a controlled manner. In *hyperthermia* applications, tissues are exposed to ultrasound at moderate intensity levels so that the temperature is maintained at a temperature of 43 to 45 °C for 10 to 30 minutes. In *noninvasive surgery* much higher intensities are used and the temperature raised to the range 60 to 90 °C for 0.1 to 10 seconds. The subject was reviewed recently by ter Haar (1995) and Sanghvi *et al.* (1996), and is featured in a special journal issue (Ebbini, 1996). Ultrasound hyperthermia and surgery are being considered in many fields of medicine, their significant applications at this time being in the fields of ophthalmology and urology. In Fig. 1 is a simplified diagram showing the basic features of an arrangement used in surgery for generating a beam of focused sound and using it to create a *lesion*, i.e., an ellipsoidally shaped volume of damaged tissue in soft tissue. Here the source is a spherical shell of piezoelectric ceramic a few centimeters in diameter, the frequency lies in the range 1 to 8 MHz, and the maximum intensity in the focal region is 300 to 2000 W/cm^2.

In other implementations the single source is replaced by an array of smaller ones, each with its own amplitude and phase; such an array can readily be steered, focused and programmed, so that multiple lesions can be produced in desired configurations. This facilitates the treatment of tumors, for example, by providing the capability of damaging the tissue in a controllable manner throughout regions of various sizes and shapes. Treatment design is greatly assisted by calculations of the expected temperature distribution, with computational or analytical solutions of the bio-heat transfer equation (A; NCRP, 1992; Ebbini, 1996; Sanghvi *et al.*, 1966) or, for very short exposures where the influence of blood flow can be neglected, the equation for thermal diffusion. Ultrasound and magnetic-resonance imaging methods are used to define the region to be treated and to visualize changes that the treatment has produced in the tissue.

2. BIOLOGICAL EFFECTS MEDIATED BY ACOUSTIC CAVITATION

2.1 Sonoluminescence

A major advance in experimental studies of cavitation came from the discovery (Gaitan and Crum, 1990; Gaitan *et al.*, 1992) that a continuous sound field of frequency 22 kHz and pressure amplitude 0.12 MPa can cause a single air bubble in liquid to undergo repeated "collapse events," i.e., implosions, at a regular rate synchronized with the sonic frequency for an indefinitely long period of time, and to generate a short flash of light during each im-

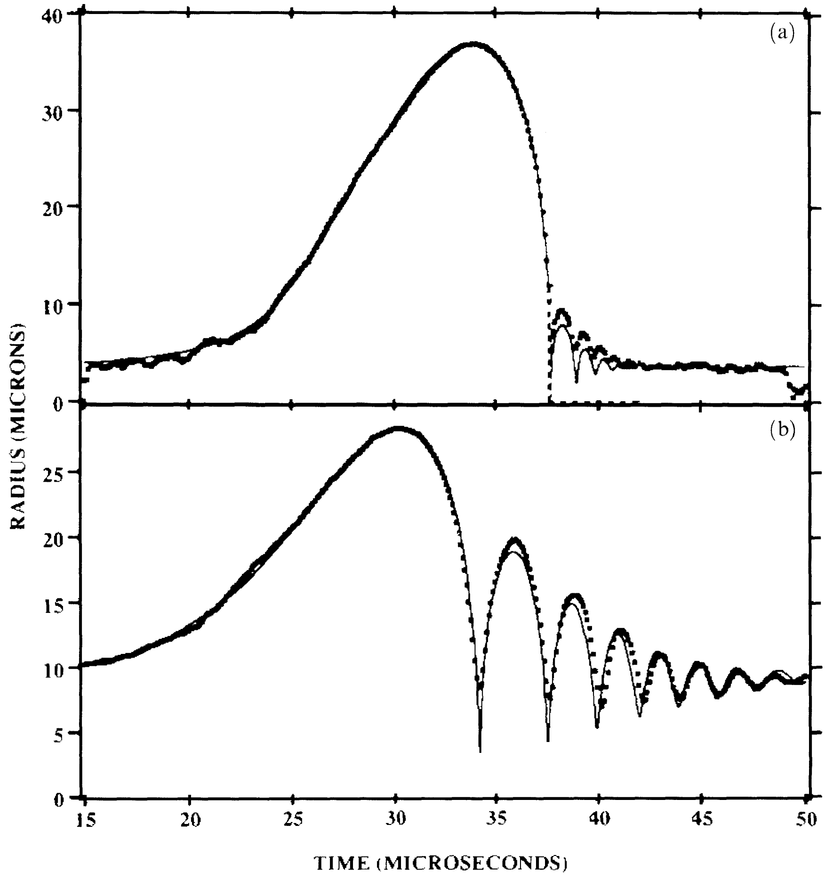

FIG. 2. Bubble radius as a function of time, repeated during each cycle, for a spherical air bubble in water driven by a sound field of frequency 26.5 kHz. The points are experimental; the solid curve is from theory. Sonoluminescence occurs under the conditions of (a), but not under those of (b), the only difference being that the pressure amplitude in the driving field was 0.133 MPa for (a) and 0.108 MPa for (b). From Barber and Putterman (1992).

plosion. These findings caused considerable interest because of the short duration of the flash (often less than 50 ps), the high regularity of the phenomenon, and the nature of the light spectrum. Optical techniques were used to determine the bubble radius R as a function of time t. A typical R *vs* t curve for one cycle of the motion for a frequency of 26.5 kHz is shown in Fig. 2; the points are experimental and the solid curves are from theory. The latter is a solution of the nonlinear equation of motion [similar to Eq. (13) of A]; the excellent agreement gives strong support for the theory. Flynn (1964) has pointed out that the violent collapse events come about because of the inertia of the liquid that rushes inward as the bubble radius decreases. The activity in and near a bubble undergoing the kind of motion illustrated in Fig. 2 has become known as *inertial cavitation* (known earlier as "transient cavitation"). The light production, known as *sonoluminescence* (*q.v.*), is critically dependent on the pressure amplitude in the driving sound field. For example, there was copious light production under conditions of Fig. 2(a) and none under those of Fig. 2(b), yet the conditions were the same except that the pressure amplitude was 0.133 MPa for the former and 0.108 MPa, about 20% less, for the latter. Interesting features of single-bubble sonoluminescence have been discussed by Crum (1994) and Putterman (1995).

Sonoluminescence produced by ultrasound in water or other liquids has been known for many years, and apparently emanates from activity of small bubbles that, in turn, owe their existence to pre-existing microscopic bodies of gas, stabilized against diffusion, called *cavitation nuclei* (see A). Such nuclei are ubiquitous in most liquids unless the latter have been very carefully prepared. An ultrasound field of sufficiently high pressure amplitude may cause free bubbles to emerge from these nuclei and, further, may produce inertial cavitation by causing the bubbles to expand quickly, then contract violently. The optical spectrum of "multibubble sonoluminescence" that appears when ultrasound is applied to water in a test tube or other vessel contains discrete lines characteristic of free radicals, especially O and OH; these are produced by dissociation of water molecules during brief periods of high temperatures (typically, several thousands of kelvins) following the violent contractions. Discrete lines are not seen in the spectra of single-bubble sonoluminescence; instead, a plot of spectral density *vs* wavelength published by Hiller *et al.* (1992) for the light generated by a single air bubble in water is a smooth curve which is fitted well over the 300 to 700 nm wavelength range by a 25000-K blackbody spectrum. Crum (1994) suggests that the conditions of single-bubble inertial cavitation, involving symmetry of the driving pressure field about the bubble center, can lead to production of much higher temperatures in the bubble (which is compressed with little loss of heat to the liquid) than are produced in the more typical experimental conditions where many bubbles are active. In the latter situation, because of high-speed bubble motions and interactions between bubbles, the latter probably do not maintain their spherical shapes as they contract. Instead, available information suggests that the motion during collapse is complicated by surface deformation accompanied by the formation of liquid jets and microbubbles (see A; SONOLUMINESCENCE). It can be expected that, because of the energy used in forming new surface area and because of increased heat transfer from the gas, the pressures and temperatures reached during collapse will be reduced.

There have been many studies in which ultrasound is applied to suspensions of biological cells *in vitro* with the consequence that inertial cavitation occurs and the cells are lysed or otherwise damaged. Sonoluminescence may have occurred, but biological effects have not been attributed directly to the light (even though its spectrum extends into the ultraviolet); instead, the effects have usually been attributed to mechanical or chemical aspects of inertial cavitation (Miller *et al.*, 1996). For example, Miller *et al.* (1995) showed that inertial cavitation generated by ultrasound in suspensions of Chinese hamster ovary (CHO) cells caused H_2O_2 to be produced, which entered surviving cells and caused single-strand DNA breaks. Kim *et al.* (1996) have shown that cavitation produced by continuous 1-MHz ultrasound with pressure amplitude about 400 kPa can make mammalian cells temporarily permeable to large molecules, and appears to provide a promising method of gene transfer. (Note also related findings for lithotriptor-produced shock waves, reported below.)

2.2 Extracorporeal Shock-Wave Lithotripsy

Much has been learned from experiments in which the source is an extracorporeal lithotriptor, a device used medically for breaking up kidney stones by means of focused ultrasound pulses of short duration and high pressure amplitude that are generated outside the patient's body and propagated into it. These high-amplitude pulses are often called *shock waves* and the procedure for applying them is *extracorporeal shock wave lithotripsy* (ESWL). Conditions are favorable for the production of inertial cavitation in water, in the field of a typical lithotriptor, because of the high acoustic pressures (up to 120 MPa) that exist in the focal region during a shock and because of the frequency spectrum, which includes considerable energy in the range 200 kHz and below.

Delius (1995) has reviewed a wide variety of effects produced by ESWL fields on cell suspensions, concluding that these are caused by shear forces resulting from cavitation. A novel finding (Gambihler *et al.*, 1994) is that mouse tumor cells can be made temporarily permeable, allowing large molecules to enter them, after which the cells remain viable. On the basis of such findings, Delius *et al.* (1994) have proposed that ESWL techniques be developed for application to patients as a mean of gene therapy. (Note related findings for ultrasound, reported above.)

Evidence has been obtained that inertial cavitation occurs in the body of patients during ESWL procedures. Coleman *et al.* (1995, 1996) used B-scan ultrasound imaging to examine a region exposed to an ESWL field while the latter was focused on stones in the kidney. In a region (possibly a fat layer) just outside the kidney, through which the shock wave is transmitted into the kidney, increases in image brightness, i.e., echogenicity, appeared when the output setting of the lithotriptor was raised to values above threshold. This increased echogenicity was attributed to gas-filled cavities that had been produced by the field. From hydrophone measurements of the acoustic pressure in water, it was determined that threshold values for the cavity formation were about 15 MPa for the positive peak pressure and 3.5 MPa for the negative peak during passage of a shock.

2.3 Pulsed Ultrasound

Acoustic cavitation, both inertial and non-inertial, capable of causing biological effects, is readily produced by ultrasound in water and in cell suspensions, even with pulsed ultrasound such as is used in medical diagnosis, where frequencies are higher (usually 2 MHz or above) than for a lithotriptor and the focal dimensions are smaller (Deng *et al.*, 1996; Miller *et al.*, 1996).

Even in some mammalian tissues, pulsed ultrasound, similar to that used in diagnostic applications, produces cavitation activity of some kind, though its nature is still under investigation; these are tissues where there are known gas-filled spaces, as in the mammalian lung and gastrointestinal system. The biological endpoint is usually structural damage, made evident by the leakage of erythrocytes from small blood vessels and capillaries on the inner surface of the lung and gastrointestinal tract. Systematic studies of lung damage produced by pulsed focused ultrasound have yielded information on thresholds for damage, in terms of the peak negative pressure p. All threshold values lie within an order of magnitude of 1 Mpa, but there is variation with age and species of the animal, and with frequency and pulse duration of the ultrasound. See, for example, Carstensen *et al.* (1992), Baggs *et al.* (1996), and Holland *et al.* (1996). Surprisingly, the thresholds for damage to mammalian lung are in the same range as thresholds for damage to fruit-fly larvae and to leaves of the plant *Elodea* (AIUM, 1993). The common element to all of these biological systems is the presence of stabilized gas-filled cavities; i.e., lung in the mammal, respiratory channels in the larvae, and intracellular gas-filled channels in the plant. For the last, the primary mechanism for damage appears to be viscous stress from acoustic microstreaming produced near vibrating intracellular channels (Miller, 1987; A). The detailed mechanisms for damage caused by ultrasound to mammalian lung or to insect larvae are, as yet, unknown.

2.4 Contrast Agents

A recent development in diagnostic ultrasound procedures is the increasing use of contrast agents (de Jong, 1996). These agents take various forms, but those being considered here are particulates that, when injected into the blood stream of a patient, cause small bodies of gas to exist there. These gas-filled cavities are surrounded by fluid, or are encapsulated by elastic shells or by viscoelastic films; they are very effective as scatterers of the incident ultrasound (at moderate pressure amplitudes) or as emitters of cavitation-generated harmonics (at higher pressure amplitudes), and thus add information to an ultrasound scan.

Contrast agents also can contribute to biological effects of ultrasound. It was found in experiments with the commercial product Albunex® that these gas-containing particles can serve as nuclei for cavitation and, when added to a cell suspension, can greatly increase the destruction of cells when the latter are exposed to pulsed ultrasound (Brayman *et al.*, 1996) or when they are exposed to lithotriptor shock waves (Miller and Thomas, 1996). Studies are in progress on the extent to which damage occurs to living mammals upon exposure to ultrasound when contrast agents are present in the circulatory system. The mechanisms for the action of contrast agents are not known in detail, but evidently include various aspects of inertial and noninertial cavitation.

2.5 Safety Considerations

Theoretical and experimental results have led to safety criteria, analogous to those developed for thermal mechanisms (NCRP, 1992), which define conditions under which tissue damage might occur as a result of cavitation. A criterion adopted by the Output Display Standard (AIUM/NEMA, 1992) is expressed in terms of a *Mechanical Index* (MI), the latter being defined as the ratio of the peak acoustic pressure, defined in a specified way and expressed in megapascals, to the square root of the center frequency, the latter expressed in megahertz. A standard formula is used for calculating the peak negative acoustic pressure in the patient's body, given the results of measurements in water. It is assumed that damage does not occur if the MI is less than 1.0 (or other assigned number). Many manufacturers provide for display of the "real-time MI", i.e., the MI appropriate for current instrument settings, on the screen of ultrasound imaging equipment, in satisfying U.S. regulatory requirements.

3. CONCLUSIONS

Biological effects of ultrasound are receiving increased attention, partly because of their relevance to safety of medical procedures, and partly because of the diverse therapeutic applications which are possible because of the ability of ultrasound to change the structure and function of cells and tissues. For continued progress, it will be necessary to achieve much better understanding of the mechanisms involved in the applications described above, and in others which it has not been possible to discuss in this brief review.

GLOSSARY

Acoustic Cavitation: The mechanical response of one or more gas-filled cavities to a sound field; the cavitation may be inertial or noninertial.

Cavitation Nuclei: Small bodies, usually gas-filled cavities, that can serve as sites for acoustic cavitation.

Extracorporeal Shock-Wave Lithotripsy (ESWL): A procedure used for destruction of kidney stones, involving production of short ultrasound pulses (with very high acoustic pressures) outside the body of a patient and focusing them on the kidney.

Hyperthermia: A procedure for killing tumor cells by raising their temperature to a critical value.

Inertial Cavitation: A class of acoustic cavitation involving growth and violent collapse of one or more cavities.

Lesion: A region of damaged tissue, such as can be produced by focused ultrasound under specific conditions.

Mechanical Index: A number calculated according to standards accepted in the U.S.A., used as a safety index for alerting the user of diagnostic ultrasound equipment to conditions under which damaging acoustic cavitation might occur in the body of a patient.

Noninvasive Surgery: A procedure, such as an application of focused ultrasound, for creating damaged tissue, especially in a tumor, which will subsequently be removed by natural processes.

Sonoluminescence: Production of light by sound in water or other liquid, usually as a consequence of inertial cavitation.

Thermal Index: A number calculated according to standard algorithms, used as a safety index for alerting the user of diagnostic ultrasound equipment to conditions under which damaging temperature elevation might occur in the body of a patient.

1. OPTICAL MICROSCOPY AND IMAGE ANALYSIS

Considerable strides have been made in recent years in developing quantitative image analysis (QIA) (Russ, 1990). Faster and greater processing-capacity computers and improvements in software have made the acquisition, digitization, storage, and image display processes much more efficient. For example, one of the most widely used applications is in the analysis of particle size distributions and particle shapes (Li *et al.*, 1995). The improved computational developments have resulted in improved resolution by enhancing the contrast between particles and displaying a variety of particles in a mixture by discrete colors. These techniques have been applied to the analysis of polymer composites, metal alloys, ceramic mixtures, and various combinations of polymer, metal, and ceramic composites (Sibilia, 1996). In addition to information on the particle sizes and shapes, QIA also provides information on the degree of mixing of the components, their ability to "wet", and their packing efficiency. Contiguity, a parameter which measures the degree of interaction between neighboring particles, is also determinable by QIA.

QIA has also been applied in the medical and biological sciences. The various features of cell structures have been much more clearly elucidated and quantified by image analysis. Furthermore, the technique has been applied to the analysis of virus-containing tissues and the micromolecular diffusion in skin.

2. MOLECULAR SPECTROSCOPY

2.1 Infrared Spectroscopy

The infrared dispersive spectrometers have essentially been replaced by Fourier-transform infrared (FTIR) spectrometers. These instruments utilize an interferometer in place of a monochromator to achieve the separation of absorbed frequencies when infrared light is passed through a sample (Ferraro and Krishnan, 1990). The advantages of FTIR are several. They have much higher source-radiation throughput, increased signal/noise ratio, reduced measurement times, and higher wavelength accuracy. These advantages have allowed infrared spectroscopy to be used in a number of new applications, as well as the conducting of more standardized experiments in a more efficient manner (Coleman, 1993).

One of the areas where FTIR has widened the scope of applications in infrared spectroscopy is in surface analysis. Infrared spectroscopy in general can be used to provide information about the molecular structure of the surfaces of materials. There are three available

techniques, which provide information at three different depth levels in materials and for different kinds of materials. The most common of these FTIR surface analytical techniques is attenuated total reflectance (ATR), which probes the depth in the range of about 0.5 to 3 μm. In this technique the sample is held in contact with a prism as shown in Fig. 1. In Fig. 1(a), a single-reflection hemispherical prism is shown while in 1(b), a multiple-reflection prism is used with the sample pressed against both prism surfaces. Light entering the prism (usually KRS-5, or some other high-refractive-index, infrared-transparent inorganic crystal) undergoes internal reflection at the prism surfaces. At the interface, the light penetrates a small distance into the sample. The depth of penetration depends on the angle of incidence of the light beam and the difference between the index of refraction of the prism (n_1) and that of the sample (n_2) (Fig. 1). The light exiting the prism is attenuated at specific frequencies because of absorption by the sample. The resulting spectrum is similar to that obtained by transmission infrared spectroscopy. The sensitivity of the ATR technique is enhanced if the multiple-pass configuration [Fig. 1(b)] is used rather than single-pass mode shown in 1(a). Applications of the ATR technique include the surface analysis of thin films, adhesives, surface contaminants, surface compositions of materials, and migration of substances to the surface of materials.

Another infrared spectroscopic surface technique is photoacoustic spectroscopy (PAS) (*q.v.*). The sampling depth of PAS is about 1 to 10 μm. In this technique the incident infrared energy that is absorbed by the sample is converted into heat. Gas, which is in contact with the sample surface, is heated by the sample and expands. The expansion of the gas produces an acoustic signal when the incident beam intensity is modulated at a frequency in the acoustic range. Microphonic detection of this signal can be made to produce an IR spectrum when it is processed by the detector amplification electronics of an FTIR spectrometer. PAS is particularly useful for examining samples as received without any further preparation. For example, powders, pellets, films, opaque materials, and rough-surfaced materials can all have their surfaces analyzed by PAS.

The third infrared surface analytical technique, which is capable of examining ultrathin (monolayer) films, is grazing incidence reflectance (GIR) spectroscopy. In this methodology the IR beam intersects the surface at a high angle of incidence. This technique is highly sensitive but has been limited to the examination of only metallic surfaces.

Another infrared technology which has been expanded through the use of FTIR is infrared microspectroscopy. Infrared spectra, with a spatial resolution of about 10 μm, can be achieved by coupling a high-quality optical microscope with an FTIR spectrometer. Spectra in both transmission and reflectance modes can be obtained. It is possible to perform localized surface analyses *in situ* using specialized ATR and GIR objectives at lower spatial resolution (about 25 μm). Mapping of individual components can also be achieved by using an x-y translation stage. Infrared microspectroscopy has been applied in analysis of contaminants or defects on surfaces of ceramic, metallic, and polymer substrates; gels and defects in pharmaceutical tablets and packages; and electronic failures; and in forensic analysis of fibers, pigments, dirt etc.

Another 'combination' technique that has been extensively applied is chromatography-FTIR. Components in the microgram and subnanogram range have been identified by this combination technique. In the GC-IR mode, compounds can be identified in the gas phase in real time. Techniques such as liquid chromatography/IR or gel permeation chromatography/IR require that the sample first be separated and collected on a disc and then analyzed.

The study of kinetic systems and transient species has also been enhanced through the application of FTIR techniques. Spectra can be obtained in times as short as 1/20 of a second with the use of conventional FTIR. If the spectrometer is operated in a step-scan mode, microsecond and even nanosecond time domains can be achieved. This allows for real-time studies of chemical reactions to detect unstable intermediates, establish reaction mechanisms, and determine kinetic parameters.

2.2 Raman Spectroscopy

Both dispersive and Fourier-transform spectrometers are used routinely for Raman measurements. A choice of incident laser frequencies, ranging from the ultraviolet to visible regions of the electromagnetic spectrum, is usually available. FT-Raman spectrometers use the same principles as FTIR but operate in the near-IR region of the spectrum and use a near-IR laser at 1.06 μm. The advantage of the FT-Raman spectrometers is that sample fluorescence can be reduced. Sample fluorescence is a common problem in Raman spectroscopy; it results in masking of the spectrum and sometimes creates totally unusable spectra.

One recent application of Raman spectroscopy is in the analysis of carbon/graphite-containing materials. Infrared spectroscopy is of little use in the analysis of such materials since they absorb too strongly throughout the IR region and provide little structural information. Raman spectroscopy, on the other hand, can distinguish between the different forms of graphite (determined by their different degrees of graphitization) and diamond.

2.3 Nuclear Magnetic Resonance Spectroscopy

Significant advances have been made in multi-dimensional high-resolution NMR. Two-dimensional NMR (2D NMR) is a methodology that provides molecular structural information in a simple visual display. High-resolution one-dimensional NMR spectra of even relatively low–molecular-weight compounds can be complex on account of the overlapping array of signals arising from a multitude of different chemical shifts and spin–spin interactions. When a second frequency dimension (2D NMR) or in some cases even 3D or 4D is utilized, structural information becomes easier to extract because the interactions between specific nuclei in the molecule become more evident.

Advances in the application of cross-polarization (CP) and high-power decoupling (DD) have also made solid-state NMR a more valuable technique. These and other advances have accelerated the development of multidimensional solid-state NMR to applications in polymers (Mathias, 1991) as well as small-molecule organic and inorganic compounds. Magnetic resonance imaging of materials is another field that is also rapidly developing in solid-state NMR.

2.4 Mass Spectrometry

Two relatively new techniques in the field of structural mass spectrometry have been used to analyze the structures of high-molecular weight polymers. They are plasma desorption mass spectrometry (PDMS) and matrix assisted laser desorption mass spectrometry (MALDI). Both techniques utilize a pulse of energy to create a thermal spike in the sample, which in turn results in the ejection of both positively and negatively charged ions into the gas phase. Time-of-flight mass analyzers are now generally used for both PDMS and MALDI. Time-of-flight mass spectrometers have only moderate mass-resolving power but have no constraints on mass range. They are also ideally suited for this application because they have the ability to detect all the ions ejected by the ion source.

3. CHROMATOGRAPHY

3.1 Supercritical Fluid Chromatography

Supercritical fluid chromatography (SFC) is yet another type of chromatography in a growing field that is more appropriately known as separation sciences. The technique requires that the sample to be analyzed must be soluble in a solvent for dilution and injection purposes and must also be soluble in the mobile phase used in the SFC method. The mobile phase is a supercritical fluid, i.e., a "gas" above its critical pressure and above its critical temperature. Most analyses are carried out at room temperature or slightly higher but rarely above 100 °C. Sensitivities by this methodology are in the parts-per-million range or better depending on the method of detection used and the nature of the sample. The principle of the method is similar to that of other chromatographies where components are separated by their ability to partition between the mobile phase and the stationary phase, which is a component of the column. Some of the supercritical fluids used in SFC are carbon dioxide, ammonia, monochlorodifluoromethane, and dichlorodifluoromethane. SFC has advantages over GC and HPLC in certain analytical applications, but it does not share the wide range of applicability of these two well established techniques.

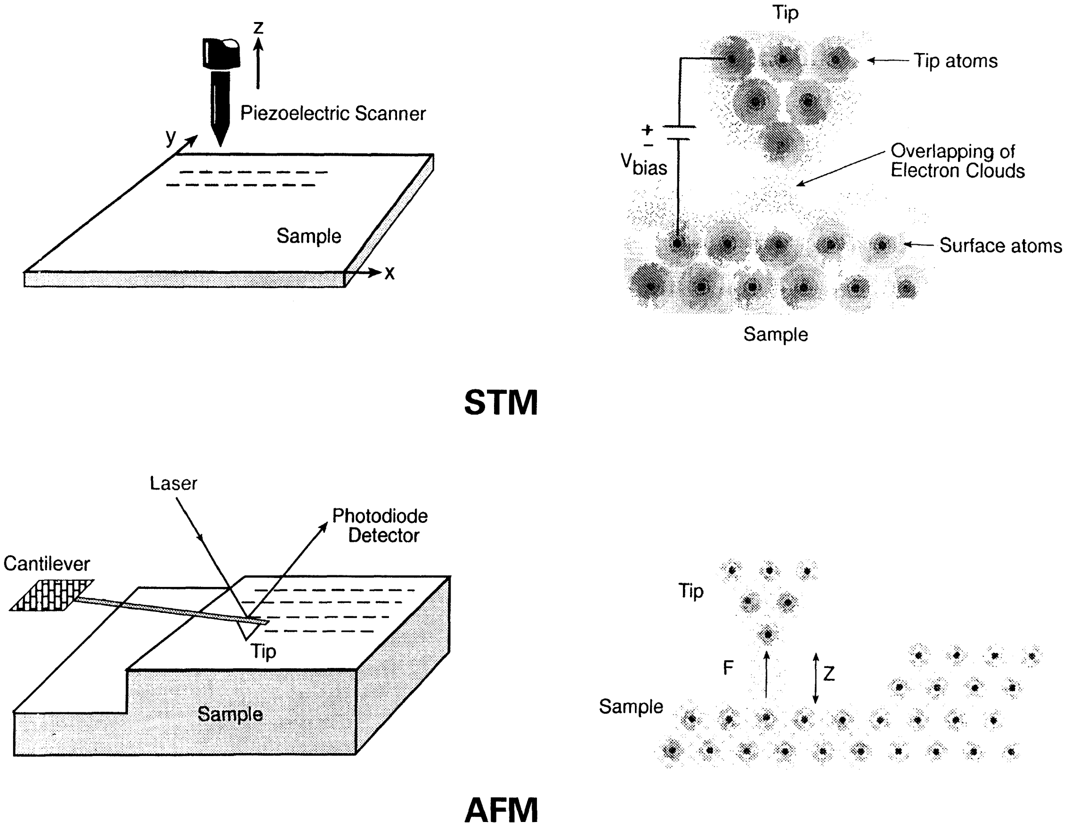
3.2 Capillary Electrophoresis

High-performance capillary electrophoresis (HPCE) (see Capillary Electrophoresis in this Supplement) is a technique that combines the strength of high-performance liquid chromatography (HPLC) and conventional electrophoresis to yield rapid, precise, automated, and highly efficient analysis of complex mixtures (Wenclawiak, 1992). It is particularly useful for analyzing both organic and inorganic compounds in aqueous media. Since HPCE utilizes such small sample sizes (nanoliters and less), it is most effective as an analytical rather than a preparative technique.

The basic principles of HPCE are rather simple. A small plug of sample solution is introduced into one end of a fused-silica capillary tube that contains an appropriate electrolyte. Upon application of a large electrical field to the solution flowing through the capillary column, the molecules in the sample migrate at different rates through the column. A number of different detectors such as ultraviolet/visible, fluorescence, conductivity, or mass spectrometry are used to detect the effluent molecules. The technique has found wide use in a broad range of applications, especially in the pharmaceutical industry.

4. SCANNING PROBE MICROSCOPY (SCANNING TUNNELING AND ATOMIC FORCE MICROSCOPY)

Scanning probe microscopy (SPM) (see Tunneling Microscopy and Spectrometry) is the term associated with a variety of techniques which measure the topography of surfaces at the atomic level. Scanning tunneling microscopy (STM) and atomic force microscopy (AFM) are two of the earlier SPM methodologies that were described in the original article. In Fig. 2 are schematic drawings showing the basic operations of an STM and an AFM. In STM the piezoelectric scanner probe passes over the surface of a relatively flat conducting sample. If a potential differ-



STM

AFM

FIG. 2. Schematic of the STM and AFM setups. From Sibilia (1996). p. 190, Fig. 8.18.

ence is maintained between the tip and sample surface as illustrated in Fig. 2, a current will be generated if the tip passes very close to the sample surface. The current is generated by electrons "tunneling" their way through the surface of the sample and through the air gap to the probe tip. As the tip is traversed over the surface it will experience an up-and-down motion corresponding to the topography of the surface at the atomic level. The motion of the probe can be sensed by a transducer and in turn can be converted to a contour map of the surface. This is only one mode of operation, and it involves feedback to the (vertical) positioning mechanism based on the magnitude of the tunneling current. In the AFM technique, the electronic forces between the probe tip and the sample surface cause a deflection in the cantilever arm. The deflections can be detected by means of a laser beam reflecting off the cantilever and into a photodiode detector. A mapping of the cantilever deflections as the probe is traversed over the sample surface results in a map of the atomic level surface topography. Basically, all the SPM techniques consist of a probe which scans the surface of a material and measures the surface topography and the specific surface interaction, which is dependent on the nature of the probe and sample type of surface being studied. Three more recent techniques (in addition to STM and AFM) to join this expanding field of SPM are magnetic force microscopy (MFM), scanning thermal microscopy (SThM), and scanning near-field optical microscopy (SNOM).

MFM is a variation of AFM that uses a ferromagnetic probe to detect the forces exerted on the tip by the stray magnetic fields of the sample. While AFM operates in a contact mode, the tip does not contact the surface in the MFM mode. Both surface topography signals, which dominate at close distances to the surface, and magnetic signals, which are more prevalent at greater distances from the surface, can be detected by moving the probe closer to or further away from the surface. This is important to establish the relationship between the topographic and magnetic data. Resolution down to 50 nm and the noncontact/nondestructive nature of MFM make this a useful addition to the SPM arsenal.

SThM uses the sample's thermal conductivity characteristics as a contrast mechanism in imaging microscopic features (Dinwiddie *et al.*, 1994). There are several variations of the thermal probe. It can be made with two wires to form a thermocouple junction at the scanning tip or it can comprise an integrated resistive thermal probe with the AFM cantilever. The probe is operated in a constant-force mode as in an AFM. SThM can collect and display topographic and thermal (conductivity or temperature) data simultaneously. Like the MFM technique, which provides both topographic and surface magnetic information, SThM provides both topographic and basic information about the conductivity/temperature characteristics of the sample surface.

SNOM is a scanning probe technique that provides optical microscopic information at a resolution better than 100 nm. The optical image is generated by means of a subwavelength optical probe that is held in close proximity to the sample (i.e., in the near field). The near-field interaction, which is based on fiber-optic waveguide theory, is monitored while the probe is scanned across the sample surface. The SNOM technique, which does not use lenses, has improved resolution over conventional optical microscopy since the diffraction limitations due to the use of lenses are eliminated. The technique has been finding application in the semiconductor, bioscience and magneto-optical device fields.

INTRODUCTION

Steady improvement in practically every area of chemical analysis has occurred since the original article appeared in this Encyclopedia. However, some areas have progressed so fast that little is similar over that time span. This update focuses on four major changes that have occurred:

1. in spectrometry, where a larger fraction of the light available for analyses can be collected through the use of multichannel monitoring;
2. in electrophoresis, where running the separations in capillary tubes has resurrected this old method of separations;
3. in mass spectrometry, where molecules with molecular weight up to 100 000 can be brought into the gas phase; and
4. in sample preparation, where microwave heating has helped to speed sample preparation to match the ever greater throughput of advanced instruments.

1. PARALLEL COLLECTION OF ANALYTICAL INFORMATION

A quiet revolution in detectors has occurred with the advent of silicon solid-state charge-transfer devices (CTDs), which include charge-coupled devices (*q.v.*) (CCDs). Contemporary CCDs now outperform photomultiplier tubes in nearly every application. Each photon that hits the CCD produces one (in the near-IR to visible range) or more (in the UV and x-ray ranges) electron-hole pairs, which are stored inside the volume under the location where the photon hit the detector. These charges are stored until the packets of charge from each pixel are read out individually and amplified. Figure 1 shows the difference between using a single detector such as a photomultiplier in conjunction with a monochromator in a scanning instrument and a CCD array in a dispersive, nonscanning instrument (a polychromator).

The scanning instrument gets it name because over time it scans the colors past a slit that selects a narrow range of the whole to produce a spectrum (a plot of light power *vs.* wavelength). However, the scanning instrument makes inefficient use of the light entering it. Most of the light—that not at the specific wavelength falling on the detector—is wasted. However, when the entire spectrum can be recorded simultaneously, far more signal is recorded per unit time. This inherently better performance is designated the multichannel advantage. Closely related is the multiplex advantage of infrared spectrometry.

Polychromators are used to great benefit in atomic emission spectrometry. Early polychromators had up to ten photomultiplier tubes set to record the lines from ten elements simultaneously. In contrast, contemporary instruments can quantitate essentially all the common elements in a sample in about a minute through a combination of the CCD-based polychromator and contemporary small computers. Improvement in the signal-to-noise ratio over the older methods can be up to a factor of 100.

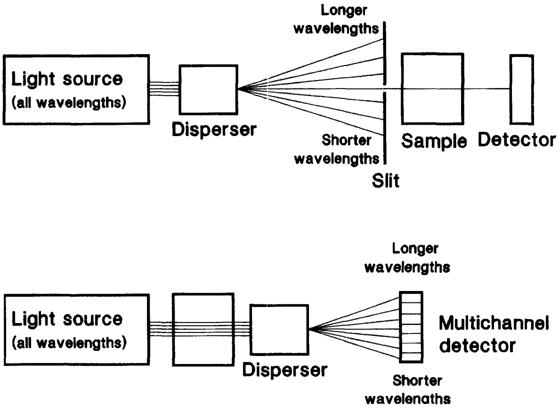

FIG. 1. Diagram of the general differences between a scanning spectrometer (top) and a polychromator system (bottom). The disperser consists of one or more gratings. The scanning spectrometer scans sequentially through the wavelengths. Here, it is shown in the middle of the range. The multichannel spectrometer has optics that are fixed in position.

Separations provide another application where polychromators are rapidly being applied. Compounds are separated in time (and volume) by column liquid chromatography (see CHROMATOGRAPHY) and then pass sequentially through a detector. The volumes containing the individual compounds are called bands. If the band holds a single compound, the spectrum is the same throughout. However, if a band is not pure, but composed of two compounds, it is likely that one is enriched at the leading edge and the other is enriched at the trailing edge. Two different spectra are seen at the edges and a combination of the two in the middle. The benefits of multiplexing are so great that multidimensional detectors have become the method of choice, since no more time is necessary for the chromatographic separation to be run. After all, why should all that extra data not be collected if it can be used to answer any questions that arise about the purity, identity, and properties of the compounds in each band?

2. ELECTROPHORESIS

Separations of different species based on their dissimilar behavior under the influence of an applied electric field are classified generally as electroseparations. There are six phenomenological rules that describe the factors that underlie the various types of electroseparations.

1. Negative ions tend to migrate toward the higher (positive) voltage and positive ions tend to migrate toward the lower (negative) voltage.
2. The average rate of migration of an analyte species is proportional to the average charge on the ion.
3. The average rate of migration of an analyte species is proportional to the average voltage applied.
4. The average rate of motion of an ion decreases as its average cross section increases. (The cross section is the area of the ion that lies perpendicular to the direction of the motion.)

The ability to separate slightly different molecules, such as deoxyribonucleic acids (DNAs) that differ by one base unit, is severely compromised by convection, however. Convection is the macroscopic mixing of liquids due to differences in density, and heating causes much convection in solutions. So,

5. the quality of electroseparations in liquids improves as the convection can be suppressed.

Heating of a liquid in electroseparations *cannot* be avoided since the electric current passing through the solution heats it. Finally,

6. the quality of electroseparations in liquids improves when the temperature can be held constant over the time of the experiment.

There are two ways to suppress convection in a liquid when gravity is present:

A. running the electroseparation in a gel, where the molecular strands of the gel stop macroscopic convection by trapping the liquid between the strands, and

B. running the electroseparation inside a small ($\sim 100\,\mu\text{m}$) capillary, where the walls of the capillary have the same beneficial effect as the gel molecules. In addition, the small size of the capillary lowers the temperature differences that can arise since the heat can leave relatively easily across the short distances to the surface of the tube.

The analytical methods that fall under the classification of electroseparations in solution are used to separate and quantitate analytes ranging from small molecules (formula weight ~ 100) to the largest macromolecules (formula weight up to 10^8) such as DNA chains or the largest proteins.

2.1 Gel Electrophoresis

The most commonly used methods of electrophoresis are done by carrying out the separation in a polymeric gel (as in *gelatin*). The gels are composed of a three-dimensional web of polymer strands having the spaces between the strands filled with liquid. Two different separating mechanisms exist: electrophoresis, that separates by the charge-to-size ratio (that is, the total electric charge on the molecule divided by its effective cross section), and sieving, that separates mostly by size. The sieving effect is caused by the macromolecules' migration being slowed by colliding with the gel molecules; larger molecules are slowed more than smaller ones. Especially prominent among the applications of gel electrophoresis is the analysis of DNA and RNA fragments, which forms the analytical basis of contemporary molecule biology of the gene.

Conditions for electrophoresis can be divided into two classes—denaturing and nondenaturing. To *denature* means to make the molecules biologically inactive. The molecules are still polymers with the monomers covalently linked in their original order, but the polymer is no longer folded into the form that it has when it is active. Detergents such as sodium dodecyl sulfate [SDS, $CH_3(CH_2)_{10}CH_2OSO_3^-Na^+$] and other nondetergent agents (*e.g.*, urea) are known to cause such denaturing. The names of the methods, such as *SDS polyacrylamide gel electrophoresis*, relate the type of gel and that it is run under denaturing conditions.

2.2 Capillary Electrophoresis

In an electrophoretic separation, both the speed of the separation and the resolution of the components improve as the applied electric field is increased. The reason that the voltage cannot be increased at will is that the heating increases to the point where the convection ruins the quality of the separation. The heating effects can be reduced drastically by running the electrophoresis inside a capillary tube having an inside diameter less than 0.1 mm and a length about 50 cm to 1 meter. Naturally, the technique is called *capillary electrophoresis* (CE) (see CAPILLARY ELECTROPHORESIS in this update volume). Another name is capillary zone electrophoresis (CZE). One reason why running in a capillary is effective follows from its electrical properties. The electrical resistance is so high that the current remains low (less than about $10\,\mu\text{A}$). As a result, the heating is reduced.

The apparatus for capillary electrophoresis is illustrated in Fig. 2. The technique has great resolving power, and methods have been developed so that electrophoresis can even be done for neutral, nonionic molecules. (This latter method is called micellar electrokinetic chromatography, abbreviated MECC.)

The analyte zones separated by capillary electrophoresis can be detected in their path through the capillary as they pass a detector, since the solution contained inside the tube move while the separation is occurring. This solution movement is called electroosmosis or electroendoosmosis.

Using a narrow capillary does involve a tradeoff: the samples must be about a nanoliter or less, and, after separation, the analytes are each in a similar volume. With such small liquid samples, only a few methods of detection can be used effectively. For example, light absorption is not routinely used to detect concentrations below $1\,\mu\text{M}$ in such small volumes. As a result, analytes are required to be at least $10\,\mu\text{M}$ to 0.1 mM. Nevertheless, nanogram to picogram quantities can be detected and quantitated, and it is this progress in detection that

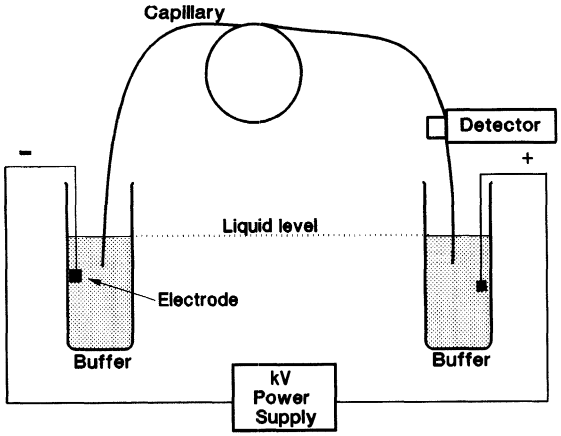

FIG. 2. Diagram of the basic parts of a capillary electrophoresis apparatus with spectroscopic detection. The sample is put in at the left side by placing the end of the capillary in the sample solution and raising its level so that the solution flows in. To run, the end is placed in a buffer set at the same height as the right end. While running, the levels of the two buffer solutions must be the same (as indicated by the dotted line) to avoid further bulk flow. The entire unit shown is held at a constant temperature.

has led to the revival of electrophoresis in this newer, capillary, form.

In running the separation, when the anode (+) is on the injection side of the capillary, this is called running in the normal mode. When the cathode (−) end is on the injection side, it is the reversed polarity mode. Voltages up to 1000 V cm^{-1} may be applied.

3. MASS SPECTROMETRY

Mass spectrometry (MS) is one of the most versatile and powerful tools of chemical analysis. Its broad usefulness is due mostly to the wide variety of capabilities possible for each of the three sections of a mass spectrometer: the mass source, the mass discriminator, and the transducer/detector. These were illustrated in the original article. The gas-phase ions are separated according to their differences in mass-to-charge ratio, abbreviated m/z.

Since its inception, mass spectrometry has been used effectively to analyze small molecules and atoms. However, a variety of sources have been devised to vaporize and ionize materials that are not initially gases, which has allowed mass spectrometry to analyze virtually all types of samples. Because of these newer vaporization/ionization methods, mass spectrometry is now firmly established in biochemical, polymer, and inorganic analysis. For molecules greater than 10 000 daltons [1 dalton (Da) = 1 unified atomic mass unit (u)], electrospray ionization (ESI), matrix-assisted laser desorption ionization (MALDI), and plasma desorption (PD) can be used. ESI has an advantage over the others in that multicharged ions (up to the range of 20 charges) are produced, which brings these heavy molecules into the m/z range of 500 to 2000. As a result, electrospray ionization permits mass spectrometry up to the 100 000-Da range on commonly available instruments. The limitation, then, is only whether such large molecules can be brought intact into the gas phase, and, apparently, many can.

Mass spectrometry also has become one of the two techniques of choice for the simultaneous analysis of many elements. The source of the ions of the elements is the inductively coupled plasma torch. This torch is a plasma formed from argon that is heated to about 3000 K with high-power radio waves. The sample in solution passes into the torch, where ions of the elements form and are passed into a mass spectrometer for analysis.

4. SAMPLE PREPARATION

Contemporary instrumentation has increased our ability to measure the contents of samples more quickly, and the bottleneck in productive analyses in many cases has become the relatively slow preparation of samples. For example, one might require a liquid solution for analysis, but the sample is soil from a field.

The conversion from a solid to the solution involves dissolution of soluble components and bringing otherwise insoluble components into solution. This latter process is called digestion.
